Abstract

If we want to understand why mathematical knowledge is extraordinarily reliable, we need to consider both the nature of mathematical arguments and mathematical practice as a social practice. Mathematical knowledge is extraordinarily reliable because arguments in mathematics take the form of deductive mathematical ***proofs***. Deductive mathematical proofs are surveyable in the sense that they can be checked step by step by different experts, and a purported proof is only accepted as a proof by the mathematical community once a number of experts have checked the proof. Hence, the reliability of the body of mathematical knowledge is in part obtained through the surveyability of proofs and the ***social*** process of proof validation. This chapter reviews work relating to (1) the norm in the mathematical community of only counting as argument deductive mathematical proof, and (2) the norm of only counting as deductive mathematical proof an argument that has been confirmed to be a deductive mathematical proof by a number of experts. The chapter also presents cases of unusual mathematical proofs or arguments that challenge these norms.

1 Introduction

The aim of this chapter is to provide an overview of work relating to what we may term the social epistemology of proof. Not much work has been done on the social epistemology of proof, but much work has been done that is highly relevant to the social epistemology of proof. The purpose of this chapter is to review this literature. The literature belongs to the philosophy of mathematical practice, and I hope to create connections between parts of the literature in the philosophy of mathematical practice that have not been connected before. Furthermore, I hope to promote social epistemology of mathematics as an interesting area of research.

If we want to understand why mathematical knowledge is extraordinarily reliable, we need to consider both the nature of mathematical arguments and mathematical practice as a social practice. Mathematical knowledge is extraordinarily reliable because arguments in mathematics take the form of deductive mathematical ***proofs***. Deductive mathematical proofs are surveyable in the sense that they can be checked step by step by different experts, and a purported proof is only accepted as a proof by the mathematical community once a number of experts have checked the proof. Hence, the reliability of the body of mathematical knowledge is in part obtained through the surveyability of proofs and the ***social*** process of proof validation.

This chapter has two main parts. The first part of the chapter reviews work relating to the norm in the mathematical community of only counting as argument deductive mathematical proof. The second part of the chapter reviews work relating to the norm of only counting as deductive mathematical proof an argument that has been confirmed to be a deductive mathematical proof by a number of experts. The chapter also presents cases of unusual mathematical proofs or arguments that either challenge the norm of only counting as argument deductive mathematical proof or the norm of only counting as deductive mathematical proof an argument that has been confirmed to be a proof by different experts.

2 The Community Value of Justification as Deductive Mathematical Proof

Many mathematicians have emphasized the major role of ***inductive*** reasoning in mathematics (see Borwein and Bailey 2003; Epstein and Levy 1995; Sørensen 2016). Mathematical results are typically discovered and tested in reliable ways before they are proved. To give an extreme example, the Riemann hypothesis has been verified in billions of instances. But there is really only one method of justification in mathematics, and this is deductive mathematical proof. Mathematical

results are established by proofs. And the Riemann hypothesis will remain a hypothesis until a deductive mathematical proof has been produced.

One way to identify the value of deductive proof is to ask why mathematicians are unwilling to accept other kinds of mathematical justification. We may wonder why the mathematical community is unwilling to accept proofs that make use of inductive evidence, even when the inductive evidence is extremely reliable, while the mathematical community does accept proofs that skip steps and are very long and complicated. I call the former randomized proofs in line with Jackson (2009). A proof that uses the Miller–Rabin primality test to establish that a specific number n is prime would be an example of a randomized proof that makes use of extremely reliable inductive evidence.

Philosophers have defended different views on whether the unwillingness of the mathematical community to accept randomized proofs is epistemically rational. Don Fallis (1997, 2000, 2002) argues that mathematicians' unwillingness to accept randomized proofs cannot be defended on epistemic grounds.

In response to Fallis, Kenny Easwaran (2009) offers an account of why mathematicians are unwilling to accept proofs that make use of inductive evidence. Easwaran claims that a randomized proof, as opposed to a traditional proof, is not transferable. By "transferable" he means that the author can give the proof to other mathematicians who can then verify that the claim established by the proof is true just by considering the steps in the proof. They do not have to rely on the testimony of the author of the proof. In the case of a proof that uses the Miller–Rabin primality test to establish that a specific number n is prime, by contrast, the reader would have to rely on the author to have performed the Miller–Rabin test correctly. Easwaran suggests that this explains why mathematicians are unwilling to accept randomized proofs. Without going into much detail, Easwaran (2009, 361) states that requiring proofs to be transferable is a way for the mathematical community to protect the quality of the body of mathematical knowledge. In this way, all the evidence for the knowledge is publicly available and can be independently checked by mathematicians with the relevant area of expertise.

Note that the fact that mathematical proofs can be independently checked by mathematicians separates mathematical proofs from scientific arguments. Scientific arguments cannot be independently checked by scientists. Scientists may have read and become convinced by a paper arguing that p from empirical data, but this does not exclude the possibility that the author of the paper has lied about having established p or has made a subtle mistake when collecting the data. Scientists can limit their dependence on the author by reproducing the experiments, but this is often not an option in practice. Reproducing experiments is expensive and time-consuming and generally does not give much credit.

Fallis (2011) agrees with Easwaran that the epistemic autonomy provided by transferable proofs can be epistemically valuable. However, Fallis argues that randomized proofs also allow mathematicians to be epistemically autonomous. Given the proof from the example above, mathematicians can just perform the Miller–Rabin test for themselves to check that n is indeed prime. It is unclear to Fallis, as it is to me, why it is important that mathematicians who independently

perform the Miller–Rabin test to establish that n is prime will not have the exact same evidence (2011, 172; Jackson 2009 gives a similar argument).

While Fallis and Easwaran disagree on what kinds of proof allow individual mathematicians to be epistemically autonomous, both Fallis and Easwaran emphasize that some level of autonomy of individual mathematicians is valuable to the mathematical ***community*** as a whole. Fallis (2011, 166–172) examines how some level of epistemic autonomy of individual mathematicians can be valuable to both the mathematical community as a whole and the individual mathematicians. It can be valuable to the mathematical community as a whole, he notes, because the community is more reliable when each proof is checked by more than one expert. Similarly, Easwaran calls transferability a "social epistemic virtue" presumably because protecting the quality of the body of mathematical knowledge is valuable to the mathematical community rather than any individual mathematician (Easwaran 2009, 343).

Don Berry (2016) also examines "mathematicians' strict insistence on proof." In line with Easwaran, Berry argues that there are good epistemic reasons for the mathematical community for only counting as argument deductive mathematical proof. Berry argues that there are some important virtues of mathematical research that are largely due to the norm in the mathematical community of only counting as argument deductive mathematical proof. And the success of mathematics, he further argues, is largely due to these virtues of mathematical research. Therefore, mathematicians are rational in their insistence on proof.

For example, Berry argues that the success of mathematics is partly due to the ***permanence*** of mathematical results. And the permanence of mathematical results, he argues, is a virtue that is due to the norm in the mathematical community of only counting as argument deductive mathematical proof. Like Easwaran and Fallis, Berry emphasizes as a virtue the possibility of ***autonomy*** for individual mathematicians when they read and assess a mathematical argument. For example, "When journal referees judge that a printed argument constitutes a sufficient basis for publication, they never rely upon trust in the testimony of the publishing mathematician" (Berry 2016, 117). This is due to the insistence on proof for "if a result were supported by inductive evidence alone, we would be required to accept the judgement of the author that this evidence is conclusive" (Berry 2016, 117). Berry emphasizes that the virtue of the possibility of autonomy for individual mathematicians helps maintain the virtue of permanence and other virtues.

To sum up, Easwaran, Fallis, and Berry agree that the norm of only counting as argument deductive mathematical proof allows individual experts to independently check mathematical arguments. And the fact that individual experts can independently check mathematical arguments is valuable to the mathematical community because it means that mathematical results can be extraordinarily reliable. This seems right. But the question remains as to how errors in a proof may be overlooked by individual mathematicians such that it makes a difference when more mathematicians check the same proof. Section "4" below addresses this question.

3 Challenging Cases I

It is worth briefly considering a phenomenon that seems to challenge the norm of only counting as argument deductive mathematical proof. I have in mind the phenomenon of ghost theorems. The notion of "ghost theorems" was introduced by Colin Rittberg, Fenner Tanswell, and Jean Paul Van Bendegem (2020, 3880) and refers to "mathematical results which are taken as accepted in a mathematical community, relied upon in talks, discussion, and proving further results, but which cannot be traced to a concrete proof in the literature." It remains to be studied how common ghost theorems are. Furthermore, it is unclear to what extent ghost theorems have unpublished proofs, but this is less important for our purposes because there is a substantial difference between unpublished proofs and published proofs. Rittberg et al. (2020, 3882–3884) emphasize that any unpublished proofs of ghost theorems are, all else being equal, less reliable than published proofs because they have not gone through the social process of proof checking that published proofs go through.

4 Proof Checking as a Social Process

A mathematical proof has traditionally been conceived as something very different from an ***argument*** as conceived in argumentation theory. In a key work in rhetoric, Chaïm Perelman and Lucie Olbrechts-Tyteca (1969) distinguish arguments from demonstrations and include mathematical proofs in the category of demonstrations. Demonstrations are impersonal as opposed to arguments which are relative to their intended audience. Perelman and Olbrechts-Tyteca (1969, 19) write that, "Since argumentation aims at securing the adherence of those to whom it is addressed, it is, in its entirety, relative to the audience to be influenced." In the same vein, Ralph Johnson writes that, "No mathematical proof had or needs to have a dialectical tier" (Johnson 2000, 270; quoted in Dufour 2013, 65). The dialectical tier of an argument is where the arguer anticipates and responds to objections to the argument.

While mathematical proofs have traditionally not been conceived as arguments, this is changing as philosophers of mathematics have started to pay more attention to ordinary mathematical proofs as they occur in actual mathematical practice. For example, Erik Krabbe (2008/2013, 193) holds a "dialectical and rhetorical view of proofs" on which "proofs may be more or less successful, depending upon context and audience." Krabbe notes that, "Some proofs are rather sketchy [relative to the intended audience], leaving much room for questioning (or work for the reader, if the author is not there to answer questions), whereas others, by answering these questions, are developed to great dialectical depth" (2008/2013, 193). Other studies similarly emphasize the audience-dependence of proofs and point out that the appropriate level of detail of proofs depends on their intended audience (see Andersen et al. 2019; Fallis 2003; Paseau 2016).

Ordinary mathematical proofs seem to be relative to their intended audience in at least some minimal sense. As mathematician William Thurston (1994, 175) has

pointed out, mathematicians "prove things in a certain context and address them to a certain audience." It seems fair to say that a proof aims to secure the adherence of the audience to whom it is addressed, since a purported proof is accepted as a proof by the mathematical community only when enough experts have read and assessed the purported proof and concluded that it, in fact, constitutes a proof. Hence, philosophers of mathematical practice have argued that for proofs to be thoroughly checked and accepted as proofs by mathematicians they need to go through a ***social*** process of verification in which the proofs are read by different experts and used in different contexts (see Rav 1999; Devlin 2003; Andersen et al. 2020).

Not until a number of experts have checked a proof does the proof count as a proof in mathematical practice. This is so because individual readers of proofs may quite easily overlook errors (see Geist et al. 2010; Müller-Hill 2011). (This may be one reason why it is becoming more common, although still rare, to formalize proofs as a way of verifying them (Avigad 2008; Avigad and Harrison 2014; Hales 2008). This kind of proof checking is not in general a social process, but the formalization of a proof will sometimes be the result of a collaborative effort.) Mathematicians themselves stress that errors in proofs may quite easily be overlooked. Philosopher Eva Müller-Hill has interviewed six mathematicians about their intuitions as to when a mathematician may be said to know that a mathematical claim is true. Five of them stressed that even an expert journal referee may overlook errors (Müller-Hill 2011, 305–310, 315–316, 319–322, 328, 342–343). In the words of one of the interviewees, prepublication peer review is just "one step in trying to make sure that nobody has overlooked a mistake in the proof" (Müller-Hill 2011, 309). That errors may quite easily be overlooked by any individual mathematician is also reflected in the fact that mathematicians seem to be hesitant to rely on a result without checking the proof of the result themselves unless a number of other experts have checked the proof (Andersen et al. 2020).

Because the vetting of a proof is a long and complex process and errors in proofs are sometimes only found after publication, some have argued that the mathematical community should have a better system for sharing publicly the errors found in published proofs (Grcar 2013; Frans and Kosolosky 2014).

I will now review a number of different accounts of proof since different accounts of proof come with somewhat different accounts of why it makes sense to have more experts check a proof. This is due to the fact that different accounts of proof come with different accounts of how individual mathematicians read and assess proofs. And, therefore, different accounts of proof come with different accounts of how errors in a proof may be overlooked by individual mathematicians.

A number of philosophers claim that ordinary proofs are what one could call ***sketches*** of formal proofs (see Avigad 2020; Azzouni 2004; Hamami 2019; MacLane 1986). A purported proof is a proof if it can be turned into a formal proof. If we conceive of proofs this way, then becoming convinced that a purported proof is a proof involves recognizing that the purported proof could be turned into a formal proof. Jeremy Avigad describes the process thus,

> Whether or not a mathematician reading a proof would characterize the state of affairs in these terms, a judgement as to correctness is tantamount to a judgment as to the existence of a formal derivation, and whatever psychological processes the mathematician brings to bear, they are reliable insofar as they track the correspondence. (Avigad 2020, 3)

On the proofs as sketches accounts, overlooking an error in a proof amounts to making a mistake in tracking the correspondence between the ordinary proof and the formal proof. Some philosophers have criticized the proof as sketch account (see Larvor 2012; Rav 1999; Tanswell 2015). The discussion is ongoing.

Others argue that we should conceive of proofs as ***narratives*** (Doxiadis 2012; Robinson 1991, 269; Thomas 2007). For example, we may conceive of a proof as a telling of how the author of the proof came from the premises to the conclusion, as a telling of a sequence of inferential actions performed by the author (Doxiadis 2012). This fits well with how mathematicians have occasionally described proving as taking a journey (as described in Lane et al. 2019, 199–200). If we conceive of proofs as narratives in this way, then coming to the conclusion that a purported proof is a proof involves an assessment of the actions performed by the author of the proof. Overlooking an error in a proof amounts to something like making a mistake when assessing whether a certain action is suitable for obtaining a certain goal.

Other accounts of proof are similar to the proof as narrative account in that they focus on actions, but they focus on the actions of the readers of proofs rather than the authors of proofs. Hence, some philosophers argue that we should conceive of proofs as ***recipes*** for how to prove propositions (Larvor 2012, 725–726; Sundholm 2012; Tanswell 2017). On these accounts, a proof as written is a recipe for the readers to follow to do an actual proof. If proofs are recipes, then reading and assessing a purported proof involve actually performing the steps in the recipe and seeing if they lead to the desired outcome. In this case, the reader is doing the proving herself under guidance, or taking the journey herself. If we conceive of proofs as recipes, then coming to the conclusion that a purported proof is a proof amounts to performing the inferential actions oneself. Overlooking an error in a proof amounts to making a mistake when doing the proof.

Finally, some philosophers have argued that we should conceive of proofs as ***dialogues*** (Dutilh Novaes 2016, 2018; Ernest 1994). Catarina Dutilh Novaes gives an account of a proof as a dialogue between two fictitious interlocutors whom she calls Prover and Skeptic. On her account,

> A deductive proof corresponds to a dialogue between the person wishing to establish the conclusion [. . .] and an interlocutor who will not be easily convinced and will bring up objections, counterexamples, and requests for further clarification. A good proof is one that convinces a fair but 'tough' opponent. (Dutilh Novaes 2016, 2617)

She adds: "Ultimately, most of the work is done by Prover, but Skeptic has an important role to play, namely to ensure that the proof is persuasive, perspicuous, and valid" (Dutilh Novaes 2016, 2618). If proofs are dialogues in this sense, then reading and assessing a proof involves assessing whether Skeptic is skeptic enough. Overlooking an error in a proof often amounts to overestimating the skepticism of

Skeptic. Note that the accounts of proofs as dialogues are perhaps especially interesting from the point of view of social epistemology because they include the social nature of dialogue in the very nature of proof.

Conceiving of proofs ***as*** dialogues should be distinguished from conceiving of proofs as the ***result of*** dialogues, as Lakatos (1976) famously did. In *Proofs and Refutations*, Lakatos illustrates how mathematical concepts can grow through a dialectic of proofs and counterexamples, using the historical example of the concept of polyhedron as used in proofs of Euler's conjecture. The concept of polyhedron becomes more clear and precise in the context of a long debate of the proofs, which are also refined in the process. The book is structured as a dialogue between a teacher and his students, with the students representing different methodological stances (see Larvor 1998, 10–11).

5 Challenging Cases II

The different accounts of proofs we have considered provide different answers to the question of why a purported proof is only accepted as a proof by the mathematical community when enough experts have read and assessed the purported proof and found no errors, that is, when the purported proof has gone through a social process of proof validation. But there are some unusual cases of proofs that challenge the validation of proofs as a social practice. More specifically, the cases challenge the norm of only counting as deductive mathematical proof an argument that has convinced a number of experts that it is indeed a deductive mathematical proof.

A number of prominent and highly praised proofs have received attention for being so long or complex that only a few mathematicians have read and checked the proofs. Famous examples of proofs that have received attention for being so long that they would be incredibly hard for any individual mathematician to read include the proof of the classification of finite simple groups (see Steingart 2012) and the proof of the Kepler Conjecture by Thomas Hales (see Devlin 2003). The famous proof of Fermat's Last Theorem by Andrew Wiles is an example of a proof that draws on different domains in such a way that only few individual experts have been able to read the proof (see Jones and Jones 1998, 217–237; Penrose 1997). These proofs are in practice not very open to checking by mathematicians. For this reason, they pose a challenge to the norm of only counting as deductive mathematical proof an argument that has been checked by a number of experts.

These are proofs of very high-profile results that ***challenge*** the norm. Very long or complex purported proofs of less important results presumably often ***succumb*** to the norm in the sense that they are not accepted as proofs by the mathematical community because they have not been vetted by enough experts. The norm of only counting as deductive mathematical proof an argument that has been checked by a number of experts limits the extent to which purported proofs can be long and complex and still be accepted as proofs by the mathematical community.

But even proofs of high-profile results by high-profile mathematicians may succumb to the norm of only counting as deductive mathematical proof an argument

that has been checked by a number of experts. The purported proof of the abc conjecture by the prominent mathematician Shinichi Mochizuki has been described as being extremely hard to even begin to comprehend (see Castelvecchi 2015; Hartnett 2014). The purported proof is from 2012 and has not yet been accepted as a proof by the mathematical community and perhaps will not be. Mochizuki had been working on the proof for many years on his own and had in that time "constructed his own mathematical universe and populated it with arcane terms like 'inter-universal Teichmüller theory' and 'alien arithmetic holomorphic structures'" (Hartnett 2014, 225). Hence, the purported proof is written in a new language and, in addition, the author is rather unwilling to explain his thinking. The behavior of the author can perhaps be described as going against the norm of the mathematical community of only accepting as justification in mathematics arguments that are open to independent checking by different mathematicians.

6 Conclusion

If we want to explain the extraordinary reliability of mathematical knowledge, we may point to the central role of deductive mathematical proofs in mathematics. But to understand the reliability of mathematical proofs, we also need to consider the relationship between mathematical proofs and mathematical practice as a social practice. We need to consider the social epistemology of mathematical proof. In this chapter, I have reviewed how philosophers have examined how mathematical proofs are valuable to the mathematical community because of their being open to independent checking by different mathematicians. I have also reviewed how philosophers have offered different accounts of how mathematicians read and assess proofs. These accounts offer different answers to the question of how individual mathematicians may overlook errors and thus of why we need a social process of proof checking.

Abstract

Proofs are central, and unique, to mathematics. They establish the truth of theorems and provide us with the most secure knowledge we can possess. It is thus perhaps unsurprising that philosophers once thought that the *only* value proofs have lies in establishing the truth of theorems. However, such a view is inconsistent with mathematical practice. If a proof's only value is to show a theorem is true, then mathematicians would have no reason to reprove the same theorem in different ways, yet this is a practice they frequently engage in. This suggests that proofs can have a wide variety of values. My purpose in this chapter is to provide a survey of some of them. I will discuss how proofs can have *practical value*, for example, by helping mathematicians to make new discoveries or learn new mathematical tools, and how they can have *abstract value*, for example, by being beautiful or explanatory. I will also explore the relationships between different proof values.

Mathematical practice · Proofs · Values

1 Introduction

Proofs are central, and unique, to mathematics. They establish the truth of theorems and provide us with the most secure knowledge we can possess. It is thus perhaps unsurprising that philosophers have thought their only job, and only value, was to establish the truth of theorems. For example, Rav describes the "standard view" in philosophy as follows: "proofs serve *only* to validate theorems on the basis of accepted axioms" (Rav 1999, 15, emphasis in original). However, as Rav also points out, the standard view is at odds with mathematical practice (Rav 1999, 15) though he has different aspects of mathematical practice in mind than what I focus on below.

If the standard view were true, then once a theorem has been proven, mathematicians would have no reason to prove it again. After all if the only value a proof has is establishing the truth of its theorem, then once mathematicians have one proof adding more would be entirely superfluous. Yet, as Avigad (2006) and Dawson (2006, 2015) emphasize, mathematicians *do* routinely reprove theorems, sometimes giving hundreds of different proofs of the same theorem. For example, 370 proofs of the Pythagorean theorem are presented in Loomis (1968), and as Avigad notes (Avigad 2006, note 2), Franz Lemmermeyer maintains a list of proofs of quadratic reciprocity (Lemmermeyer n.d.), which currently has over 240 entries. This indicates that, contra the standard view, proofs have value beyond establishing their theorems.

The purpose of this chapter is to survey some of the wide variety of values proofs can have, other than establishing the truth of theorems. As we will see, some of these values are possessed by all proofs, but the majority are only possessed by some proofs. I will here be concerned only with informal proofs and not with formal

derivations. That is to say, I will focus only on proofs as written by mathematicians in journal articles or textbooks, for example, and not on logical derivations made in formal deductive systems. This is not to deny that formal proofs are valuable. For example, they can be more valuable than informal proofs when it comes to ensuring the correctness of a result. Indeed significant mistakes have been made in published informal mathematical proofs. For example, Kempe's (1879) invalid proof of the four color theorem stood for 11 years before Heawood (1890) discovered the error. The prevalence of mistakes, as well as the ever increasing complexity of mathematics, has led some mathematicians to adopt the use of proof assistants (a type of computer software) in their work. Proof assistants help mathematicians to translate their informal proofs into formal ones where each step is made explicit and verified to be logically correct. Thus some mathematicians argue "that the use of a formal proof . . . will contribute to enhancing rigour and gaining confidence in the correctness of long and complex proofs that are not amenable to human verification" (Hanna and Larvor 2020, sec. 4.1). For an overview, see Avigad (2018).

In what follows I will organize the values proofs can have into two categories: practical and abstract. Proofs have practical value when they help mathematicians to achieve pragmatic goals, such as making new discoveries or learning new mathematical tools. Proofs have abstract value when they go beyond helping mathematicians to achieve pragmatic goals by having a quality that is either intrinsically valuable or that yields something that is. Examples of abstract values include explanatory power and beauty. As we will see, there are interconnections between these different values. For example, sometimes a particular abstract value is also often associated with specific practical values, and sometimes one particular abstract value is strongly associated with other abstract values.

Admittedly, the distinction between practical and abstract values is not always sharp. In particular, it can sometimes be difficult to determine whether a property that yields practical benefits is intrinsically valuable (or provides us with something that is). For example, intuitiveness is a valuable proof property and arguably has practical benefits like helping mathematicians to make new discoveries because intuitive proofs are easy to work with. But it seems hard to say whether intuitiveness is valuable for its own sake or whether it is valuable only for its practical consequences (Many thanks to an anonymous reviewer for this example). This does not mean, however, that the distinction between abstract and practical values is untenable. For while there will be borderline cases, there will be others that are more clear-cut. In Sect. 3, I identify four abstract values whose classification appears to be less controversial. This is not to say, however, that the classification of these values as abstract cannot be challenged. For example, further analysis of an ostensible abstract value could reveal that it is not an abstract value after all, perhaps by reducing it to something else that is more easily recognized as not having (or providing anything of) intrinsic value. At the beginning of the discussion of each value, however, I explain why I classify it as an abstract value. I hope that this will illuminate how the notion of abstract value is to be understood in practice.

The structure of this chapter is as follows. I first discuss practical values that proofs can have in Sect. 2 before considering abstract values in Sect. 3. Then, in Sect. 4,

I discuss the relationships between particular abstract and practical values. Next, in Sect. 5, I examine connections between the individual abstract values. Finally, in Sect. 6, I look at potentially fruitful avenues for future work on the values of proofs.

2 Practical Values

Philosophers, mathematicians, and mathematics educators have identified a variety of ways that proofs can have practical value. That is to say, they have identified ways that proofs help mathematicians to achieve important goals that ensure continued mathematical progress. As we will see, some of these practical values are common to all proofs, while others are only provided by some proofs. We will also see that there are close connections between some of these individual practical values. Below I will first briefly summarize the individual practical values before discussing (i) whether the individual values are provided by all or only some proofs and (ii) how they are related.

2.1 Individual Values

2.1.1 Making Mathematical Knowledge Accessible

Easwaran (2009) argues that traditional mathematical proofs have a property that distinguishes them from other arguments: transferability. To say an argument is transferable means that an expert in the field would already believe the premises of the argument and would come to accept any inferences made simply by considering them themself (Easwaran 2009, 354). So, for example, a mathematician reading a proof does not have to rely upon the testimony of the proof author or accept any appeals to authority to know the theorem. Proofs thus contrast with arguments in the physical sciences, which often do require readers to rely on testimony. For example, scientific arguments require readers to accept the authors' testimony about the experiments that figure in their arguments (Easwaran 2009, 359).

Easwaran suggests that transferability has an important practical benefit: it makes mathematical knowledge more accessible to the community. This is because transferability means that the mathematical community can be "self-monitoring" (Easwaran 2009, 356), i.e., members of the mathematical community can check through proofs and ensure any errors are corrected. If proofs were not transferable this would not be possible, since some steps could not be checked, relying, for example, on testimony or appeals to authority (Easwaran 2009, 356). As traditional mathematical proofs are transferable, one way they have practical value is thus by making mathematical knowledge accessible.

2.1.2 Power of Different Methodologies

Dawson notes that one reason mathematicians reprove theorems is to "demonstrate the power of different methodologies" (Dawson 2006, 277). For example, he

mentions Bishop's *Foundations of Constructive Analysis*, which contained proofs to show "how large a part of abstract analysis can be developed within a constructive framework" (Dawson 2006, 277). Avigad offers another example: "Dedekind often went out of his way to show how the new methods developed in his theory of ideals result in perspicuous proofs of established theorems of number theory, from Fermat to Kummer" (Avigad 2006, 107). A second way that proofs can thus have practical value is by showcasing what different methodologies can do.

2.1.3 New Ways of Thinking

Weber (2010) notes that mathematicians hope to learn new ways of thinking when they read proofs. He identifies two ways mathematicians learn to think differently: by "reconceiving mathematical domains and learning new proof techniques" (Weber 2010, 32). Proofs that reconceive mathematical domains help mathematicians to develop their intuitions and refine their mental models, giving them a new way of representing the mathematics in question (Weber 2010, 32–34). This in turn can help mathematicians to see why a theorem they initially found implausible turned out to be true (Weber 2010, 32).

Proofs that help mathematicians learn new techniques provide them with tools to add to their mathematical toolbox that can then be used and adapted to solve new problems (Weber 2010, 34–35). As a simple illustration, Weber borrows an example from Rav (1999, 21): Euclid's proof of the infinitude of the primes. This proof shows that given any finite collection of primes we can construct a new but distinct prime. The technique for constructing this new prime can be used to prove new theorems, for example, that there are infinitely many primes of the form $4n + 3$ (Rav 1999, 21).

Although Weber focuses on techniques, Rav (1999) points out that proofs can convey other tools, for example, concepts and ideas. As he puts it "Proofs are for the mathematician what experimental procedures are for the experimental scientist: in studying them one learns of new ideas, new concepts, new strategies—devices which can be assimilated for one's own research and be further developed" (Rav 1999, 20).

We have thus seen a third way that proofs can have practical value: by helping mathematicians to learn new ways of thinking, i.e., by developing new mental models, refining their intuitions, and learning new tools.

2.1.4 Systematization, Discovery, and Communication

De Villiers (1990) draws attention to a number of practical values of proof. First he notes that when mathematicians have a number of known results, they often want to better organize them in a more systematic way. They thus engage in "a posteriori axiomatization and defining" (De Villiers 1990, 20) to obtain "a deductive system of axioms, definitions and theorems" (De Villiers 1990, 20). As De Villiers points out, proofs play an important part in this systematization by relating different mathematical statements together as part of an organized whole.

Secondly, while proofs are traditionally thought of as belonging firmly to the context of justification, De Villiers points out that they can stimulate new discoveries. Using examples from geometry he shows that sometimes a proof of one theorem

can lead us to see that the result generalizes and thus to discover a new theorem. In his examples, it is the proofs themselves that highlight the crucial feature that allows the result to generalize, a feature that, De Villiers claims, would likely have been missed by other attempts to generalize the original theorem, for instance by experimenting with examples (De Villiers 1990, 21).

Finally De Villiers highlights the importance of proofs for mathematical communication in a way that bears some similarities to Easwaran's discussion of transferability. As De Villiers notes, mathematicians communicate with each other in proofs, and so proofs can be seen as "a form of social interaction" (De Villiers 1990, 22). This means that mathematicians have to agree on what counts as an acceptable argument and so proofs are scrutinized, refined, and rejected if a counterexample is found. This in turn has safeguarded mathematics, preventing mathematicians as a group from making or accepting big mistakes.

De Villiers thus identifies three ways that proofs can have practical value: (i) by helping to systematize a mathematical subfield; (ii) by stimulating new discoveries; and (iii) by safeguarding mathematics from mistakes.

2.2 Discussion of Practical Values

Some of the practical values of proofs discussed above are shared by all proofs in virtue of their being proofs. These include: making mathematical knowledge accessible, systematizing mathematical knowledge, and safeguarding mathematics from mistakes. As all traditional proofs are transferable, they all make knowledge of their corresponding theorem accessible to the community. As all proofs highlight the relationships between mathematical statements, at least to some degree, presumably they all help contribute to the systematization of mathematics. Finally, as all proofs serve as a means of communication between mathematicians and so will be refined if necessary, presumably all proofs help prevent the community from accepting mistakes.

Other practical values only seem to be provided by some proofs. These include: showcasing the power of different methodologies, providing mathematicians with new ways of thinking, and promoting discoveries. For example, a proof that uses standard techniques in a standard way is not going to illustrate the power of different methodologies; a proof that uses a variety of new methods, however, might. Similarly a proof that uses standard tools in a standard way is unlikely to teach mathematicians new ways of thinking. A proof that introduces a new technique or a new way of representing a mathematical concept, however, can. Finally a brute force proof using standard tools, for example, is unlikely to inspire mathematicians to make new discoveries. A proof that exploits a relationship in an unusual way or that uses new concepts or methods, however, may well do so.

Some of the individual practical values discussed above are interrelated. First, proofs that illustrate new methodologies seem likely to teach mathematicians new ways of thinking. After all, proofs that showcase different methodologies will use new ideas or tools or use existing ones in unusual or unexpected ways. This means

they will plausibly convey new representation systems or new methods and techniques to mathematicians who read them. Proofs that provide new ways of thinking, however, will not necessarily also illustrate new methodologies. For example, a proof that provides a new way of thinking could introduce a new method, but that method might not be part of a larger system that constitutes a new or different methodology.

Secondly, proofs that provide new ways of thinking also tend to stimulate discoveries. This is because proofs that yield new ways of thinking help provide mathematicians with new tools that they can use to work on new problems, increasing their chances of success. However, there may be proofs that stimulate discoveries without providing mathematicians with new ways of thinking. For example, it might be possible for a proof to promote further discoveries by drawing attention to a certain relationship between mathematical objects that can be proven to generalize using standard techniques. This would lead to new discoveries but would not necessarily provide new ways of thinking.

Finally, note that the six practical values of proofs discussed here may not be the only practical values proofs can have. Future work may reveal additional such values possessed by some or all proofs and should more deeply explore the relationships between them.

2.3 Summary

We have discussed six ways proofs can have practical value by: (i) making mathematical knowledge more accessible; (ii) showing what different methodologies can do; (iii) helping mathematicians learn new ways of thinking; (iv) systematizing mathematics; (v) stimulating new discoveries; and (vi) safeguarding mathematics against mistakes. Three of these practical values are possessed by all proofs: (i) making mathematical knowledge more accessible; (iv) systematizing mathematics; and (vi) safeguarding mathematics against mistakes. The remaining three are only possessed by some proofs. Further, as we saw, some of the individual practical values are connected. In particular, if a proof shows what a different methodology can do then it also likely helps mathematicians learn new ways of thinking and if a proof helps mathematicians to learn new ways of thinking it also likely stimulates new discoveries.

3 Abstract Values

Philosophers, mathematicians, and mathematics educators have identified and analyzed different ways in which proofs can have abstract value. That is to say, they have developed accounts of qualities that proofs can have that are (or provide something that is) intrinsically valuable. Due to space considerations I discuss below only four such abstract values: (i) explanation; (ii) beauty; (iii) fit; and (iv) motivation. Other important abstract values include, for example, depth

(see, e.g., Arana 2015; Gray 2015; Lange 2015; Stillwell 2015; Urquhart 2015) and purity (see, e.g., Detlefsen 2008; Detlefsen and Arana 2011). Unlike some of the practical values discussed in Sect. 2, none of the abstract values discussed here are possessed by all proofs. In other words, while some proofs will possess one (or more) of these abstract values, others will not.

Proofs with abstract value can also have practical value. We have already seen that all proofs have the practical values of making mathematical knowledge accessible, systematizing mathematics and safeguarding it from mistakes, so proofs with abstract value will have these practical values as well. Moreover, certain abstract values are closely associated with particular practical values, so that a proof with such an abstract value will likely have the associated practical values as well. I discuss these connections in Sect. 4. Then, in Sect. 5, I take up the issue of connections between the individual abstract values themselves.

3.1 Explanation

Mathematicians aim not just to prove new theorems, but to give mathematical explanations. Sandborg (1997) looks at reviews of mathematical papers from the 1980s and 1990s and identifies a wide variety of positive remarks about the explanations those papers provide. Below are just two examples:

> The paper under review makes a very nice contribution to the theory by giving a theoretical explanation of this bifurcation (Marsden 1985, quoted on pg 42 of Sandborg (1997)).

> Although [the authors] had previously proved (by a different method) that their algebras were Noetherian, the present paper gives a more fundamental explanation of this fact (Smith 1991, quoted on pg 35 of Sandborg (1997))

Perhaps the most obvious way mathematicians can provide explanations is by giving explanatory *proofs*. For example, Haigh, whose proof of Pick's theorem is discussed by Sandborg, remarks "I was surprised when I first met this theorem, and the proofs I read [. . .] did not allay my surprise, so I looked for a more explanatory proof" (Haigh 1980, 173).

This suggests that mathematical explanation, and explanatory proofs in particular, are highly valuable. Comparison with scientific explanation suggests that mathematical explanation is also an abstract value. For example, Strevens writes:

> If science provides anything of intrinsic value, it is explanation. Prediction and control are useful, and success in any endeavor is gratifying, but when science is pursued as an end rather than as a means, it is for the sake of understanding—the moment when a small, temporary being reaches out to touch the universe and makes contact (Strevens 2011, 3)

We could very easily imagine something similar being said about explanation in mathematics, and, in particular, explanatory proofs:

> If mathematics provides anything of intrinsic value, it is explanation. [. . .] When mathematics is pursued as an end rather than as a means, it is for the sake of understanding—the moment when a small, temporary being reaches out to touch the mathematical universe and makes contact.

Spelling this out more explicitly, explanation give us something that is intrinsically valuable: mathematical understanding. This means that explanation is an abstract value.

Although explanatory proofs have abstract value, we have not identified what, exactly, such proofs are. In fact, there is little consensus over the nature of explanatory proofs. For example, Lange describes the situation regarding the explanatory power of just one type of proof, proof by induction, in the following terms:

> Some philosophers appear quite confident that these arguments are generally explanatory, even in the face of other philosophers who appear equally confident of their intuition to the contrary (Lange 2009, 204).

Many philosophers have, nonetheless, developed accounts of explanatory proofs, including Steiner (1978), Kitcher (1989), Sandborg (1997), Cellucci (2008), Frans and Weber (2014), Lange (2014), Inglis and Meja-Ramos (2019), and Baron et al. (2019). Here I will focus on the accounts provided by Steiner, Kitcher, and Lange.

3.1.1 Steiner's Account

Central to Steiner's account of explanatory proofs is his notion of characterizing properties. A characterizing property is "a property unique to a given entity or structure within a *family* or domain of such entities or structures" (Steiner 1978, 143, emphasis in original). Note that a mathematical object can have different characterizing properties. Steiner gives the example of 18, which can be characterized as the successor of 17 or as $2 \cdot 3^2$ (Steiner 1978, 143). For Steiner, an explanatory proof is one which is clearly dependent on a characterizing property of something mentioned in the theorem. Moreover, an explanatory proof has to be clearly generalizable in the following sense: if we replace the original characterizing property with a characterizing property of a different, but related, object then we obtain a different theorem (Steiner 1978, 147).

An example of an explanatory proof on Steiner's account is the following proof of the theorem that $1 + 2 + \ldots + n = n(n + 1)/2$ (Steiner 1978, 136):

Proof Let $S = 1 + 2 + \ldots + n - 1 + n$. Then note:

$$\begin{array}{rcccccccccc} S & = & 1 & + & 2 & + & \ldots & + & n-1 & + & n \\ S & = & n & + & n-1 & + & \ldots & + & 2 & + & 1 \\ \hline 2S & = & (n+1) & + & (n+1) & + & \ldots & + & (n+1) & + & (n+1) \end{array}$$

Consequently $2S = n(n + 1)$ and so $S = n(n + 1)/2$. □

This is explanatory, according to Steiner, because it relies on a characterizing property of the sum *S*: its symmetry (Steiner 1978, 144–145). Moreover, as his account requires, we can deform it to obtain new results. For example, by omitting the even terms from the sums, we obtain a proof that $1 + 3 + 5 + \ldots + 2n - 1 = n^2$.

Steiner's account has been much discussed and criticized, with numerous counterexamples being proposed (see Resnik and Kushner 1987; Weber and Verhoeven 2002; Hafner and Mancosu 2005; Lange 2014; Pincock 2015). As just one example Hafner and Mancosu (2005) analyze Pringsheim's proof of Kummer's convergence test. This proof was designed to be explanatory, but Hafner and Mancosu argue that there is no appropriate characterizing property that can be appealed to in this case, and so the proof fails to be explanatory on Steiner's account.

3.1.2 Kitcher's Account

Kitcher (1989) develops an account of scientific explanation based on unification. He writes:

> Science advances our understanding of nature by showing us how to derive descriptions of many phenomena, using the same patterns of derivation again and again, and, in demonstrating this, it teaches us how to reduce the number of types of facts that we have to accept as ultimate (or brute) (Kitcher 1989, 432).

As Kitcher notes, his account can also be applied to mathematics, though he does not fully flesh out how to do this. A very rough adaptation is as follows: A proof is explanatory if and only if it instantiates argument patterns from the *explanatory store* of the field it is in, where the explanatory store is the collection of argument patterns that does the best job of unifying the field, i.e., maximizing the number of theorems that can be derived while minimizing the number of legitimate argument patterns needed for the derivations.

Like Steiner's account of explanation, the Kitcher-style account has faced considerable criticism. For example, Hafner and Mancosu (2008) present a detailed case study from real algebraic geometry and argue that the account does not judge the explanatoriness of proofs in a way that matches up with mathematicians' judgments. Further Lange criticizes a Kitcher-style account on the grounds that it would label as explanatory many proofs that do not appear to be genuinely so, such as proofs of geometric theorems that proceed by "algebraically grinding out the result" (Lange 2014, 523).

3.1.3 Lange's Account

More recently, Lange has developed an account of mathematical explanation. He argues that there is only a distinction between explanatory and nonexplanatory proofs when there is a striking or "salient" feature in the result itself, such as a prominent symmetry or unity (Lange 2014, 489). When there is such a feature, Lange suggests that an explanatory proof is one which traces that striking feature back to a similar type of striking feature involved in the "setup" or "problem" (Lange 2014, 525).

However, Lange's account is also subject to criticism. For example, Lange (2016a, 440) claims his account would judge Galois's proof of the unsolvability of

the quintic as explanatory but not Abel's, which means it would agree with judgments many mathematicians make about the explanatory power of these proofs. However, D'Alessandro (forthcoming) argues that Lange's account *does* judge Abel's proof to be explanatory. If he is right, then Lange's account diverges from intuitive judgments about the explanatory value of this proof.

3.1.4 Summary

Mathematicians value proofs that are explanatory. As explanation provides understanding, which is intrinsically valuable, it is an abstract value. There is, however, little consensus as to what an explanatory proof really is and so further work is needed to gain a deeper understanding of this value. For example, additional case studies could be used to assess existing accounts of explanation or to serve as a starting point from which to develop new accounts of explanatory proofs.

3.2 Beauty

Many mathematicians and philosophers value proofs that are beautiful. Below are some representative quotations:

> Mathematics, rightly viewed, possesses not only truth, but supreme beauty—a beauty cold and austere, like that of sculpture, without appeal to any part of our weaker nature, without the gorgeous trappings of painting or music, yet sublimely pure, and capable of a stern perfection such as only the greatest art can show (Russell 1907, 60).

> A mathematician, like a painter or a poet, is a maker of patterns. If his patterns are more permanent than theirs, it is because they are made with ideas.
>
> [. . .]
>
> The mathematician's patterns, like the painter's or the poet's must be beautiful; the ideas like the colours or the words, must fit together in a harmonious way. Beauty is the first test: there is no permanent place in the world for ugly mathematics (Hardy 1992, 13–14).

> Theorems, proofs, entire mathematical theories, a short step in the proof of some theorem, and definitions are at various times thought to be beautiful or ugly by mathematicians. Most frequently, the word "beautiful" is applied to theorems. In the second place we find proofs; usually, but not always, a proof that is deemed to be beautiful tends to be short (Rota 1997, 171).

Many mathematicians think beauty is intrinsically valuable. For example, Montaño reports "Mathematicians such as Bertrand Russell (1919), Hardy (1967), or Paul Erdös (Hoffman 1998) have argued that beauty is among the things that make mathematics valuable in itself" (Montaño 2012, 21). This suggests that beauty is an abstract proof value.

But what, exactly, does it mean for a proof to be beautiful? Perhaps surprisingly, there has been less interest in developing a philosophical account of beautiful proofs than explanatory ones. For example, Breitenbach and Rizza (2018) note that recently there have only been "a handful of attempts" to analyze mathematical beauty.

Nonetheless a number of philosophical accounts have been given, including those by Rota (1997), Cellucci (2015), Breitenbach (2015), Giaquinto (2016), and Dutilh Novaes (2019). Here I focus on Rota's well-known account and Cellucci's account that criticizes and builds on Rota's.

3.2.1 Rota's Account of Beautiful Proofs

While it may be natural to think of mathematical beauty as something that is immediately recognized in a flash, Rota argues that this is an error which he calls the "light bulb mistake" (Rota 1997, sec. 6). Instead, he claims that the process of appreciating a beautiful piece of mathematics is much more messy and requires considerable effort. For example, "[a] great many beautiful arguments require an extensive buildup, and are long-winded" (Rota 1997, 179). Moreover, we may only recognize a proof as beautiful once we have seen other ugly or cumbersome proofs.

Rota claims that understanding the "light bulb" mistake can help us to unravel the nature of mathematical beauty. To see why, we first need to understand three other claims that he makes. The first is that mathematical beauty does not come in degrees (Rota 1997, 180). In other words, a piece of mathematics is either beautiful or it is not—there is no middle ground. The second is that mathematicians criticize each other's work by asking what it is good for (Rota 1997, 178). When they ask this, mathematicians are not indicating that they cannot verify the correctness of a theorem or a proof. Rather, although they can verify it, they feel something important is still missing: enlightenment (Rota 1997, 180–181).

Rota does not offer a full analysis of enlightenment. However, he suggests that it involves, for example, grasping the role of a mathematical statement, seeing how different mathematical statements are connected to each other and recognizing how a statement is relevant (Rota 1997, 181). Rota emphasizes that this is not just psychological. Rather it has a logical component and is objective: "The property of being enlightening is objectively attributed to certain mathematical statements and denied to others" (Rota 1997, 181). Nonetheless enlightenment, unlike beauty, comes in degrees, as it allows for some statements to be more or less enlightening than others. This leads us to Rota's third important claim: mathematicians do not like the concept of enlightenment, in part because it is fuzzy, but also because it is not amenable to formalization (Rota 1997, 181).

With Rota's three core claims identified, we can now understand how grasping the "light bulb" mistake reveals the nature of mathematical beauty on his account. When mathematicians ask "What is this good for?" they are asking for enlightenment. However, they do not want to explicitly acknowledge enlightenment because it is fuzzy and not easily formalizable. The concept of mathematical beauty, however, is not fuzzy—it does not admit degrees. Moreover, in the grip of the "light bulb" mistake, mathematicians think that grasping beauty is instantaneous and forget how messy the process really is. They thus talk about mathematical beauty when they really mean enlightenment: "The comfortable one-shot but misleading idea of mathematical beauty saves us from having to deal with the messy situation of a concept having degrees. All talk of mathematical beauty is a copout from confronting the logic of enlightenment" (Rota 1997, 182). A beautiful proof, on Rota's account, is thus really an enlightening

one: "We say that a proof is beautiful when such a proof finally gives away the secret of the theorem, when it leads us to perceive the actual, not the logical inevitability of the statement that is being proved" (Rota 1997, 182).

3.2.2 Cellucci's Account of Beautiful Proofs

Cellucci (2015) criticizes Rota's account of mathematical beauty for not providing further details about the nature of enlightenment (Cellucci 2015, sec. 6). He further notes that Rota's use of the term "enlightenment" runs dangerously close to making the same light bulb mistake that Rota decried. More precisely, Cellucci notes that "enlighten" is often used to mean "to provide insight" which has connotations of grasping something instantly (Cellucci 2015, sec. 8).

Cellucci's own proposal is to analyze mathematical beauty in terms of understanding rather than enlightenment. On his account, a piece of mathematics, such as a proof, is beautiful when it provides understanding. Understanding itself is analyzed as "the recognition of the fitness of the parts to each other and to the whole" (Cellucci 2015, sec. 8). Because of this, understanding is taken to be a truly aesthetic property on Cellucci's account (Cellucci 2015, sec. 8). Applying his account to proofs, Cellucci says "There is a fitness of the parts of a demonstration to each other and to the whole when it is clear what the whole idea of the demonstration is, what the contribution of each part of the demonstration to the whole idea is, and why such contribution is essential" (Cellucci 2015, sec. 10). A proof that exhibits such fit yields understanding and is thus beautiful.

Cellucci (2015, sec. 11) presents the solution to the problem of constructing a square with half the area of a given square as an example of a beautiful proof. The diagram in Fig. 1 shows the large, given square with solid lines which has an area equal to eight right-angled triangles. The area of the square with dotted lines, on the other hand, is easily seen to be equal to four right-angled triangles. This square therefore has half of the area of the given square. As Cellucci simply remarks "The demonstration is beautiful because it provides understanding" (Cellucci 2015, sec. 11).

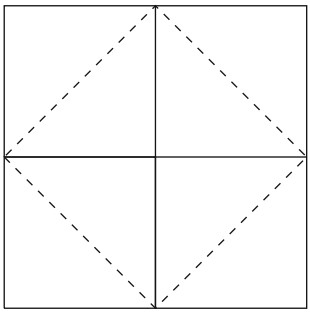

Fig. 1 The dotted square has an area half that of the large given square

3.2.3 Summary

Beautiful proofs are highly valued by mathematicians. Moreover, as mathematical beauty is intrinsically valuable, it counts as an abstract proof value. However, the topic of beautiful proofs has been less thoroughly investigated than explanatory proofs. Further work to analyze beautiful proofs and to evaluate existing accounts of such proofs would therefore help us to gain a deeper understanding of mathematical beauty.

3.3 Fit

Closely related to mathematical beauty is the notion of *fit*. Proofs that are particularly fitting are thus unsurprisingly judged to be valuable:

> [O]ne can often experience a feeling in mathematics that a claim is *right*, that a certain proof *fits* a theorem, or that a particular argument is *exactly* the one needed. Similarly one can feel that one proof has a better fit for a certain theorem than another, or that another proof, while being technically correct, jars with the statement of a theorem, being somehow the wrong kind of argument for the given claim (Raman-Sundström and Öhman 2018, 184–185, emphasis in the original).

> Scientists talking about their own work and that of other scientists use the terms "beauty," "elegance," and "economy" with the euphoria of praise more characteristically applied to painting, music, and poetry. Or there is the exclamation of recognition—the "Aha" that accompanies the discovery of a connection or an unexpected but utterly right realization in art and science. These are epithets of the sense of "*fit*"—of finding the most appropriate, evocative and correspondent expression for a reality heretofore unarticulated and unperceived, but strongly sensed and actively probed (Wechsler 1988, 1, emphasis added).

Quotes such as these already suggest that fit is an abstract value. For further evidence of this, note that elsewhere Raman-Sundström argues that mathematics "involves family relationships, and inner coherences that are deeply, and objectively, satisfying" (Raman-Sundström 2016, 284) and that "the better the fit between ideas, and the better we understand mathematics, the better it coheres" (Raman-Sundström 2016, 283). Given that fit is a property involving "deeply, and objectively, satisfying" (Raman-Sundström 2016, 284) coherences, it appears to be intrinsically valuable (Raman-Sundström is, however, somewhat hesitant about calling fit a value of proofs in the sense of being "something valued on a biological level, and/or valued as part of a good mathematical education" (Raman-Sundström 2016, 283)). Further, by providing us with understanding it gives us something else that is also intrinsically valuable.

But what, exactly, is a fitting proof? This question has been explored by Raman-Sundström (2016) and Raman-Sundström and Öhman (2018). Below we will consider the account developed in Raman-Sundström and Öhman (2018).

3.3.1 Raman-Sundström and Öhman's Account of Fitting Proofs

Raman-Sundström and Öhman (2018) offer an analysis of a variety of different ways in which a proof can be fitting. They identify three general types of fit—direct, presentational, and familial—which they then break down further, giving a total of six different criteria. Direct fit concerns the way the proof connects to the theorem,

presentational fit focuses on how the proof fits with the reader, and familial fit is about how the proof fits with mathematics more generally.

Direct fit has two subtypes: coherence and specificity (Raman-Sundström and Öhman (2018), 3–4). A proof meets the criterion of *coherence* when it uses the same language and conceptual resources as its theorem. A proof meets the criterion of *specificity* when the tools used by the proof are of the appropriate power. In other words, the proof neither resorts to brute force methods nor high-powered methods that deliver more than is needed.

Presentational fit has two flavors: level of detail and transparency (Raman-Sundström and Öhman 2018, 4–5). A proof meets the criterion of *level of detail* when it provides appropriate details, given the background of the intended reader. For example, a proof that gives every single step in a computation is likely to fail the level of detail criterion, because a reader could easily do some of these steps herself. A proof that skips too many steps is also likely to fail this criterion, because a reader cannot figure out what these steps are by himself/herself. A proof meets the criterion of *transparency* when its argument is clear, without any deus ex machina steps, so that a reader can easily understand the idea of the proof. Proofs that are highly transparent make it easy for the reader to see "what is going on" (Raman-Sundström and Öhman 2018, 188) in the argument.

Familial fit has two subtypes: generality and connectedness (Raman-Sundström and Öhman 2018, 5). A proof meets the criterion of *generality* when it can be generalized to prove other theorems. A proof meets the criterion of *connectedness* when the ideas or tools used in the proof connect to the ideas or tools used in other proofs, though not via generalization.

Raman-Sundström and Öhman illustrate how these criteria are to be applied in practice by analyzing eight proofs of four different theorems (Raman-Sundström and Öhman 2018, §3). Below we will consider one of these proofs: a trigonometric proof of the Pythagorean theorem. Recall that the Pythagorean theorem states that for a right-angled triangle with hypotenuse c and other sides a and b, the sum of the squares on the sides a and b is equal to the square on side c. A trigonometric proof, found in 2009, is given below (Raman-Sundström and Öhman 2018, 195–197). The proof relies on the subtraction formulas: $\cos(\alpha - \beta) = \cos\alpha\cos\beta + \sin\alpha\sin\beta$ and $\sin(\alpha - \beta) = \sin\alpha\cos\beta - \cos\alpha\sin\beta$.

Proof Suppose that c is the hypotenuse of the right-angled triangle and the other sides are a and b. Let α be the angle opposite a and β be the angle opposite side b. Assume WLOG that $0 < \beta \leq \alpha < 90^{\circ}$. Then we have

$$\begin{aligned}\cos\beta &= \cos(\alpha - (\alpha - \beta)) = \cos\alpha\cos(\alpha - \beta) + \sin\alpha\sin(\alpha - \beta)\\ &= \cos\alpha(\cos\alpha\cos\beta + \sin\alpha\sin\beta) + \sin\alpha(\sin\alpha\cos\beta - \cos\alpha\sin\beta)\\ &= \left(\cos^2\alpha + \sin^2\alpha\right)\cos\beta.\end{aligned}$$

Hence $\cos^2\alpha + \sin^2\alpha = 1$ and thus, from the definitions of sine and cosine and scaling, the Pythagorean theorem is proven. □

According to Raman-Sundström and Öhman, this proof is fitting in only two of the senses they identify: specificity and level of detail (Raman-Sundström and Öhman 2018, 196–197). The proof meets the criterion for specificity because it uses appropriately powerful resources: the subtraction formulas. The proof meets the criterion for level of detail because it is concise but still provides all of the steps needed to follow the proof easily.

The proof fails to meet the remaining four criteria of fit: coherence, transparency, generality, and connectedness (Raman-Sundström and Öhman 2018, 196–197). The proof fails the criterion of coherence because the Pythagorean theorem, stated above, is given in terms of areas, while the proof makes no mention of areas and is instead entirely trigonometric. The proof fails to be transparent because it is not a very natural approach to take. For example, the reader may wonder why the proof author decided to rewrite $\cos\beta$ as $\cos(\alpha - (\alpha - \beta))$ (Raman-Sundström and Öhman 2018, 196). The proof fails to be general because the core idea of the proof does not easily generalize to other theorems. Finally, the proof is not connected because the only family of proofs it could be said to belong to are those that use trigonometric identities. However, this does not really seem to be a meaningful family, given that it is so broad (Raman-Sundström and Öhman 2018, 196).

3.3.2 Summary

Mathematicians value proofs that are fitting, where a proof can be fitting in a variety of different ways. As fit involves deeply pleasing coherences, it appears to be intrinsically valuable, but it also provides something else of intrinsic value: understanding. It is therefore an abstract proof value. However, the topic of fitting proofs has only recently attracted attention. It would thus benefit from further investigation to evaluate the criteria of fit already identified by Raman-Sundström and Öhman and to look for additional ways in which a proof can be fitting.

3.4 Motivation

The final abstract value of proofs that we will consider is motivation. Mathematicians care about motivation, as evidenced by the fact that they often make explicit remarks about the motivational power of a proof. For example:

> Here we offer a new and motivated proof of Eisenstein's theorem, relying on the basic theory of differential operators for Jacobi forms together with a classical identity for the first quasi-period of a lattice (Rolen 2015, abstract).

> We present a short and motivated proof of Riemann's functional equation for Riemann's zeta function (Knopp and Robins 2001, 1915).

> We give a generalization for Hajós' theorem. The proof of this generalization is simpler and the steps are better motivated than the proof of the original result (Corrádi and Szadó 1993, abstract).

Motivated proofs, like explanatory ones, provide understanding. For example, Pólya remarks that when an unmotivated proof of Carleman's inequality was supplemented with discussion designed to make it more motivated, "The derivation [. . .] became also more understandable" (Pólya 1949, 690). As motivated proofs provide us with understanding, which is intrinsically valuable, motivational power is an abstract value.

But what makes a proof motivated? Pólya (1949), Sandborg (1997), and Morris (2020) have all tackled this question. I will present the accounts of Pólya and Morris below.

3.4.1 Pólya's Account

As mentioned above, Pólya discusses motivation in the context of a proof of Carleman's inequality. Carleman's inequality states the following: Let a_1, a_2, a_3, . . . be a sequence of nonnegative real numbers, not all equal to 0. Then $\sum_{n=1}^{\infty}(a_1a_2a_3\ldots a_n)^{\frac{1}{n}} < e\sum_{n=1}^{\infty}a_n$. The proof, presented below, is taken verbatium from Pólya (1949, 684–685):

Proof Define the numbers $c_1, c_2, c_3, \cdots$ by

$$c_1c_2c_3\cdots c_n \;=\; (n+1)^n$$

for $n = 1, 2, 3, \cdots$. We use this definition, then the inequality between the arithmetic and the geometric means, and finally the fact that the sequence defining e, the general term of which is $[(k+1)/k]^k$, is increasing. We obtain

$$\begin{aligned}
\sum_{n=1}^{\infty}(a_1a_2\cdots a_n)^{1/n} &= \sum_{n=1}^{\infty}\frac{(a_1c_1a_2c_2\cdots a_nc_n)^{1/n}}{n+1}\\
&\le \sum_{n=1}^{\infty}\frac{a_1c_1+a_2c_2+\cdots+a_nc_n}{n(n+1)}\\
&= \sum_{k=1}^{\infty}a_kc_k\sum_{n\ge k}\frac{1}{n(n+1)}\\
&= \sum_{k=1}^{\infty}a_kc_k\sum_{n=k}^{\infty}\left(\frac{1}{n}-\frac{1}{n+1}\right)\\
&= \sum_{k=1}^{\infty}a_k\frac{(k+1)^k}{k^{k-1}}\frac{1}{k}\\
&< e\sum_{k=1}^{\infty}a_k.
\end{aligned}$$

□

Although this proof is perfectly correct, Pólya notes that readers will be puzzled by the very first step: the introduction of the auxiliary c_i sequence. He imagines that complaints could reasonably be made, for example:

> It pops up from nowhere. It looks so arbitrary. It has no visible motive or purpose (Pólya 1949, 685).

> Look here, I am not here just to admire you. I wish to learn how to do problems by myself. Yet I cannot see how it was humanly possible to hit upon your . . . definition. So what can I learn here? How could I find such a . . . definition by myself? (Pólya 1949, 685)

Pólya suggests that reactions like these indicate that a reader wants the steps in a motivated proof to be not just correct, but also *recognizably appropriate* (Pólya did not introduce the specific term "recognizably appropriate"—I am introducing it here for clarity and convenience. Instead, Pólya notes that a step must be appropriate and should also "*appear so* to the reader" (Pólya 1949, 685, emphasis in the original)). For Pólya, a proof step is appropriate "if it is essentially connected with the purpose, if it brings us nearer to the goal" (Pólya 1949, 687). Note, however, that it is crucial that the steps in a proof are *recognizably* appropriate if the proof is to be well motivated. Indeed, the step that introduces the c_i sequence in the unmotivated proof of Carleman's inequality *is* appropriate, though it fails to be *recognizably* so. In Pólya's words: "this step [that introduces the c_i sequence] is certainly appropriate. In fact, the argument based on this definition proves the proposed theorem, and proves it rather quickly and clearly. The trouble is that the step in question, although vindicated in the end, does not appear as justified from the start" (Pólya 1949, 686). Unfortunately, Pólya does not provide further analysis of what it means for a step to be recognizably appropriate.

3.4.2 Morris's Account

Morris (2020) suggests that there are two related, but distinct, reasons why the introduction of the c_i sequence in Pólya's proof is problematic. The first reason is that the role of the step, that is the task it is meant to perform in the overall argument, is unclear (Morris 2020, 29). In other words, it is hard for a reader to identify how exactly the c_i sequence interacts with other parts of the proof to ensure the result follows. The second reason is that the insight that led to the introduction of the c_i sequence, i.e., where it came from, is unclear (Morris 2020, 30). In other words, it is hard for a reader to figure out what led the proof author to come up with and introduce that sequence.

This leads Morris to suggest that a proof is motivated if and only if the role of each step and the insight behind each step are clear, i.e., the reader can identify the tasks each step is meant to carry out and where each step could have come from (Morris 2020, 31). Whether the role of and insight behind each step are clear depends on the audience and so the notion of motivated proofs she develops is a relative one. She takes it to be relative to a given mathematical *context*, that is, a specific

mathematical background that readers of the proof are assumed to have. So while the proof of Carleman's inequality is unmotivated for students with only a limited mathematical background or context, it may be motivated for experts with an extensive background in inequalities.

3.4.3 Summary

Mathematicians value proofs that are well motivated. Like explanation, motivation provides understanding, which is intrinsically valuable, and so motivation is an abstract proof value. To my knowledge, however, motivation has only been investigated by Pólya, Sandborg, and Morris and would therefore benefit from further work. For example, Morris notes that there may be other senses in which a proof can be motivated which "focus on . . . a proof's interestingness or its connections to other results" (Morris 2020, 28). Developing accounts of such alternative forms of motivation would therefore deepen our understanding of this abstract proof value.

4 Relationships Between Abstract and Practical Values

A proof can have both practical and abstract value. Recall from the discussion of practical values in Sect. 2.2 that *all* proofs have the practical values of making mathematical knowledge accessible, systematizing mathematics and safeguarding mathematics against mistakes. Proofs with abstract value thus always have these practical values as well. However, they are often associated with additional practical values, as I will discuss below.

4.1 Explanation

It seems plausible to think that an explanatory proof may explain its theorem by introducing new concepts and methods and thus have the practical value of helping the reader to learn new ways of thinking. Further, it seems reasonable to think, as De Villiers does, that since an explanatory proof "reveals the underlying properties and reasons for the validity of a result, [it] may upon further reflection, sometimes lead to the discovery of immediate generalizations, specializations or other variations" (de Villiers 2017, 2). In other words, it seems plausible to think that explanatory proofs also have the practical value of promoting new discoveries. However, Morris's (forthcoming) arguments suggest that the situation is not quite so straightforward.

First consider the practical value of helping mathematicians learn new ways of thinking. Morris (forthcoming) argues that to help mathematicians learn tools like new concepts and methods from a proof, the proof must be well designed and presented so that it manages information well. She claims that, in general, current accounts of explanatory proofs are *not* sensitive to such issues, meaning that proofs deemed explanatory by such accounts may manage information poorly and make it

difficult for readers to learn new tools from them. She provides a concrete example in the form of a proof of Fermat's little theorem that, she argues, is explanatory according to Lange's account but which does a bad job of managing information, making it difficult for readers to learn the tools it uses. If Morris is right, then while some explanatory proofs may teach mathematicians new tools, others will be poorly designed and presented and so will not. We thus cannot say that explanatory proofs in general have this practical value.

Next consider the benefit of stimulating discovery. Recall that, in the quote from De Villiers above, explanatory proofs were *sometimes* said to lead to new discoveries. This qualification is important—we should not expect explanatory proofs to have this benefit generally (Although see Cellucci (2008, 2014) for an account of mathematical explanation that connects explanation directly to discovery). Indeed Lange is quite explicit that something can be explanatory without leading to further discoveries: "A new proof technique can explain why some theorem holds even if that technique allows no new theorems to be proved" (Lange 2014, 523). Further, Morris's argument about the practical value of helping mathematicians to learn new tools seems to apply here as well. If accounts of explanatory proofs are not sensitive to issues of design and presentation, then, at least according to these accounts, there can be explanatory proofs that manage information poorly. Although such a proof will still identify the reason why the theorem is true, it will not make it easy for the reader to grasp that reason. If the reader does not grasp this, however, it is difficult to see how the proof can help her to make further discoveries.

4.2 Beauty

There is reason to think that beautiful proofs often have the practical values of stimulating new discoveries and helping mathematicians to learn new ways of thinking.

First consider the practical value of stimulating new discoveries. Cellucci (2015, sec. 15) argues that there is a relationship between beautiful *hypotheses* and discovery, but there is reason to think that there is also a connection between beautiful *proofs* and discovery. On Cellucci's account, beautiful proofs provide understanding by making clear what the idea of the argument is, how each part of the proof contributes to it, and why each such contribution is necessary. Plausibly this may suggest ways to adapt or generalize the argument and thus put mathematicians in a good position to discover and prove new theorems.

Moreover, because of their connection to understanding, beautiful proofs may plausibly introduce mathematicians to new ways of thinking. For example, by making it clear how its different parts fit together, a beautiful proof may help mathematicians to refine intuitions or mental models of the mathematics in question. Beautiful proofs may also promote understanding of how their parts fit together by introducing new methods or concepts, thus providing those who read them with new mathematical tools.

4.3 Fit

There are potential connections between the criteria of fit identified by Raman-Sundström and Öhman and the practical values of helping mathematicians to learn new ways of thinking and making new discoveries.

Consider first fitting proofs that meet the criterion of coherence. Such proofs use the same language and conceptual resources as the theorem and so are very similar to proofs that are *pure*. For example, Detlefsen roughly characterizes purity as "enforc [ing] a certain symmetry between the conceptual resources used to prove a theorem and those needed for the clarification of its *content*. The basic idea is that the resources of proof ought ideally to be restricted to those which determine its content" (Detlefsen 2008, 192–193, emphasis in original). It has been claimed that pure proofs can help stimulate new discoveries since they serve as "a more effective instrument for gaining further knowledge" (Detlefsen 2008, 191). Detlefsen unpacks the reasoning behind such a claim as follows:

> The idea seems to be that (i) a specialist is most likely to do something significant with any solution to a problem in her speciality, [. . .] (ii) this advantage is enhanced if a solution is given in terms of concepts most familiar to her, and [. . .] (iii) the purer the proof the more it conforms to this type of solution (Detlefsen 2008, 190–191)

Given the similarity between pure and coherent proofs, if the former stimulate new discoveries, we should expect the latter to as well. However, there is reason to be skeptical of the claim that pure proofs stimulate new discoveries, since they may be harder to understand than impure proofs. As an example of a pure proof that may be more difficult to understand than impure proofs of the same theorem, we can consider Selberg's (1949) proof of the prime number theorem. The prime number theorem is a result in number theory describing the distribution of the primes. The original proofs by Hadamard (1896) and de la Vallée Poussin (1896) made heavy use of analysis. This means they are impure, since analysis involves conceptual resources that go beyond the statement of the theorem. Selberg's proof did not use analysis and was thus much purer than previous proofs. However it has also been described as "more difficult to understand" (Hua 2012, 217) than more modern proofs that do use analysis and are thus impure.

Presumably, if a proof is harder to understand, regardless of whether it involves "concepts most familiar to" (Detlefsen 2008, 191) a specialist, it will make it more difficult to adapt or generalize to make new discoveries than an impure proof. The argument that coherent proofs promote new discoveries because they are like pure proofs is thus unconvincing.

Fitting proofs that are specific may have the practical benefit of helping mathematicians learn new ways of thinking. For example, Raman-Sundström and Öhman note that proofs that score high on the criterion of specificity use tools that go "above and beyond the standard brute-force methods for approaching a proof of a theorem at hand" (Raman-Sundström and Öhman 2018, 187). Specific proofs may thus help the reader to learn new mathematical tools, at least if they are appropriately designed and

presented. As we have seen in Sect. 2.2, introducing mathematicians to new mathematical tools often leads to new discoveries. Proofs that satisfy the criterion of specificity may therefore stimulate new discoveries as well.

Fitting proofs that have an appropriate level of detail may not, in virtue of this alone, teach readers new ways of thinking or prompt them to make new discoveries. However, the criterion of level of detail is still important to the attainment of these practical benefits. Suppose, for example, a proof has too much or too little detail. Then the proof manages information poorly. A proof that manages information poorly can be confusing to the reader and thus prevent him/her from learning new tools or making new discoveries from it. So while level of detail may not by itself bring practical benefits, it contributes to their attainment.

Transparent proofs seem likely to introduce a reader to new ways of thinking. Raman-Sundström and Öhman remark that "if a proof is transparent, a reader with the appropriate background should be in *an ideal position to grasp the ideas of the proof*" (Raman-Sundström and Öhman 2018, 188, emphasis added). Ensuring that readers can grasp the ideas of the proof helps them to refine their intuitions and mental models about relevant mathematical concepts and potentially to understand new methods and techniques used within the proof as well. Given the connection between helping mathematicians learn new ways of thinking and making new discoveries, we can expect transparent proofs to stimulate new discoveries as well.

Fitting proofs that score highly on the criterion of generality are likely to have the practical value of promoting new discoveries, at least if they are appropriately designed and presented. After all, the definition of proofs that score highly on this criterion is that they can be generalized to prove new theorems!

Finally, the criterion of connectedness can plausibly help readers to develop new ways of thinking, so long as mathematicians reading the proof are in a position to recognize a fitting proof's connectedness. If a mathematician is able to recognize a proof's connectedness, then by seeing that the ideas or tools it uses are shared by a family of other proofs, the reader can refine their mental models or intuitions. Further, if a reader comes to see that a technique or method can be used in a variety of different circumstances, their may learn that the scope of that tool is more extensive than they first thought. While this is not exactly the same as learning a completely new method, it is very similar to it. Given that proofs that help mathematicians learn new ways of thinking often stimulate new discoveries, connected proofs should also lead mathematicians to new discoveries, at least if their connectedness is recognizable.

4.4 Motivation

There are strong connections between motivated proofs and the practical values of helping mathematicians to learn new ways of thinking and stimulating new discoveries.

Morris claims that motivated proofs help their readers to understand how to use the tools they contain as well as the circumstances under which it is useful to apply

them, both of which are important to successfully learning new mathematical tools. In particular, the reader of a motivated proof can identify the tasks each step performs which helps them learn how to use new resources the proof contains (Morris 2020, 39). The reader can also identify where each step could have reasonably come from, which helps them to get an idea of the circumstances under which it might be helpful to apply new resources the proof uses (Morris 2020, 39). Motivated proofs are thus likely to help mathematicians learn new ways of thinking.

As we have seen in Sect. 2.2, proofs that help mathematicians learn new ways of thinking often also stimulate new discoveries. Further, Morris argues explicitly that identifying the tasks a step is meant to perform and where it could have reasonably come from can stimulate new discoveries (Morris 2020, 39).

4.5 Summary

We have seen that proofs with abstract values are connected, to varying degrees, to the practical values of learning new tools and making new discoveries. We also noted that, just by being proofs, proofs with abstract values have the practical values of helping to make mathematical knowledge accessible, systematizing mathematics and safeguarding mathematics from mistakes. This leaves only one practical value unmentioned: illustrating the power of different methodologies. There is, in fact, little reason to think that proofs that have the abstract values discussed here will also tend to have this practical value. Indeed, there does not seem to be anything in the nature of explanation, beauty, fit, or motivation that suggests that proofs with these values often introduce or utilize an entirely different methodology.

5 Relationships Between Abstract Values

Given the discussion of the relationships between practical and abstract values of proofs, we may wonder whether, and to what extent, the abstract values themselves are related (Important empirical work on relationships between proof values has been conducted by Inglis and Aberdein (2015) and Inglis and Aberdein (2016)). In particular, are proofs with a given abstract value likely to also have a different abstract value? For example, are explanatory proofs also likely to be beautiful? Below I consider the relationship between each of the abstract values discussed in Sect. 3. I start with, and provide the most detailed discussion of, the relationship between fit and motivation and provide shorter sketches of the relationships between the other abstract values.

5.1 Fit and Motivation

Raman-Sundström and Öhman's criteria of presentational fit—transparency and level of detail—have strong connections to Morris's account of well-motivated

proofs. First consider transparency. Morris (2020) argues that a well-motivated proof is likely to be transparent. If a proof is well motivated, relative to a given context, then the reader can identify the tasks each step is intended to perform as well as where they came from and this means they should also be able to see "what is going on" in the proof, thus making it transparent (Morris 2020, 43). However, Morris suggests that there may be transparent proofs that fail to be well motivated: "perhaps it is possible to understand the core ideas of a proof and have a high level grasp of 'what is going on' within it while still finding a few steps involving the technical details to be puzzling" (Morris 2020, 43).

Next consider the level of detail. Given that a well-motivated proof, on Morris's account, must manage information well, we can also expect well-motivated proofs to be fitting in the sense of having an appropriate level of detail. However, having an appropriate level of detail is not, by itself, sufficient for a proof to be well motivated. Presumably the trigonometric proof of the Pythagorean theorem given in Sect. 3.3 will fail to be motivated relative to a standard geometric context, but, as was noted there, it does satisfy the level of detail criterion.

There are also strong connections between the two types of familial fit—generality and connectedness—and Morris's account of motivated proofs. In particular, it seems plausible to suggest that motivated proofs are likely to score highly on these two criteria. As we have seen, Morris argues that motivated proofs are likely to have the practical values of helping mathematicians to learn new tools and promoting new discoveries. If a motivated proof promotes discoveries because the underlying idea generalizes, then it will score highly on generality. And if a motivated proof promotes discoveries because it helps the reader to learn and subsequently reuse new tools that it contains, then it will likely score highly on connectedness. However proofs that score highly on generality or connectedness will not necessarily be motivated, at least on Morris' account. This is because a proof can presumably be generalizable or connected and yet fail to be well designed and presented, making it difficult for the reader to grasp the role of and insight behind each step.

There are fewer connections between the criteria of direct fit—coherence and specificity—and well-motivated proofs. First consider coherence. As we have seen in Sect. 3.3.2, coherence is similar to purity, in that a coherent proof uses the same conceptual resources and language as the theorem. However it seems plausible to imagine a coherent proof that nonetheless fails to be well motivated on Morris's account because it is too difficult for a reader to identify the role of and insight behind its steps. Selberg's proof of the prime number theorem, already discussed in Sect. 3.3.2, may be such an example. This proof scores high on coherence because it does not use analysis, but it has been described as "difficult to understand" (Hua 2012, 217). It is thus likely that it will be difficult for a reader to identify the role of each step as well as the insight behind it relative to certain contexts, meaning that it is not well motivated. In fact, the mathematician Levinson wrote an article which aimed "to give a self-contained and motivated account of an elementary proof of the prime number theorem" (Levinson 1969, 225). Presumably he would have no reason to do this if Selberg's original proof had been motivated. Similarly, a

motivated proof does not need to be coherent. As mentioned earlier, there are proofs of the prime number theorem that use analysis, and so fail to be coherent, but are easier to understand, and so may be motivated relative to an appropriate context.

Consider now specificity. Again there is little reason to expect a connection between specificity and well-motivated proofs. The trigonometric proof of the Pythagorean theorem, given in Sect. 3.3, for example, scored highly on specificity, but would likely be unmotivated relative to a standard geometric context. Similarly, proofs that are motivated may fail to be specific. For example, the well-known proof of the irrationality of $\sqrt{2}$ that uses the unique factorization theorem is plausibly well motivated relative to appropriate contexts. However, Raman-Sundström and Öhman argue that this proof is not specific: "[The unique factorization theorem] is adequate to prove the theorem, but is overly powerful. In fact, only the number of factors 2 in [the prime decomposition of certain numbers] is needed for the conclusion to be drawn" (Raman-Sundström and Öhman 2018, 191).

5.2 Explanation and Beauty

It seems plausible to think that there is a strong connection between proofs that are beautiful and proofs that are explanatory. Lange (2016b), for example, argues that explanatory proofs, on his account, are also beautiful. He writes that explanatory proofs "derive their beauty from exactly what gives them their explanatory power, namely, from their exploiting precisely the feature in the setup that is salient in the theorem (such as its symmetry, unity, or simplicity)" (Lange 2016b, 45). However, Lange remains agnostic about whether beautiful proofs are also explanatory, noting that his account "does not rule out beautiful, nonexplanatory proofs of theorems that have explanations" (Lange 2016b, 46).

On the other hand, Giaquinto (2016) suggests that there are reasons to be skeptical of the claim that explanatory proofs are beautiful. In particular, he argues that many explanatory proofs are also "facile" and that, for this reason, they fail to be beautiful (Giaquinto 2016, 67–68). Giaquinto also suggest we should be skeptical of the claim that beautiful proofs are explanatory, at least until we have more data. For while it may initially seem plausible to suggest that beautiful proofs tend to be explanatory, he presents a proof of the infinitude of the primes due to Erdös as a potential counterexample. This proof has been described as beautiful, but Giaquinto argues that it fails to be explanatory (Giaquinto 2016, 68–70).

5.3 Explanation and Fit

Raman-Sundström and Öhman (2018) suggest that there are relationships between explanatory proofs and their criteria of coherence, transparency, and connectedness. Recall that, on Steiner's account, an explanatory proof clearly depends on a characterizing property of something mentioned in the theorem. Raman-Sundström and

Öhman then note that this relates to coherence: "A proof that has the same terms as a theorem, which is how we have characterized coherence, seems similar to a proof that evidently gives rise to a particular result" (Raman-Sundström and Öhman 2018, 205). They further suggest that connectedness is related to both Steiner's and Kitcher's account of explanatory proofs, since familial relationships enter into Steiner's account via characterizing properties and into Kitcher's via the explanatory store (Raman-Sundström and Öhman 2018, 206).

Raman-Sundström and Öhman also suggest that their notions of coherence and transparency have a place in Lange's account. Recall that, for Lange, an explanatory proof traces a salient feature, like symmetry or unity, in the result back to its setup. Raman-Sundström and Öhman argue that coherence is similar to how Lange understands unity and that transparency relates to his notion of salience. Lange describes a unified proof as one which "exploits a property that all of the cases covered by the theorem have in common and treats all of those cases in the same way" (Raman-Sundström and Öhman 2018, Lange quoted on pg 206) and Raman-Sundström and Öhman take this to be connected to coherence in a "fairly straightforward" (Raman-Sundström and Öhman 2018, 206) way. They further suggest that coherence can justify the salience of a feature of the result and that transparency can help us to access "the underlying ideas" (Raman-Sundström and Öhman 2018, 206).

5.4 Explanation and Motivation

While we might expect there to be a close relationship between explanatory proofs and well-motivated ones given that both types of proof are connected to understanding, Morris (2015, 2020) argues that there are significant differences between them. In particular, she notes that accounts of explanatory proofs do not usually take into consideration whether a reader will *recognize* the explanation. However, for a proof to be well-motivated with respect to a given context, the reader must identify and thus recognize the tasks each step performs as well as where each step came from (Morris 2020, 42). She also points out that explanatory and well-motivated proofs differ in their practical value, as motivated proofs are likely to successfully convey new ways of thinking to their readers but the same cannot be said for explanatory proofs (Morris 2020, 42).

Morris further provides examples to illustrate that there can be explanatory proofs which are not well motivated and vice versa. For example, Steiner remarks that many inductive proofs will fail to be explanatory on his account but Morris suggests that inductive proofs can be well motivated relative to a suitable context (Morris 2015, 108–110). Hafner and Mancosu (2008) argue that proofs using a decision procedure in the theory of real-closed fields are explanatory according to Kitcher's account (and use this to criticize his account) but Morris argues that, because these proofs can be inordinately long and tedious, they are not well designed and so may fail to be motivated (Morris 2015, 106–108).

5.5 Beauty and Fit

It seems that there are strong connections between beautiful proofs and fitting proofs, especially given that Cellucci's account of beauty was analyzed in terms of fit. As we saw in Sect. 3.3, a proof is beautiful on Cellucci's account when the parts of a proof fit together, i.e., "when it is clear what the whole idea of the demonstration is, what the contribution of each part of the demonstration to the whole idea is, and why such contribution is essential" (Cellucci 2015, sec. 10). Proofs that are beautiful, on Cellucci's account, thus also seem to be what Raman-Sundström and Öhman call transparent, since they will help the reader to grasp "what is going on" (Raman-Sundström and Öhman 2018, 188) in the proof.

It is less clear, however, whether proofs that are transparent will also always be beautiful. For example, perhaps it is possible to grasp "what is going on" in the proof at a high level without fully grasping the contribution made by some of the more technical parts of the proof, or without fully grasping why they are essential. Such a proof would be transparent, at least at a high level, but would not be fully beautiful on Cellucci's account.

In addition to a connection between beauty and transparency, Raman-Sundström and Öhman note that there may be connections between beauty and level of detail and connectedness. As level of detail connects to the length of proofs, they suggest that it may also be related to beauty, given the common intuition that short proofs are more beautiful (Raman-Sundström and Öhman 2018, 207). Regarding connectedness, Raman-Sundström and Öhman suggest that a proof that scores highly on this criterion lets you see it from a different perspective, and this, in turn, may make it beautiful (Raman-Sundström and Öhman 2018, 207).

5.6 Beauty and Motivation

Morris (2020) argues that there is a connection between beautiful proofs and well-motivated proofs in the following sense: well-motivated proofs will tend to be beautiful, at least on Cellucci's account. As a motivated proof, on Morris's account, will help the readers to identify the tasks each step is intended to perform as well as where each step could have reasonably come from, they should thus be able to grasp the idea of the proof, the contribution of each of its parts, and why each part was required (Morris 2020, 43). Thus motivated proofs will be beautiful.

Perhaps it is possible, however, for there to be proofs that are beautiful on Cellucci's account, but not well motivated on Morris' account. After all, Cellucci's criteria for a beautiful proof do not explicitly include making clear where each step in the argument could have come from. Perhaps, then, there could be a proof whose overall idea is clear, whose steps have a clear contribution and are clearly needed, but which contains a step that does not make it easy to see how the author could have come up with it.

5.7 Summary

We have seen that there appear to be significant connections between many of the abstract values of explanation, beauty, fit, and motivation. However, deeper investigations are required to fully understand the nature of the relationships between them. For example, as we saw above, Giaquinto urges caution in accepting the claim that beautiful proofs are explanatory until we have more data and case studies. Further, although we saw Morris highlights important differences between motivated and explanatory proofs, she also remarks that the relationship between them is "both interesting and complicated and should be further explored" (Morris 2020, 43). Finally, Raman-Sundström and Öhman invite additional analysis on the relationships between fit and other values when they describe their own discussions on the topic as "more stubs than full articulations" (Raman-Sundström and Öhman 2018, 205).

6 Conclusion

In this chapter I have surveyed some of the wide variety of ways in which proofs can have value. I divided these values into two categories: practical and abstract. Proofs have practical value when they help mathematicians to achieve their goals, such as making new discoveries or learning new tools. Proofs have abstract value when they have qualities that are (or provide something that is) intrinsically valuable, such as beauty or explanatory power.

As we have seen, there are important interconnections between the values proofs can have. Some practical values are closely associated with others, so that proofs with one value often also have the other. For example, proofs that have the practical value of illustrating new methodologies will likely also have the practical value of helping mathematicians to learn new ways of thinking. Abstract values are also closely associated with practical values. For example, motivated proofs are likely to also have the practical values of helping mathematicians learn new mathematical tools and stimulating new discoveries. Finally some of the abstract values themselves are closely related. For example, the abstract value of fit has connections to beauty, explanation, and motivation.

An important future task is to investigate more deeply these individual proof values as well as the relationships between them. For example, we have seen that there is little consensus over the nature of explanatory proofs, while beautiful, fitting, and motivated proofs have received correspondingly little attention. These values would thus all benefit from further analysis. As another example, while intuitively there seems to be a close relationship between beautiful proofs and explanatory ones, as Giaquinto pointed out, we need a more thorough investigation to be able to make any definitive conclusions.

While a wide variety of proof values have been identified and analyzed, there are still more to be investigated. As just one example, mathematicians often indicate,

even in their research papers, that they value proofs that are "intuitive." Below are some representative quotes:

> We give a simple, intuitive proof of a known theorem (Scovel 1985, 751).

> Our proof here is, hopefully, more intuitive and easier to motivate than the existing proofs (Granville et al. 2018, sec. 1).

> The purpose of this paper is to provide a simple and intuitive proof of Weber's result (Derks 2005, sec. 1).

A second future task is thus to identify additional proof values and to develop precise accounts of them.

Continuing to investigate the value of proofs has three main benefits. The first two are practical: (i) further analysis may yield advice about how to *write* proofs with particular values and (ii) understanding the value of proofs may be of use in mathematics education. As an example of (i), Morris's (2020) analysis of motivated proofs includes discussion of how to write them, drawing on work by Avigad (2020) and Sieg (2010) on the design of mathematics. Regarding (ii), mathematics teachers may wish to adopt instructional strategies that emphasize the value of proofs beyond simply establishing that their theorems are true (see, e.g., Hanna (1995)). Having more precise accounts of the values of proofs can be helpful in this regard (see e.g. Hanna (2018)). The third benefit of continued investigation into the value of proofs is more abstract: proofs are central and unique to mathematics and so by deepening our understanding of their value, we similarly deepen our understanding of mathematics itself.

Abstract

Over the past half-century, formal, machine-executable proofs have been developed for an impressive range of mathematical theorems. Formalists argue that such proofs should be seen as providing the fully worked out proofs of which mathematicians' proofs are sketches. Nonformalists argue that this conception of the relationship of formal to informal proofs cannot explain the fact that formal proofs lack essential virtues enjoyed by mathematicians' proofs, the fact, for example, that formal proofs are not convincing and lack the explanatory power of their informal counterparts. Formal proofs do not yield mathematical insight or understanding, and they are not fruitful in the way that informal proofs can be, for instance, in suggesting novel approaches to old problems. And yet, there is a clear sense in which the formalist is right: Formal proofs do seem to make explicit what is otherwise taken for granted in the mathematician's reasoning. Very recent work uncovers the source of the dilemma by showing that rigor does not entail formalism insofar as rigor, unlike formalism, is compatible with contentfulness. Mathematical proofs, were they to be recast in a Leibnizian language, at once a characteristica and a calculus, would be, or could be made to be, completely gap-

free and hence machine checkable. Because as so recast they would be grounded in mathematical ideas, they would not be machine executable. It is on just this basis that a compelling account can be given of the fact that formal proofs are mostly irrelevant to mathematicians in their practice.

1 Introduction

Formal, machine-executable proofs, envisaged already by Leibniz, are a reality. And at least some mathematicians see in such proofs the future of mathematics. Most mathematicians hold that automated deduction belongs, and always will belong, only at the fringes of mathematics. For philosophers, formal proofs of mathematical theorems constitute a problem. Such proofs are not compelling to the practicing mathematician. They cannot serve as vehicles of mathematical understanding. And they are of no use in teaching mathematics to students. The philosopher aims to know why it is given that formal proofs appear, at least, to be nothing more than fully rigorous versions of the everyday proofs that mathematicians esteem. The problem, in short, is to understand the nature of the relationship between a mathematician's proof and a formalization of that same proof. Is, for example, the formalization even correctly described as a mathematical counterpart of the proof it purports to formalize? And if it is not, how is it that something of intrinsic mathematical interest and value is transformed in the process of formalization into something that is not, apparently, mathematical at all?

According to formalists, although mathematicians do not in their practice produce properly formal, machine-executable proofs, mathematicians' proofs do serve as sketches of real, that is to say, formal, rigorous proofs. Nonformalists reject the account, and in recent decades, philosophers of mathematical practice have shown what mathematicians in their practice already intimate, that formal proofs do not play any of the roles mathematicians' proofs play in mathematical practice. Not only do they not convince or verify, but they also do not, for instance, deepen mathematical understanding, provide new resources for tackling outstanding problems, or reveal any interesting relations among apparently disparate sorts of mathematical issues and ideas. And there is a deeper problem as well, one that is of real philosophical significance outside the domain of the philosophy of mathematics. Mathematical reasoning, at least in the cases of concern here, is deductive, and the logic on the basis of which formal proofs (and computing generally) are conducted provides a complete theory of deduction. It would seem, then, that formal proofs of mathematicians' theorems must reveal the essence of mathematical reasoning, or at least something of fundamental significance to such reasoning, and thereby something of

significance to reason itself. And yet, again, formal proofs seem, on the whole, to be utterly irrelevant to mathematicians' practice. *How can this be?* Insofar as they are strictly and manifestly logical, formal proofs must reveal something fundamental about mathematical reasoning, and thereby about rationality generally. And yet, because they are strictly logical, purged of all mathematical content, mathematical concepts, ideas, and methods, formal proofs seem not to reveal anything fundamental about mathematical reasoning in practice nor, presumably, about what it is to be rational. What, then, *is* the relationship between a mathematician's proof and its fully formalized counterpart?

2 Some Early History

Although it was only developments in the nineteenth and twentieth centuries that would reveal the full nature and extent of the problem of formal proof in mathematical practice, the roots of the difficulty stretch back to the seventeenth century, to the first full flowering of the symbolic language of algebra in Descartes' *La Géométrie* (1637). Indeed, its outlines are discernable already in the ancient Greeks, in the dispute between Plato, for whom mathematical knowledge is a matter of grasping, seeing with the mind's eye the forms of things mathematical, and Aristotle, the founder of the science of logic, who looks instead to mathematical reasoning, the syllogism, to understand the nature and peculiar value of mathematical knowledge. In the seventeenth century, Descartes will take the part of Plato, arguing that it is not by reasoning but instead by intuition that one truly knows in mathematics. Leibniz, taking the part of Aristotle, holds that it is proof rather than insight and intuition that establishes truth in mathematics. In the background of both is a conception of language that had by then already been realized, at least in part, in Descartes' symbolic language.

Leibniz first explores the idea of what he thinks of as a universal language (which we here consider as a language for mathematics in particular) in his "Dissertation on the Art of Combinations" (1666). It is the idea of a language that is at once a *characteristica,* a language within which to exhibit the contents of concepts, and a *calculus,* a system of rules governing reasoning on the basis of those contents. Descartes mentions the idea of such a language in a letter written to Mersenne on November 20, 1629. To learn the positional system of Arabic numeration is to learn to write and to compute with numbers in that written system of signs no matter what one's native tongue. Perhaps, then, the same could be done for all the words of natural language – or at least, for such words that pertain to mathematics and mathematical reasoning.

The ways words of natural language are formed from sounds and other words clearly bear no internal, systematic relationship to the ways the concepts signified by the words are formed from simpler concepts. But perhaps a system of written signs could be devised in which there was such a relationship. Such a system would involve simple signs for primitive concepts and complex signs for other concepts that would show in their composition how the contents of those concepts depend on

and are built up out of the contents of the primitive concepts. Even more than the positional system of Arabic numeration that Descartes refers to in his letter to Mersenne, Descartes' symbolic algebra provides the model. In that language, one displays what it is to be, for example, an even number, $2n$ for natural number n, an odd number, $2n - 1$, the length of the hypotenuse of a right triangle the other two sides of which have lengths a and b, $\sqrt{(a^2 + b^2)}$, and so on. This expressive project is, however, only half the story. A Leibnizian universal language also provides rules governing the manipulation of those signs in chains of reasoning; it is not only a characteristica but a calculus. Again, Descartes' symbolic language provides the model. We begin, for example, with the idea of a product of two sums of integer squares. What is to be shown is that that product is itself a sum of integer squares. The first step is to formulate the concept of a product of two sums of integer squares in the language, to show in a complex of primitive signs of the language what is it to be such a product: $(a^2 + b^2)(c^2 + d^2)$. Familiar rules license successive rewritings of that collection of signs as follows.

$$\begin{aligned}
&\left(a^2 + b^2\right)\left(c^2 + d^2\right) \\
&= a^2c^2 + b^2c^2 + a^2d^2 + b^2d^2 \\
&= a^2c^2 + b^2d^2 + b^2c^2 + a^2d^2 \\
&= a^2c^2 + 2acbd + b^2d^2 + b^2c^2 - 2bcad + a^2d^2 \\
&= (ac + bd)^2 + (bc - ad)^2
\end{aligned}$$

Because this last complex of signs sets out the content of the idea of a (particular sort of) sum of two integer squares, we are done. We have demonstrated in a way that is quite rigorous and largely gap-free that a product of two sums of integer squares is itself a sum of integer squares. For Leibniz, such a chain of reasoning is a paradigm of proof, and thereby of knowledge, insofar as it "renders truth stable, visible, and irresistible, so to speak, as on a mechanical basis" (Leibniz 1675, p. 166). The symbolic and rule-governed reasoning of the new algebra provided in this way a model for a kind of mechanical reasoning, one that would, Leibniz thought, put an end to all controversies. Where there are disagreements, disputants need only take up their pens and calculate; the result of the calculation must be agreed to by all, just as it is in the case of an arithmetical calculation.

For Leibniz, this power of the calculus to "[render] truth stable, visible, and irresistible . . . as on a mechanical basis" was sufficient reason to esteem formal proof above all in mathematics. Descartes disagreed because he was less concerned with disputes and compelling agreement than he was with insight and understanding. Already in Rule Three of the *Regulae,* Descartes suggests that intuition is simpler and more certain than deduction. It is in Descartes' Second Replies (to Objections to his *Meditations),* in a discussion of the analytic and synthetic methods of demonstration in geometry, that Descartes explains the distinctive value of intuition relative to deduction.

As Descartes explains, whether the method is that of analysis or that of synthesis, the order of argumentation is the same: "the items which are put forward first must be

known entirely without the aid of what comes later; and the remaining items must be arranged in such a way that their demonstration depends solely on what has gone before" (Descartes 1641, p. 110). The reasoning in both cases is deductive, at least in a broad sense ("what comes later depends solely on which has gone before"), and it is noncircular (what is first put forward "must be known entirely without the aid of what comes later"). Nevertheless, Descartes thinks, the two methods are very different.

> Analysis shows the true way by means of which the thing in question was discovered methodically and as it were a priori, so that if the reader is willing to follow it and give sufficient attention to all points he will make the thing his own and understand just as perfectly as if he had discovered it for himself. But this method contains nothing to compel belief in an argumentative or inattentive reader, for if he fails to attend even to the smallest point, he will not see the necessity of the conclusion. Moreover, there are many truths which – although it is vital to be aware of them – the method often scarcely mentions, since they are transparently clear to anyone who gives them his attention (Descartes 1641, p. 110).

This method is, furthermore, "a priori" because it is prior to the method of synthesis.

> Synthesis . . . employs a directly opposite method where the search is, as it were, a posteriori (though the proof is often more a priori than it is in the analytic method). It demonstrates the conclusion clearly and employs a long series of definitions, postulates, axioms, theorems, and problems, so that if anyone denies one of the conclusions it can be shown at once that it is contained in what has gone before, and hence the reader, however argumentative or stubborn he may be, is compelled to give his assent (Descartes 1641, pp. 110–111).

In a synthetic demonstration, everything on which the proof depends is explicitly stated in advance in axioms, definitions, postulates, (previously demonstrated) theorems, and (previously solved) problems. Because it is, the proof compels assent by anyone, no matter how argumentative or stubborn, who accepts those axioms, definitions, postulates, theorems, and problems. But of course, one can set out everything on which a proof depends only after one has the proof itself, only after one has achieved, analytically, knowledge of the "primary notions" and has drawn (materially valid) conclusions from them. It is for just this reason that the analytic method, unlike the synthetic method, requires a reader to "make the thing has own and understand it as perfectly as if he had discovered it for himself." The analytic method employs unstated rules of material inference to draw conclusions from evidently true premises. In this case, one is to *see* that the truth of the premises entails the truth of the conclusion, but in order to see that, one must actually think about what the premises mean, and what they entail. The synthetic method, because and insofar as it relies only on formally valid rules of inference, does compel assent. But because it does not require that one actually thinks about what is being claimed in the premises, it does not ensure understanding. It follows, Descartes thinks, that the synthetic method "is not as satisfying as the method of analysis," that the analytic method is "the best and truest method of instruction" (Descartes 1641, p. 111).

What, then, is wanted in a mathematical demonstration? Does one want to be convinced that the conclusion follows from the premises by seeing precisely on what it depends, all assumptions, rules, and definitions having been laid out in advance? Or does one instead seek to understand, to grasp the course of reasoning in a way that provides mastery of that reasoning, the sort of mastery that is displayed in, for example, applying the ideas of the proof to new and different mathematical problems? Clearly, one who understands a proof will be convinced by it. The problem for Descartes is that one who is properly convinced by a proof may nonetheless not understand it, and will not understand it if all they focus on is the necessity of the steps of reasoning in light of what has gone before. For Leibniz, the principal issue is conviction, and thereby agreement: what matters to him is that a proof be compelling independent of understanding, that it be (capable of being) seen to be nothing more than the mechanical manipulation of meaningless signs according to rules. And we can understand how this is to work if we consider again our little demonstration that the product of two sums of integer squares is itself a sum of integer squares. Although as presented that demonstration was not fully rigorous, gap-free, clearly it could have been made to be; we could have stated in advance all the rules and assumptions on which that course of reasoning depends so that even someone knowing nothing of what the collections of signs mean, what concepts they articulate, could see that the end point is derivable from the starting point by applying rules to what is given in the order and manner displayed. But of course, the relevant ideas, that of a sum of integer squares, of a product of such sums, and so on, would still be there. One could still follow the reasoning as a course of reasoning on the basis of mathematical ideas. What distinguishes the current debate between formalists and nonformalists, we will see, is that this seems no longer to be true. As currently understood, and as Rav (1999) already emphasizes, the problem of formal proof in mathematical practice is that *either* the proof is grounded in mathematical ideas, *or* it is merely a matter of the mechanical manipulation of meaningless signs according to stipulated rules. It cannot be both.

3 The Contemporary Debate

The paradigm of mathematical reasoning for both Descartes and Leibniz is the sort of symbolic, algebraic construction first introduced in Descartes' *La Géométrie* and developed further by Leibniz, Newton, Bernoulli, Euler, and others. By the dawn of the twentieth century, it had come to seem that mathematical reasoning as it ought to be conducted is not a matter of constructive algebraic problem solving in the symbolic language of arithmetic and algebra but instead deductive from concepts. It involves, to put it as Kant had by then taught us to do, not an intuitive use of reason, the construction of concepts in pure intuition, but instead a discursive use of reason, strictly logical, deductive reasoning on the basis of defined concepts. But how can one learn anything new by deductions from definitions of concepts? How can a deductive proof extend our knowledge? If Kant is right, logic is merely formal, devoid of all content, and deductive reasoning is merely analytic, explicative.

Though one might through such reasoning make something hitherto implicit explicit, nothing truly new can emerge from such reasoning. There appeared, then, to be only two options: either to argue that mathematical reasoning is deductive, and hence merely formal and explicative rather than ampliative, or to argue contrapositively, that mathematical reasoning is ampliative, a source of new knowledge and insight, and so cannot be merely formal, merely deductive.

Poincaré (1920, pp. 133–134) argued contrapositively. Although one *can* break a strictly mathematical mode of inference down into a series of little, strictly logical steps, to break it down is to destroy the mathematics of the reasoning. One can no more learn about mathematics, or indeed learn *mathematics,* by focusing on the strictly logical inferences of which its modes of inference are in some sense composed than one can learn about, say, an elephant (Poincaré's example) by focusing on the cells of which it is in some sense composed.

Suppose that the mathematician infers some conclusion from a set of premises by means of a form of inference that the mathematician claims is mathematically valid, and that our mathematician can convince other mathematicians that the conclusion does indeed follow, can get them to see, to grasp the validity of the inference. Others, those who are not mathematicians, are utterly baffled; they simply cannot see how the conclusion follows. So, the logician breaks the inference down into a series of little, strictly logical steps, and now even a nonmathematician can see that the conclusion can be derived from the premises. The problem, as Poincaré sees it, is that what the nonmathematician is now seeing is not mathematics but only logic. The mathematics has been lost in the course of the dissection of its modes of inference into their logical parts. What is distinctive of mathematical insight, on this account, is that it enables one to recognize irreducible mathematical wholes; valid mathematical modes of inference that *can* be broken down into strictly logical steps but *qua* mathematical are essential unities and cannot be so reduced to logic. On this view, what the nonmathematician lacks is the ability to discern those unities in addition to the logical steps into which they can be broken. The nonmathematician is like one who can see only the cells of the elephant, the elephant as a collection of cells but not also the elephant, that is, the essential unity in virtue of which it is an elephant, an animal of a certain sort.

But there is also another way in which there might be distinctively mathematical modes of reasoning in addition to logical ones, namely, if there were primitive modes of material inference in mathematics, ineliminable relations of entailment among the concepts of mathematics.

Suppose that being F entails being G for mathematical concepts F and G, not logically, as would be the case if, say, being F were a matter of being G and H, but in virtue of what it means to be F and G. A mathematical inference would then be an inference that depended in this way on the meanings of the mathematical ideas involved. Understanding those ideas would enable one to recognize the validity of the inferences, and although one could always express those relations of entailment in generalized conditionals and treat them as premises, thereby turning one's materially valid inference into a formally valid inference, to do so would again be to lose sight of the mathematics involved.

> Even though the warrant for "if **p**, then **c**" may be based on a grasp of the mathematical architecture linking **c** with **p**, the modus ponens counterpart nonetheless *abstracts away from* this grasp of architecture itself and focuses instead on its net classical effect, that is, on the classical semantico-epistemic status (e.g., truth, certitude of truth, a priori certitude of truth, etc.) and logical form of the belief (viz., "if **p**, then **c**") which it warrants … It treats grasp of an architecture as merely the means by which the classical semantico-epistemic status of "if **p**, then **c**" is established while viewing the semantico-epistemic status itself, rather than the means of establishing it, as the matter of primary epistemic importance (Detlefsen 1992, p. 369).

Although the (materially valid) rule that enables one to infer **c** on the basis of **p** shows that knowing that **p** provides a good reason for inferring that **c**, if the inference the rule governs is replaced by another, strictly logical inference involving also the conditional "if **p**, then **c**," then **p** no longer serves as the ground for **c**. What one now has is a logically valid inference, and what one now knows is only that, given that the premises are true, the conclusion is also true. One has lost sight of why the conclusion is true: that **p** no longer can be seen to serve as the reason for inferring that **c**. And this happens because of what had been functioning as a rule of inference regarding what is a reason for what has been reduced to a merely truth-functional conditional, that this is true if that is true, thereby robbing the original premise of its status as a reason. What had been a good mathematical ground for inference is reduced to a merely logical ground. And now, just as Descartes says, one need not think at all to see that the conclusion follows but only (mindlessly) apply rules of logic to given claims among which are the conditionals codifying primitive entailment relations among mathematical concepts.

Poincaré, like Kant, is concerned to understand how mathematical proofs can constitute real extensions of our knowledge, but whereas Kant focuses on mathematical judgment, the possibility of synthetic a priori knowledge in mathematics; Poincaré is concerned instead with mathematical reasoning, the possibility, as we might say, of synthetic a priori inference. Much as a synthetic a priori judgment is necessary without being logically necessary, so the reasoning of the mathematician seems to be necessary, that is, truth preserving, without being logically necessary, merely a matter of making explicit something contained already implicitly in one's starting point. Poincaré does not deny that the mathematician's proof can be formalized, rendered logically valid, merely explicative. What he denies is that such a formalized proof is mathematics.

The idea of fully formalized, machine-executable mathematical proofs has now been realized in the formalization of many interesting and significant proofs (among them, Gödel's incompleteness theorem, the fundamental theorem of algebra, the prime number theorem, and the four-color theorem). And one important consequence of such work has been the development of extensive libraries of mathematical theories (for example, of elementary number theory, linear algebra, and finite group theory) to be drawn on in formalizations. Given these advances in automated deduction, it can seem not at all unreasonable to think – following Mac Lane and Bourbaki (see Hamami 2019), and more recently, Azzouni (2004, but see also Azzouni 2013), Avigad (2006), and Weir (2016) – that although mathematicians' proofs provide sketches of real, or complete proofs, it is the formalization that

actualizes the potential of such sketches to prove this or that theorem. One might well think, then, that "over the next hundred years or so, computers will gradually be able to do more and more of what mathematicians do . . . eventually supplanting us entirely" (Gowers 2002, p. 134). Nonetheless, as Gowers also notes, his is a minority view: "most mathematicians are far more pessimistic (or should that be optimistic?) about how good computers will ever be at mathematics." After all, it is one thing to come up with a conjecture, that is, to postulate some mathematically interesting connection among mathematical ideas, and reflecting on those ideas, to find some way of showing that the postulated connection is real, both of which mathematicians are very good at, and quite another to have a formalized, machine-executable proof. Indeed, as Robinson (1997, p. 54) notes, "the translation from informal to formal is by no means a mere matter of routine. In most cases it requires considerable ingenuity, and has the feel of a fresh and separate mathematical problem in itself. In some cases the formalization is so elusive as to seem impossible." More than two decades on, although much has changed in the domain of formalization, the problem of formalizing a given mathematical proof remains, in general, "painstakingly difficult" (Avigad 2018, p. 687). And yet, Avigad is surely also right to suggest that "we should be open to the possibility that new technologies can open new mathematical vistas and afford new types of mathematical understanding" (Avigad 2018, p. 688).

Formalized proofs, according to many, are not more rigorous by mathematicians' standards of rigor than informal proofs (Kreisel 1970; Thurston 1994; Robinson 1997; Marfori 2010). Nor, others have argued, do such proofs explain or ground such rigor as mathematicians' proofs enjoy (Tanswell 2015; Paseau 2016). Formal proofs do not seem to advance mathematical understanding (Rav 1999; Detlefsen 2008). They generally lack the explanatory power of ordinary proofs (Robinson 2000). And sometimes, as Manders (1987) argues, they are simply unintelligible. In short, "a formal, symbolic proof is for the most part humanly incomprehensible and does nothing to augment our understanding" (Avigad and Harrison 2014, p. 73). But this, as Avigad and Harrison go on to suggest, is unproblematic: "formal verification is not supposed to replace human understanding or the development of powerful mathematical theories and concepts . . . Rather, they are intended to supplement the mathematics we do with precise formulations of our definitions and theorems and assurances that our theorems are correct."

We have seen that according to some, for instance, Plato, Descartes, and non-formalists, the virtue of a (successful) train of mathematical thought lies in the insight and understanding it affords. For others, among them, Aristotle, Leibniz, and the formalist, it lies instead in the power of the train of thought to show indubitably that some theorem is true and thereby to end once and for all disagreements as to its truth. The two desiderata, insight and understanding, on the one hand, and conviction and truth, on the other, are not incompatible. And the Leibnizian idea of a universal language, at once a characteristica and a calculus, shows that they are not insofar as such a language enables one to express in a specially devised system of written signs the contents of concepts on the basis of which to reason. The manipulation of signs in such a language is everywhere governed by antecedently stated

rules, and because it is, the reasoning can be mimicked by a machine. But the mathematician's reasoning in such a language is not, or at least need not be, merely mechanical; a Leibnizian language is not only a calculus, but also a characteristica within which to display the contents of mathematical ideas, what it is to be this or that mathematical object, or property, or relation, and to do so in a way that renders the reasoning tractable. In a Leibnizian language, ideas are expressed in a way enabling rigorous rule-governed reasoning *in* the system of signs. Thus, while it is possible in a case of such reasoning to ignore meanings and mathematical ideas, it is equally possible to attend to them, to ignore trivial and routine steps so as to focus on the *ideas* of the proof. A demonstration in a Leibnizian universal language in this way provides, or at least can provide, *both* insight and understanding *and* conviction and truth.

The idea of a Leibnizian language for mathematics is realized in part in the symbolic language of arithmetic and algebra within which to exhibit in written signs the contents of concepts and to reason rigorously on the basis of those contents to new and significant mathematical truths. The reasoning is at once compelling and a vehicle of understanding. The same cannot be said for reasoning in a formalized proof of contemporary mathematics. Although a mathematician's informal proof of, say, the prime number theorem enables insight and understanding, and thereby conviction, at least for the mathematician, the corresponding formalization, while it may compel assent (even in the most stubborn and argumentative reader), does not seem to enable insight and understanding. Formalization thus seems, as Poincaré already suggested, somehow to undermine the unity and integrity of the mathematician's course of reasoning. Breaking down a chain of mathematical reasoning into a series of little, strictly logical steps transforms a rich and meaningful mathematical demonstration into something lifeless, mathematically inert. And in a way, this is not surprising given that, in logic, validity is, we think, a matter of form rather than of content. Indeed, that is precisely why such reasoning can be mechanized, executed in a computer program run on a machine. But if reasoning is merely mechanical, insofar as it is reasoning, then as the formalist tends to think, the solution of our difficulty must lie elsewhere, perhaps outside of logic and the philosophy of mathematics altogether, in, say, human psychology (Goldfarb 1988), or in some other not strictly rational dimension of mathematical practice (Azzouni 2004).

If deductive rationality is, in essence, a matter of the manipulation of meaningless signs according to rules, then the problem of formal proof in mathematical practice is not a problem about the nature and function of mathematical reasoning but instead an altogether different sort of problem, a problem in social epistemology, say, or in psychology or sociology. But can this be right? The task of logic is to provide an adequate account of the nature and form of deductive reasoning, a paradigm of which is reasoning in contemporary mathematical practice. Indeed, as Burgess (1992, p. 9) points out, mathematical logic "was developed ... as an extension of traditional logic mainly, if not solely, about proof procedures in mathematics." And certainly, this logic has proved extraordinarily fruitful in the domain of machine reasoning, in computing: "the clear recognition of just how much reasoning – that is, as far as results are concerned, never mind the processes – can be mechanized is

surely the most outstanding contribution of 20th century logic *sub species aeternitatis*" (Kreisel 1985, pp. 143–144). And yet, as developments over the past half-century seem clearly to show, formal proofs are irrelevant to the practice of most mathematicians. Can it really be true, as some philosophers of mathematical practice have argued, that "mathematical logic cannot provide the tools for an adequate analysis of mathematics and its development"? (Mancosu 2008, 5)

4 More History

The symbolic language of algebra that Descartes introduced in 1637 proved over the course of the seventeenth and eighteenth centuries to be "the greatest instrument of discovery in the history of mathematics" (Grabiner 1974, p. 357), so much so that to an eighteenth-century mathematician such as Euler it could seem that his pencil surpassed him in intelligence. Grabiner (1974, p. 355) provides a nice example of just this intelligence.

> He [Euler] began with the identity
>
> $$\cos nz = (\cos z)^n - n(n-1)/2!(\cos z)^{n-1}(\sin z)^2 + [n(n-1)(n-2)(n-3)]/4!(\cos z)^{n-4}(\sin z)^4 - \ldots$$
>
> Let z be an infinitely small arc, and let n be infinitely large. Then:
>
> $$\cos nz = 1,\ \sin z = z, n(n-1) = n^2, n(n-1)(n-2)(n-3) = n^4, \text{etc.}$$
>
> The equation now becomes recognizable:
>
> $$\cos nz = 1 - n^2z^2/2! + n^4z^4/4! - \ldots$$
>
> But since z is infinitely small and n infinitely large, Euler concludes the nz is a finite quantity. So let $nz = v$.
>
> The modern reader may be left slightly breathless; still we have
>
> $$\cos v = 1 - v^2/2! + v^4/4! - \ldots$$

Although in no way a rigorous course of reasoning, this demonstration is nonetheless compelling, and, as was invariably true of Euler's work, it is perfectly correct. It is a paradigm of the eighteenth-century practice of mathematics, a practice that would yield an astonishing array of new results, however informal, lax even, the method of demonstration.

Eventually, the requirement of rigor would reassert itself – though not in order to avoid errors. Like mathematicians of any era, "eighteenth-century mathematicians had an almost unerring intuition" (Grabiner 1974, p. 358). The motivation to be more rigorous in their definitions and reasoning lay instead in "the mathematician's

need to teach": "A mathematician could understand well enough about a concept to use it, and could rely on the insight he had gained through his experience. But this does not work with freshmen, even in the eighteenth century" (Grabiner 1974, p. 360; see also Kitcher 1981). In mathematics, the problem is not, and may never have been, argumentative and stubborn interlocutors. The problem is nonmathematicians, that is, most immediately, the need to teach those who are not yet and may never become mathematicians. The foundational work of the eighteenth and nineteenth centuries, the paradigm of which was the rigorization of the calculus, was first done in, or for, the classroom.

This foundational work was, furthermore, just one manifestation of the revolutionary transformations in mathematical practice that occurred over the courses of the nineteenth century, one aspect of what Stein (1988, p. 238) describes as "a second birth of the subject—its first birth having occurred among the ancient Greeks" (see also Macbeth 2014). Over the course of the nineteenth century, most markedly in the work of Riemann and Dedekind following him, mathematicians came to eschew the symbolic language of arithmetic and algebra that had hitherto proven so fruitful, to reflect directly on concepts and to reason deductively on the basis of their contents, "to conquer problems," as it was sometimes put, "with a minimum of blind calculation, a maximum of clear seeing thought" (Stein 1988, p. 241). The algebraic, computational, constructive practice of the seventeenth and eighteenth centuries was in the nineteenth century to be replaced by a new, wholly conceptual approach, *Denken in Begriffen* (Laugwitz 1999). And at least at first, there was no Leibnizian symbolic language within which to do this work, nothing that could play the role the symbolic language of arithmetic and algebra had played, nothing to serve at once as a characteristic and a calculus for this new practice of thinking in concepts. All the great works of Riemann and Dedekind, of Weierstrass and Bolzano, could only be reported (in natural language); it could not be displayed. And this remains true even today. As Avigad (2006) notes, even a canonical text such as Birkhoff and Mac Lane's *A Survey of Modern Algebra* does not show chains of mathematical reasoning, whether or not gap-free, but only describes how the reasoning goes, or would go were one actually to reason from the given concepts to the derived theorem.

5 What Is a Mathematical Proof?

A mathematical proof, as described by Hanna (1995, p. 46), "is a transparent argument, in which all the information used and all the rules of reasoning are clearly displayed and open to criticism." And this is the right way to think about a mathematician's proof insofar as "it is in the very nature of proof that the validity of the conclusion flows from the proof itself, not from any external authority." Of course, what counts as a transparent argument will depend on the context. What counts as transparent to a mathematician working in the same subfield will not so count for a mathematician working in a different field; what counts as transparent for mathematicians generally will not so count for graduate students; what counts as

transparent for graduate students will not so count for undergraduates, and so on – though not, as Rav (1999) suggests, infinitely. What may be taken for granted as known and beyond criticism depends on one's audience. Nevertheless, what Hanna describes as transparency is crucially important, something that is "in the very nature of proof." A proof is self-standing. That is, unlike a report of empirical findings, a mathematical proof itself carries its evidential force; the intentions, reliability, and trustworthiness of its author are irrelevant to its cogency. One can, at least in principle, see for oneself that things are as the author of the proof claims. The proof is, as it is sometimes put, "transferable" (Easwaren 2009). Indeed, it is in just this sense that mathematical knowledge is a priori: It is a priori not because it is infallible but because and insofar as it does not rely on empirical evidence, whether that of one's own senses or that given on the testimony of another. A mathematical proof is a priori insofar as "the validity of the conclusion flows from the proof itself."

What Hanna describes as transparency is obviously very closely related to the idea of rigor insofar as a rigorous proof is one in which everything on which the chain of reasoning depends is stated explicitly and in advance, all definitions, all assumptions, and all rules of inference. In a rigorous proof, the reasoning is, as Frege thinks of it, gap-free (see Fallis 2003; Hamami 2014; Anderson 2020 for discussion of the idea of a proof gap). But as we have already seen, and contrary to what is often assumed, rigor does not require formalization. Being mechanically checkable is a good test of rigor: If all the steps of reasoning can be made merely mechanically, without appeal to meanings, solely by applying given rules to the given collections of signs in virtue of their shapes, then it is evident that everything on which the proof depends has been set out in advance. The proof is rigorous. But one need not purge a proof of meaning in order to state in advance everything on which it depends. To rigorize a proof is not thereby to formalize it, to replace all its meaningful signs with meaningless marks; it is perfectly possible to render a proof rigorous and gap-free without formalization. And that is to say that although a fully rigorous proof must be machine *checkable,* it does not follow that such a proof is machine *executable,* a chain of reasoning that could (in principle) be carried out by a machine just as well as, and in the same sense as, it is carried out by the mathematician. The fact that a mathematician's proof can be made rigorous and gap-free does not show, as many formalists and nonformalists assume, that the reasoning of the mathematician is merely mechanical, nothing more than the manipulation of meaningless marks according to stipulated rules.

A mathematician's proof can be at once rigorous and fully meaningful. And yet, it is often assumed (falsely) that to render a proof fully rigorous, wholly gap-free, just is to just formalize it, to make it into something that a machine can do as well as any human being. In order to avoid unthinkingly making that assumption, we need explicitly to distinguish between the language of logic that is used in formalizations, on the one hand, and a Leibnizian language, on the other. In particular, we need to remember that our logic is a calculus, that it is not also a characteristica. Indeed, the whole point of logic is to focus on form rather than content and meaning. The aim is not to express content but to abstract from it, leaving only (logical) form. And so it is with a formalization: "the very purpose of formalization is to squeeze out the sap of meanings in order not to blur focusing only on the logico-structural properties of

proof" (Rav 1999, p. 12). By contrast with the strengths of the symbolic language of arithmetic and algebra within which to express mathematical ideas in ways that facilitate rigorous reasoning, the great strength of logic lies in its having nothing to do with meaning, in its being a matter of the merely mechanical manipulation of meaningless signs according to rules. And thus, it can seem to follow that to reason logically is to reason as a machine reasons. Should we be surprised, then, to find that the formalizations of mathematicians' proofs according to the standards of logic are at once a *tour de force* in the science of computing and seemingly irrelevant to the practice of mathematics?

6 Resolving the Antinomy

Formal proofs, unlike the proofs mathematicians develop and esteem, are completely rigorous and gap-free; all definitions and assumptions are set out in advance, and all steps of reasoning conform to some small set of basic rules of logic. Thus, it comes to seem to the formalist to be obvious that the relationship of the informal proofs of mathematicians to formal, machine-executed proofs is that of a sketch to a fully worked out chain of reasoning. The nonformalist sees that this cannot be right but seems to have no way of explaining to the formalist just what has gone wrong. Again, the reasoning of the mathematician is deductive, and logic provides a complete theory of deduction. It must then be the case that a formal proof is, in essence, a fully worked out version of the informal proof of the mathematician. Only, it seems not to be. The problem is somehow to move beyond this stalemate.

Over the course of the nineteenth century, we have seen the practice of mathematics was radically transformed, and with that transformation came a renewed call for rigor in the practice.

> After deserting for a time the old Euclidean standards of rigor, mathematics is now returning to them, and even making efforts to go beyond them . . . Proof is now demanded of many things that formerly passed as self-evident. Again and again the limits to the validity of a proposition have been in this way established for the first time. The concepts of function, of continuity, of limit, and of infinity have been shown to stand in need of sharper definition. Negative and irrational numbers, which have long since been admitted into science, have had to submit to a closer scrutiny of their credentials.
>
> In all directions, these same ideals can be seen at work – rigor of proof, precise delimitation of extent of validity, and as a means to this, sharp definition of concepts (Frege 1884, §1).

But again, this demand was not motivated by any perceived need to render the practice less error-prone or to resolve disputes regarding the validity of results. Mathematicians are not infallible; they do make mistakes. But they do not make mistakes very often, and generally such mistakes as they do make are mathematically significant insofar as they serve ultimately to improve mathematicians' grasp of mathematical concepts they have been working with all along. What enables mathematicians to discover and avoid errors is not formalization but understanding.

> Mathematicians can and do fill in gaps, correct errors, and supply more detail and more careful scholarship when they are called on or motivated to do so. Our system is quite good at producing reliable theorems that can be solidly backed up. It is just that the reliability does not primarily come from mathematicians formally checking formal arguments; it comes from mathematicians thinking carefully and critically about mathematical ideas (Thurston 1994, p. 170).

Thus,

> We are most certain to avoid gaps in reasoning when premises *explain* conclusions . . . The greater such explanatory transparency, the more confident we can be that unrecognized information has not been used to connect a conclusion to premises in ways that matter. To the extent, then, that formalization decreases explanatory transparency, it also decreases rigor (Detlefsen 2008, p. 19).

And as we have seen, formalizing a mathematician's proof does decrease transparency, and so also rigor, and it does so precisely because and insofar as it purges a proof of all content and meaning, all mathematical ideas. But again, we must not confuse the logic of formalizations with a Leibnizian language for mathematics, a language within which to express mathematical ideas and to reason from them.

Philosophers sometimes claim that much as the signs of standard logic are abbreviations for words so the signs that comprise the writing systems that have been devised for reasoning in mathematics, paradigmatically, the symbolic language of algebra, are nothing more than abbreviations for words. But this does not seem to be right. The systems of signs that have been devised (and universally used) for mathematics are instead the signs of a Leibnizian language. That is, as Jourdain notes, echoing again Euler's sentiment,

> it is important to realize that the long and strenuous work of the most gifted minds was necessary to provide us with simple and expressive notation which, in nearly all parts of mathematics, enables even the less gifted of us to reproduce theorems which needed the greatest genius to discover. Each improvement in notation seems, to the uninitiated, but a small thing; and yet, the pen sometimes seems to be more intelligent than the user. (Jourdain 1912, p. 16)

The formula language of arithmetic and algebra is one such language. But by the nineteenth century, mathematics had grown out of that language. Frege took it upon himself to provide mathematics with another; he devised what he called a *Begriffsschrift,* a concept-script, one that (although it would come to be read as a mere calculus) was self-consciously designed to serve not only as a calculus but also, and equally, as a characteristica, as a mathematical language within which to exhibit the contents of mathematical concepts and to reason deductively on the basis of those contents. Macbeth (2014; see also Macbeth 2005) argues that he succeeded, and that in so doing Frege shows how mathematical reasoning can be at once deductive and ampliative. What matters for purposes here is how exactly a Leibnizian language for contemporary mathematics would (and if *Begriffsschrift* is such a language, does) differ from the language of logic, what it is that enables such a

system of signs to function as a Leibnizian language, at once a calculus and a characteristica.

We have seen that for the philosopher the problem of formal proof in mathematical practice is the problem that, so it seems, a formal proof both must and cannot clarify the nature of mathematical practice. A formal proof must clarify the nature of mathematical reasoning because mathematical reasoning is deductive and the rules governing a formal proof are those of deductive reasoning. And formal proof cannot clarify the nature of mathematical reasoning because the reasoning in a formal proof is merely mechanical, without content. What we are now in a position to see (following Macbeth 2015, 2018) is that the move from an informal to a formal proof involves not one but two conceptually distinct steps. One step, the step of rigorization, is to fill in all the gaps, include all the steps of reasoning, even the most trivial and obvious, and to state in advance everything on which the reasoning depends, all definitions, all assumptions, and all rules of reasoning. The second, conceptually distinct step is to replace all meaningful expressions with meaningless signs.

Suppose, for example, that the mathematician infers from the fact that some number *n* is a square root of 4 that *n* is a fourth root of 16. Our mathematician can make the inference rigorous by explicitly adding the rule on which it depends, that being a square root of 4 entails being a fourth root of 16. Our mathematician can also go on to show how this entailment is derivable from basic truths of arithmetic. The reasoning, that is to say, can be rendered even more rigorous by proving everything that can be proved, by isolating a small set of basic truths of arithmetic and deriving from those basic truths all other entailments on the basis of which to make the original step of reasoning. It is in just this way that the original step of inference is rendered fully rigorous, gap-free.

But our mathematician can also do something quite different with the original inference. First, the relevant entailment is again made explicit in a premise so that the inference now goes like this: being a square root of 4 entails being a fourth root of 16; *n* is a square root of 4; therefore, *n* is a fourth root of 16. This inference is deductively, that is, logically, valid. It is valid in virtue of its form, and what that means, we think, is that the fact that it is about the number *n,* and square and fourth roots, is irrelevant to its validity. The inference is valid in virtue of the fact that it has this form: being *F* entails being *G, o* is *F*; therefore, *o* is *G*. To formalize the step of inference is to replace in this way all meaningful, nonlogical expressions with meaningless marks, here "*F*," "*G*," and "*o*." And now, we have something that can be implemented in a machine. We have reduced the mathematician's reasoning to the manipulation of meaningless marks according to stipulated rules.

In standard logic, to say that an inference is valid in virtue of its form is to say that its content, in our example, its being about numbers, squares, and fourth roots, is utterly irrelevant to its validity. There is, however, another way to understand the notion of validity in virtue of form. Following Peirce (1992, p. 131) and Ryle (1950), we can say that an inference is valid in virtue of its form just in case it is an instance of something more general, a rule that applies also in other cases. We can, that is, think of the rule "if being *F* entails being *G* and *o* is F, then *o* is *G*," as perfectly

meaningful despite being maximally general, as being meaningful in essentially the way that the rule "if a number is a square root of four then it is a fourth root of sixteen" is meaningful. So understood, the difference between the two cases is only that the law of logic is more general, a rule of logic rather than of mathematics. Logic, on such a view, is not the articulation of mere form, of form as it contrasts with content and truth. Logic (on such a view) is a science, the science, as Frege once put it, of the most general laws of truth.

As we are taught to understand it, the validity of an inference concerns form as it contrasts with content and truth. The validity of inference is thereby conceived not only formally, however, but also on the model of containment: An inference is valid just if the information in the conclusion is contained already in the premises, even if only implicitly. Deduction on this model is not only truth preserving, in that it is impossible to derive a falsehood from true premises; it is also merely explicative. Nothing can be inferred that was not contained already in one's starting points, one's premises (We have seen already that this presents a problem for any adequate understanding of reasoning in mathematics insofar as the mathematician's deductive proofs seem often to extend our knowledge.). Here again, there is an alternative, and our little example involving square and fourth roots can help to remind us what it is. We have an inference that we expressed thus:

> Being a square root of four entails being a fourth root of sixteen.
> The number *n* is a square root of four.
> Therefore, *n* is a fourth root of sixteen.

What is at issue now is the status of the first premise, what Aristotle calls the major. There are two options. Either we treat premise as a rule governing (material) inferences, or we treat it as a claim about how things actually are, whether or not they could be otherwise (Sundholm 2012 also makes this point.). On the latter option, we read the major as setting out a piece of information, the fact (possibly necessary) that all numbers that are square roots of 4 are fourth roots of 16. Given this piece of information, together with the information in the minor premise, that the number *n* is a square root of four, it clearly must be true, indeed, it has already been implicitly stated that *n* is a fourth root of 16. The inference so understood does not merely state in the premises everything that is needed to infer that *n* is a fourth root of 16. The premises already state that *n* is a fourth root of 16, though not in so many words. The information that the number *n* is a fourth root of 16 is contained already in the information provided by the premises: *If* all square roots of 4 are fourth roots of 16 *and n* is a square root of 4, then, whether or not anyone knows it, it is settled that *n* is a fourth root of 16. Such an inference can extend our knowledge only in the sense of revealing, or at least reminding us of, something to which (on pain of irrationality) we are already committed, something that we already believe – if only implicitly.

The other option is to treat the first premise, the major, as the expression of a rule of inference, as licensing inferential steps, acts of reasoning, from appropriate premises to the relevant conclusion. The minor then gives us a premise to the effect that the number *n* is a number to which the rule given in the major applies, and so,

applying the rule given in the major to the instance given in the minor, we make our inference, infer that *n* is a fourth root of 16. In this case, although our premises give us everything we need in order to draw the relevant inference, give us, that is, both the rule licensing the inference and an instance to which the rule applies, the premises do not contain already the information contained in the conclusion. Everything needed to *get* that information is supplied, but the inference must still be made; one must actually apply the rule to the instance in order to derive the conclusion. The step of reasoning from the premises to the conclusion must be taken, and it must be taken because, on this reading, the conclusion is contained in the premises not implicitly, needing only to be made explicit, but instead potentially: Actually to have the conclusion, realizing thereby the potential of the premises to yield a conclusion, something must happen. The inference must be drawn. In that case, to borrow Frege's (1884, §88) imagery, the conclusion is contained in the premises not as beams are contained in a house, that is, implicitly, but as the plant is contained in the seed, that is, potentially.

To say that a proposition has the form of a generalized conditional is understood in standard logic as saying that it is a claim about all objects of a certain sort. But the expression of a rule also has the form of a generalized conditional insofar as it includes, in the antecedent, a specification of the circumstances of application of the rule, and is something that applies, in principle, in a variety of cases. A rule is constitutively conditional and inherently general. In some contexts, then, something of the form of an English sentence, "all S is P," may mean not that every object that is S is also P but instead that it can be inferred from the fact that a thing is S that it is P, that being S entails being P – even if in other contexts, a sentence of just that same form means instead that as a matter of (contingent or necessary) fact, all the Ss there are also P. Recall, now, that in a Leibnizian language all rules governing inferences are made explicit as claims, that is, as generalized conditionals; however, they are to be read. The language is a calculus. But we also know that a Leibnizian language is equally a characteristica, a language within which to display the contents of concepts on the basis of which to reason. What we need to see (if only in outline here) is how this is to work, how it is that the contents of concepts can be displayed in complexes of signs that, in combination with the generalized conditionals of the system, enable reasoning *in* the system of signs.

We want to understand how a system of written marks might enable the mathematician to display the contents of mathematical concepts in a way that enables rigorous, gap-free reasoning in the system of signs. Following Macbeth (2015, 2018), we use the following simple example to illustrate the essential point. Imagine, to begin with, a person able to count but who does not know even the simplest facts of arithmetic, and suppose further that this person wishes to know what is the sum of seven and five. A good, if merely mechanical, way of finding that out would be to count out seven things, then five more, and then to count the whole collection that results. We can do this with strokes on the page (or screen). Here are seven things: ///////. Now we add five more to that given array: /////// (already given) plus /////. Counting the number of strokes in all gives the answer that is wanted, namely, 12. Clearly, this is not yet mathematics. It is furthermore clear that in such a case the

answer, 12, is contained already in the given parameters of the problem as those parameters have been set out: if one has 7 things (strokes, say) and adds 5 more, then one has 12 things (strokes), whether or not one knows that one does. That 7 and 5 is 12 is, to this way of thinking, analytic: Being 12 is contained already in being $7_{+}5$.

If one thinks of 7 + 5 merely mechanically, as a matter of adding 5 things to 7 things already given, then the fact that 7 + 5 equals 12 would seem to be analytic in Kant's sense. And yet, Kant claims in the B Introduction to the first *Critique* that the arithmetical truth that 7 + 5 equals 12 is not analytic but instead synthetic, that being 12 is not contained already in the concept of the sum of 7 and 5, despite its being a priori that the sum of 7 and 5 is 12. And as Macbeth shows, we can understand how this works if we conceive the strokes not as mere things but instead as tokenings of the primitive sign type of an exceedingly simple Leibnizian language. The language has one primitive sign, the stroke, and we are to display the arithmetical contents of numbers, in particular, their various multiplicities, in this language by combining strokes in complex signs. In this language, a collection of seven strokes is not merely that, a collection of seven things; it is instead a meaningful complex sign that designates a number, *one* number, namely, the number seven, and it does so through a display of what it is to be that number, namely, a particular multiplicity (Obviously for other mathematical purposes, we would want to think differently about what it is to be the number seven, for example, as the successor of the number six, and in that case would display a different content, which would require as well devising a different Leibnizian language.).

We start, then, with complex signs for our two numbers, the number seven, the content of which is exhibited in the language in a complex of seven strokes, and the number five, the content of which is exhibited in a complex of five strokes. So far, then, we have a display of two numbers in an array such as this: /////// /////. Each of the two collections of strokes designates a number, and it does so through what we can think of as a Fregean sense, something that displays what it is to be those numbers, namely, again, certain multiplicities. So far, then, there is nothing that can be taken to designate the number 12. If, however, we have a rule licensing a certain rewriting of signs, a rule to the effect that if one has a number designated by m strokes and a number designated by n strokes, then one may rewrite to give two numbers that are designated by $m + 1$ strokes and $n - 1$ strokes respectively. Applying the rule to our original numbers /////// and /////, and to the results of applications of that rule, we eventually arrive at the number ////////////, that is, a complex sign that designates the number 12. We have shown, through a chain of (excessively simple) mathematical reasoning, that the sum of the numbers 7 and 5 is the number 12. The result is manifestly synthetic a priori in Kant's sense. Although (a representation of) the number 12 is not contained already in (the representations of) the numbers 7 and 5, (a representation of) 12 can be constructed from (representations of) those numbers by successive applications of an explicitly stated rule. The rule and the starting point give us everything we need to construct a sign designating the number 12, but that sign does, nonetheless, need to be constructed. It is contained in the starting point not implicitly but only potentially. It is contained in the starting point as the plant is contained in the seed.

7 Conclusion

The philosophical problem of formal proof in mathematical practice is the problem of the relationship between a mathematician's proof and its fully formalized counterpart. It can seem that this problem is merely one of emphasis, of the relative value of, on the one hand, mathematical insight and understanding, and on the other, indubitability and persuasiveness. Mathematicians' proofs, so it can seem, focus on the former, formal proofs on the latter. Closer inspection showed that things are more complicated, that we need to distinguish among many, quite different parameters along which the two types of proof differ.

First, and most obviously, there was the issue of rigor, of gap-free proof. Although the mathematician's proof is transparent insofar as the validity of the conclusion "flows from the proof itself," as mathematicians are in a position to see, a mathematician's proof is almost never rigorous in the sense of being wholly gap-free. But there is no reason why it could not be made to be rigorous in this sense. Mathematicians' proofs could, with effort and application, be written so that everything on which the reasoning depends was set out in advance. Formal proofs are also so written, as of course they must be if they are to be machine executable.

A related but more substantial difference between a mathematician's proof and a formal proof is, we saw, that the mathematician's proof is meaningful and the formal proof is not. Even were it to be rendered altogether gap-free, the mathematician's proof would still be a chain of reasoning about mathematical concepts and how they are related; it would still contain whatever proof ideas the transparent but not rigorous proof contains – though it would likely take a trained eye to discern those ideas amid the welter of (in most contexts, needless) detail. The formal proof, by contrast, is nothing more than a series of moves in an automated system designed to transform arrays of marks into other arrays of marks.

But we have seen that even this does not exhaust the differences between the two sorts of proofs. After all, were the only difference between the two sorts of proofs to be that one is gap-free and purged of all meaning, while the other is neither, it would be inexplicable why mathematicians cannot simply reinject the meaning into a formal proof and recover thereby (a fully rigorous version of) the original mathematician's proof. To understand why this is not possible, we needed to distinguish between three different sorts of languages: (1) everyday, natural language, the language that is currently used in mathematics textbooks to describe the sort of reasoning from concepts that is involved in proving theorems in contemporary mathematical practice, (2) the language of standard logic, the signs of which are abbreviations of words of natural language and enable the perspicuous display of (what is assumed to be) the logical forms of sentences of natural language, and (3) a Leibnizian language, a specially devised written mathematical language within which to display the contents of mathematical concepts in a way enabling rigorous reasoning in the system of signs. We saw that the symbolic language of arithmetic and algebra is such a Leibnizian language, for at least a part of mathematics, and noted as well that Frege took his *Begriffsschrift* to provide such a language for the mathematical practice of deductive reasoning from concepts that came to dominate

mathematical practice over the course of the nineteenth century. As we saw, a Leibnizian language can replace natural language for the purposes of reasoning in mathematical practice precisely because and insofar as it is not merely a calculus but also a characteristica enabling one to reason in the language on the basis of the contents of concepts.

Were mathematicians' proofs to be formulated in a Leibnizian language, and made fully rigorous, gap-free, then they would be machine checkable. But as we have seen, they would still be different from formal proofs insofar as they would not also be machine executable. The mathematician's reasoning, even that conducted in a Leibnizian language, is fully contentful, a form of mathematical reasoning on the basis of mathematical ideas (as we see already in seventeenth- and eighteenth-century mathematics conducted in the symbolic language of algebra). A formal proof is not contentful. Indeed, it is only because it is not contentful that a formal proof is not only machine checkable but also properly machine executable. Of course, we can read expressions in a Leibnizian language mechanically, from which it follows, that were the mathematician's proof to be written in a Leibnizian language, and then automated, it would be possible for the mathematician to recover the ideas of the proof from the formalization. That this is not possible in the case of formalizations currently available is, we saw, because such formalizations begin not with a Leibnizian language within which to formulate mathematical ideas but instead with the relatively impoverished resources of standard logic. Indeed, it is that poverty of resources that may explain the fact that formalizing a proof generally amounts to a wholly new sort of mathematical problem. Is it any wonder, then, that formalized proof (as currently understood) has so little to offer to the practicing mathematician?

Abstract

In the historiography of mathematics, proof and computation have regularly been perceived as opposed to each other in ways that have significantly obscured the discussion of the relationships between these two mathematical practices. This essay intends to draw on recent work in the history and the philosophy of mathematics to offer some reflections on these relationships.

In memory of his passion for a global history of proof and, more generally, of science

1 An Introduction to Proof and Computation: Some Historiographic Remarks

In the depictions of an opposition between proof and computation, there are recurring themes that need to be highlighted and analyzed. With a view to pointing out problems in these commonplaces, I will start by quoting a few statements that illustrate widespread representations of proof and computation and in which these mathematical activities appear opposed to each other.

Let me begin with a statement by Jean-Baptiste Biot (1774–1862) that I have often quoted, but which remains useful inasmuch as it presents a concentration of many of the usual *clichés* on this issue. Indeed, in an 1841 review of a book by Jean-Jacques Sédillot, published in 1834 under the title *Traité des instruments astronomiques des Arabes*, Biot pointed out what, for him, was:[1]

> this peculiar habit of mind, following which the Arabs, as the Chinese and Hindus, *limited* their scientific writings to the statement of a *series of rules*, which, once given, *ought only* to be *verified* by their *applications*, *without* requiring *any logical demonstration* or *connections* between them: this gives those *Oriental nations* a remarkable character of *dissimilarity*, I would even add of *intellectual inferiority*, *comparatively* to the *Greeks*, with whom *any proposition is established by reasoning, and generates logically deduced consequences.* This *fixed* writing of scientific methods, in the form of *prescriptions*, must have represented an important *hindrance* for the development of *new* ideas for peoples for which it was in use, and it is in sharp *contrast* with our *European* motto: *nullius in verba.*

Here, Biot outlines an opposition between two types of mathematical practice. The practice with which he begins is clearly associated with computation, the term "rules" referring to the lists of operations – which we now call "algorithm" – that need to be "applied" to solve mathematical problems (to which Biot refers using the term "applications"). In Biot's view, works that contain such algorithms are characterized by several features. First, the rules are given as a series of disconnected statements. In particular, they present no logical connection with each other. Moreover, practitioners did not establish that "rules" were correct, but they simply "verified," that is, checked them: For Biot, the "applications" (the mathematical problems) were used precisely to this effect. Last, but not least, as the end of the declaration makes clear, Biot considered that the operations composing the text of a

[1] (Biot 1841, 674). Except for the Latin quotation (*nullius in verba*, "on the word of no one"), my emphasis. The Latin sentence is the motto of the Royal Society, and can be interpreted as referring to modern science. The first part of this excerpt is quoted in Charette 2012: 274. It is a great pleasure to thank the editors, Joachim Frans and Bart van Kerkhove, as well as Richard Kennedy, for their close reading of this article.

rule were "prescriptions," which simply required obedience and thus impeded the development of the critical mind that was essential for modern science.

The mathematical practice that, in the contrast Biot draws, he associates with proof is opposed point by point to the previous one: in this context, propositions are proved to be true, and by the effect of proof, they are connected with each other. What is more, for Biot, this practice invites practitioners to exert a critical mind towards authorities, which enables "the development of new ideas."

Several dimensions of the declaration look outdated and shocking to the modern reader: The fact that Biot's account associates each of the two practices with "peoples," and notably non-Western "peoples" lumped together, on one side, and "the Greeks" as well as the "Europeans," on the other; the fact that he gives the distinct mathematical practices identified as deriving from characteristics of the "peoples," which the practices in turn illustrate; and the fact that he takes the opposition that he asserts as a sign of the "intellectual inferiority" of the former peoples in comparison to the latter. However, these dimensions of Biot's assertions should not hide the elements of the representation of an opposition between computation and proof that he puts forward and that are still quite widespread.

A similar opposition using elements of the same kind is encountered in many coeval sources. Suffice it to mention the assessment that we read in William Whewell's *History of the Inductive Sciences*, first published in 1837, which reads as follows:

> The Arabs are in the habit of giving *conclusions without demonstrations*, *precepts without the investigations* by which they are *obtained*; as if their *main object* were *practical* rather than *speculative*,—the *calculation* of *results* rather than the *exposition* of *theory*. (Whewell 1837: 249, my emphasis)

Here, the term "precepts" replaces that of "rules," the emphasis being placed on the intention of obtaining "results" instead of providing the reasoning that had led to the "conclusions," or of presenting theory. For Whewell, this difference derives from a contrast between two main aims of the different practices: he associates with calculation a "main object" that is "practical," whereas, when reasoning and theory are emphasized, the "main object" is "speculative." The context makes clear that, in Whewell's view, just as in Biot's, the latter aim and practice characterize "the Greeks," while the former goal and the related practice is the proper of "the Arabs." However, what matters more for us here is the representation of computation that emerges from this assessment.

In fact, to this day, we still encounter echoes of views of this kind. This can be seen, for example, in the comments on proof and calculation that Ian Hacking puts forward in his 2000 essay: "What Mathematics Has Done to Some and Only Some Philosophers" and notably in the section titled "The Unpuzzling Character of Calculation."[2] I will focus on this facet of his essay, without discussing the broader

[2] (Hacking 2000), in particular, pp. 101–103. Note that similar ideas are put forward in (Hacking 2009: 72–87) and in (Hacking 2014: 99–100, 138–139, 145).

issues in the context of which Hacking deploys his representation of the opposition.

For Hacking, "a great many of the philosophers whom we still read have been deeply impressed by mathematics, and have gone so far as to tailor much of their philosophy to their vision of mathematical knowledge, mathematical reality, or, what [he] *think*[s] is *crucial*, *mathematical proof*" (p. 83, my emphasis). In this context, Hacking discusses features of mathematical proof that appear as essential to him in this respect, relying to this effect on the dialogue that Socrates has with the slave in the context of Plato's dialogue *Meno*. Indeed, in this exchange, a proof is developed that establishes that the area of a square whose side is the diagonal of a given square has an area double of that of the original square (Hacking 2000: 92–99).

Hacking emphasizes features of the proof that he will subsequently use to outline a clear-cut contrast with calculation. First, the proof is "compelling" (p. 98), establishing that the theorem is "necessarily true" (p. 97). Moreover, through the proof, we "can see" "*why* what we have found out is true" – a "fact" that "is one of the core phenomena of *some* proofs (. . .)" (p. 94, my emphasis). In addition, he argues, "the proof in *Meno* is perspicuous" or "surveyable" (p. 95). Following Russell, Hacking stresses that the proof gives us "the power of *anticipating* facts about things of which we have *no experience*" (p. 96, my emphasis).

Each of these remarks has a counterpart in Hacking's comments on calculation, which are grouped together in a passage where he gives an example of calculation that illustrates his view of it. The passage reads as follows:

> So let us turn to calculation, ordinary calculation. There is *nothing perspicuous about calculation*. There is *no feeling of compulsion*. There is *no sense of understanding*.
> (. . .) Divide 471 by 9. I can do this in my head. Nine into 47 goes 5 times, 2 to carry, and into 21 it goes twice, 3 to carry, so 471 divided by 9 is 52 and 3/9, or 52 1/3. I *quickly check to see that is correct*, by multiplying 52 1/3 by 9 in my head; yes, that's right, 471."
> "That is the result: 471 divided by 9 equals 52 1/3. *Must* it be the result? Do I see why this is the result? No, it simply is what happens *when I follow rules that I had learned before I was six years old*, and have used ever since. (Hacking 2000: 101, my emphasis)

The assertions about calculation are manifestly correlated point by point with the previous remarks about proof, resulting in a description of a clear-cut contrast between proof and computation. This representation evokes the way the contrast was portrayed by nineteenth century authors that we have evoked above. What is more, for Hacking too, the opposition is correlated with an opposition between peoples, as is made clear by his ensuing remarks:

> Most mathematics is not like the proof in *Meno* (. . .). Kant distinguished arithmetic from geometry. (. . .) Kant's distinction (. . .) can be paired, very loosely, *with two distinguishable modes of human cognition* (. . .), the *visual* and the *combinatorial*. It is a *happy accident that geometry and algebra took root in different places in different ways, among different peoples.* Of course there was a Greek study of numbers, but *geometry was the model of the mathematical*, and numbers were to a large extent understood as measures, as lengths. *Arithmetic and algebra are of Indian and Arabic devising.* That most combinatorial of

> concepts, the *algorithm*, is named after a 10th century mathematician, whose name, when Europeanized, is Al Gorismi.[3]

The correlation asserted between, on the one hand, "the Greeks" and geometry and, on the other, some Orientals and computation cogently evokes the nineteenth century statements quoted above. That said, in fact Hacking opposes the knowledge that can be acquired by a mathematical proof – such as the one presented in the *Meno* – and the knowledge available to an "Athenian land surveyor," who, in Hacking's imagination, operated with measurement and calculation.

Two remarks highlight how Hacking represents the knowledge of the latter as inferior to that of the former. First, the surveyor can only "*check* the 'anticipation'" provided by the proof in the *Meno* (p. 96, my emphasis), and, if he does not, "he *must* have made an error, or perhaps the land has shifted" (p. 96, emphasis in the original). Second, for other theorems, such as the one stating the incommensurability of the diagonal of a square and its side, the surveyor does not "anticipate nature," by which Hacking means that the experience of the measurement does not enable us to "check" the statement. However, he continues, the proof enables us to assert that "our measurement is inexact." (p. 96).

Only for one aspect does Hacking point out an interaction between the two practices of proof and computation. This interaction derives from a virtue that Hacking attaches to "calculation," as follows:

> Calculation has, however, a *virtue* altogether different from the insight of the theorem imparted by Socrates' talk and his squiggles on the sand. In the case of a calculation *you get practical certainty*, it seems, because each individual step can be *checked*. (Hacking 2000: 103, my emphasis)

In Hacking's view, this virtue inspired Leibniz's conception of proof as calculation:

> Leibniz was a member of the first European generation that could imagine that proof was essentially combinatorial, a matter of *checking the manipulation of signs*. (. . .) The starting points for proofs would be statements of identity, not real statements at all, not worth calling axioms (which have some content), but just identities. *Proof would proceed by rules of inference for manipulating signs*." (. . .) Leibniz "was overwhelmed by his sense of *proof as a sequence of steps* each connected to its predecessor by a single combinatorial *transformation of signs.*[4]

[3] (Hacking 2000: 99), my emphasis. Al Gorismi probably refers to al-Khwarizmi (ninth century). The assertion about the nature of number in Greek texts such as Euclid's *Elements* require qualification. Interestingly, in this context, the assertion is correlated with the subsequent assertion of a social distinction between the philosopher and the mathematician, on the one hand, and the "land surveyor" on the other. See below.

[4] (Hacking 2000: 103, 105, respectively, my emphasis). On this point, see (Hacking 1973).

The foregoing analysis has shed light on several recurring features that have been used to oppose proof and computation. Is it the case that there is "nothing perspicuous about calculation"? Can we accept the idea that, in computation, there is "no feeling of compulsion," "no sense of understanding"? Is it the case that calculation amounts to following rules and can only be checked – and quickly checked? What exactly does "checking" mean in this context? And what is exactly the concept of "calculation" that presides over these representations? I will now turn to a discussion of these issues in the context of a completely different analysis of the relationship between proof and computation.

2 Proof and Computation in the Context of the History of Proving the Correctness of Algorithms

Just as Biot indicated, Chinese, Sanskrit, and Arabic sources from the ancient world abound in mathematical texts dealing in one way or another with computation. As we will see, *pace* Biot, this does not mean that these sources limit themselves to prescribing orders. Moreover, we should not forget that, if we set aside Euclid's *Elements* (and, in this case, only Greek sources) and Apollonius's *Conica*, Greek and Latin sources also as a rule refer to computations. However, Chinese, Sanskrit, and Arabic sources, to which we will add hieratic and cuneiform sources that were not known in Biot's time, will suffice here to highlight problems in the understanding of computation that we have outlined above and to develop our discussion about proof and computation.

2.1 Why There Is No Feeling of Compulsion in Calculation

As we have seen, Hacking opposed proof and computation from the viewpoint that the former elicited a feeling of compulsion, and not the latter. However, is this comparison justified?

In Hacking's example quoted above, to divide 471 by 9, a sequence of operations is followed, and it yields $52 + 1/3$. To this, Hacking immediately appends another procedure, which he concludes by "that's right." In other words, the result is correct. This second part highlights that the computation is in fact a statement: it asserts that, if I apply a given sequence of operations to two numbers, I obtain the quotient of one by the other. Like any assertion, it can become the object of a proof. More generally, any computation is an assertion claiming that the application of a list of operations to some given numbers yields another number sought-for. Its correctness requires a proof.

If we observe the text of Plato's *Meno* more closely, we see that the requirement to construct a square whose area is the double of that of a given square is followed by a complex exchange between Socrates and the slave. Indeed, the dialogue entwines two types of statements. On the one hand, Socrates performs the construction of the

square sought-for step by step, much in the same way as a computation is carried out. On the other, Socrates regularly adds to these steps assertions regarding the successive states of the diagram constructed. The sequence of the latter assertions, in the end, forms a proof establishing that the area of the square constructed is the double of that of the original square. What communicates a feeling of compulsion is not the construction part, but the proof part of the dialogue.

Similarly, from a logical viewpoint, what might communicate a "feeling of compulsion" is the proof of the correctness of the computation, not the statement of the computation. Socrates' geometrical construction is not compelling – in any event, as little compelling as a computation: only the proof of the statement might be. The opposition of proof and computation from this perspective is thus misleading (Chemla 2012b).

Concerning the *Meno*, Hacking writes: "The fact that we can see not only that the theorem is true, but also why it must be true, is one of the core phenomena of *some* proofs, the sheer feeling of having 'got it'" (Hacking 2000: 94, emphasis in the original). The same assertion could be put forward with respect to the proof of the correctness of a computation. However, to examine this issue, we need first to address a more basic question: how can a proof of this kind be conducted? In what follows, we will rely on ancient sources to highlight key operations in this type of proof and thereby point out a dimension of the history of proof that has been overlooked in a historiography that has mainly focused on proving the truth of theorems (Chemla 2012a).

To begin with, a remark about computation is necessary to clarify the discussion. Let us return to the text of Hacking's calculation to formulate it. The text in question combines a list of operations with the sequence of related results. The first operation can be formulated as follows: the divisor "into" the first sequence of digits to the left of the decimal expansion representing the number that is greater than the divisor "goes" so many "times." Its results are 5, on the one hand, and 2, on the other. Proving the correctness of the algorithm involves proving that the sequence of operations actually yields the quotient. It also involves proving that the execution of each of these operations yields correct numerical results.

The significance of distinguishing between these two facets appears clearly with the example of an algorithm given to compute the area of a circle, which I will take from *The Nine Chapters on Mathematical Procedures* (*Jiu zhang suanshu* 九章算術) (Chemla and Guo 2004). This Chinese mathematical classic, which, in my view, was completed in the first century CE, is composed of problems and related algorithms, and it illustrates several facets of computation in which I am interested here. In what follows, I will thus regularly return to it. This classic is all the more interesting because it was handed down with a commentary that Liu Hui 劉徽 completed in 263 and a subcommentary that Li Chunfeng 李淳風 presented to the throne in 656, these two layers of exegesis offering systematically proofs of the correctness of the algorithms.

The first algorithm that *The Nine Chapters* gives to compute the area of a circle reads as follows:

PROCEDURE: HALF OF THE CIRCUMFERENCE AND HALF OF THE DIAMETER BEING MULTIPLIED ONE BY THE OTHER YIELDS THE *BU* OF THE PRODUCT/AREA.
術曰: 半周半徑相乘得積步。[5]

The commentary ascribed to Liu Hui that features immediately after the text of the algorithm proves geometrically that the algorithm is correct. However, it points out that it cannot lead to any numerical computation that would be exact. The example thus highlights the distinction that we must make between the correctness of the list of operations and that of its execution. In this case, no exact value can be given simultaneously for the operands of the algorithm.

Further, the comparison between this algorithm text and the text given by Hacking to illustrate what he means by computation illustrates several ways in which a computation can be formulated.

The text of an algorithm can bring into play ordinary operations ("halving," "multiplying") or other operations ("to carry"). It can also refer to the operations in various ways. In the case of the algorithm in *The Nine Chapters*, the key operation of multiplication takes as operands the results of two operations of halving, which must be performed first. In Hacking's text, the computation unfolds in time linearly, following the sequence of operations given by the text.

In fact, this latter feature is correlated with another characteristic trait that opposes both texts. Hacking's computation refers to an algorithm through its execution on a paradigm, that is, using the case of the division of 471 by 9. One might consider this text as reflecting the treatment of a particular case. However, one might also consider that the same text outlines the general algorithm in the same way as, in a grammar book on the French language, the conjugation of all the verbs of the first class is given using that of the verb *chanter*. Indeed, in some sources, general procedures are expressed in this way. Such a formulation for an algorithm is complete only if the execution for the paradigm illustrates all the situations to which, for other numbers, the division might confront the practitioner. In the case of the area of the circle, the algorithm in *The Nine Chapters*, in contrast, is given without reference to any paradigm. In fact, it could be applied to numbers expressed with respect to any numeration system and to any way of carrying out the operations mentioned. With these remarks in mind, let us turn to some key operations involved in proving the correctness of algorithms.

2.2 The Various Practices Attached to Checking

For Hacking, the proof in the *Meno* establishes the fact stated by the theorem in such a manner that knowledge of the theorem enables someone possessing it to "check"

[5] (Chemla and Guo 2004). To distinguish the text of *The Nine Chapters* from that of the commentaries, I put the quotations of *The Nine Chapters* in capital letters and those of the commentaries in lower-case. *Bu* refers to a measurement unit of distance as well as a measurement unit of surface (in the latter case, the number of *bu* refers to the area of a rectangle whose length has this measurement in *bu* and whose width is 1 *bu*.)

the correctness of the surveyor's results. In contrast, in his view, checking is what would establish the correctness of the execution of division he presents. Checking is indeed one way of approaching the correctness of an algorithm. Let us examine the various meanings that checking could take in this context as well as some conditions of validity for proofs of this kind.

Hacking's way of checking his calculation proceeds by applying the inverse computation to the result (i.e., multiplying the result by the divisor). Restoring the dividend is what leads Hacking to assert: "that's right." In this case, checking is carried out by applying a *procedure*, and its outcome in fact *might* establish the correctness of the result. The same conclusion would apply to the common way of checking the result of any arithmetical operation by "casting out nines": a positive outcome simply enables us to assert that the result *might* be correct. For a checking like Hacking's to enable us to actually draw the conclusion that the result is correct, we would indeed need to establish the correctness of the procedure used for checking. Moreover, let us insist: what is checked in this case is *merely* the fact that the result of the execution of *this* division is correct. However, it says *nothing* about either the correctness of the procedure or that of its execution.

Checking procedures of the same kind as Hacking's are regularly encountered in the Rhind mathematical papyrus. This document, which was the result of illegal excavations in Egypt, is written in hieratic and is believed to contain mathematical problems and procedures dating to the first centuries of the second millennium BCE. T. Eric Peet translates a term introducing this type of checking as "proof" (Peet 1923: 22, 70–76), a translation that was used to the same effect and further discussed by Gillings (1972: 232–234).

However, there is more: if we grant the correctness of the procedure for multiplication used to carry out the inverse operation, Hacking's checking procedure can work to check the result of his division of 471 by 9 *only because* the result of the division is given as exact. If the result had been given as the integral part of the quotient (52), this practice of checking would fail. If, in addition, the result of the division of 10 by 3 was given as 3.33, the same checking procedure would not succeed either.

These last remarks hold true when checking the result of an *execution*. They also hold true when an algorithm *qua* algorithm is proved to be correct through showing that the inverse algorithm (whose correctness has already been established), applied to the magnitude and numerical value yielded by the former algorithm, restores a magnitude and its numerical value that this algorithm had taken as its starting point. We find a case of this kind in *The Nine Chapters* (Chemla 1997/1998). The commentary ascribed to Liu Hui that establishes the correctness of the procedure in this way links the validity of the cancellation of the division and the square root extraction put into play in the procedure, by application of the inverse operation, to the fact that the algorithm for root extraction given in *The Nine Chapters*, like that for division, always yields exact results. In this way, as long as the correctness of the algorithms for multiplication, division, and root extraction is established, the checking procedure that consists in applying the inverse algorithm establishes the correctness of the original algorithm. As we show in Sect. 2.5, in fact, this practice of

proving the correctness of algorithms is merely one type among others, which all fall under a more general practice of proof.

These practices of checking, whether they establish the correctness of the result of the execution or that of the algorithm *qua* algorithm, can be characterized by the fact that they start from the result of a procedure (whether it be the magnitude obtained, the numerical value yielded, or both). In fact, in his discussion, Hacking refers to a different meaning of checking with respect to a calculation, when he introduces the "virtue" of "practical certainty" that would be brought about by calculation. Indeed, the certainty in question derives, in his view, from the fact that precisely "each individual step can be checked." The algorithm to compute the area of a circle quoted above from *The Nine Chapters* makes clear that the type of "checking" Hacking has in mind in this case does not apply to the algorithm *qua* algorithm, but to its execution. Indeed, the execution is what draws on the signs that represent the mathematical objects dealt with and proceed by mere "transformation of signs." We can think of a written procedure to carry out a multiplication for instance. A checking procedure in this case verifies that each of the successive manipulations conforms with the rule followed. It bears on the actions and not on the result of the global computation. Moreover, the efficiency of a checking of this kind will depend on the nature of the signs chosen for the execution and also on the type of manipulation put into play. In any event, Leibniz's idea to gain "practical certainty" for procedures of proving to which Hacking refers relied on this precise dimension of a practice of computation. We return to this issue below.

However, as many ancient sources illustrate, checking is not the only way of approaching the correctness of an algorithm. In fact, nowhere in the commentaries on *The Nine Chapters* do we find actors – actors here referring to the characters of the past whom we observe and thus being opposed to the observers whom we are – checking the numerical result of an algorithm. By contrast, they systematically seek to establish that the procedures given in *The Nine Chapters* actually yield the magnitude sought-for. In addition, for cases like the area of the circle, they discuss in which respect the numerical value obtained corresponds to it. The certainty thereby obtained is thus different from the "practical certainty" Hacking envisages. Let us examine the operations that such proofs put into play to this effect.

2.3 Practices of Proving the Correctness of an Algorithm and the Issue of Understanding

The oldest extant texts attesting to proofs of the correctness of algorithms are arguably mathematical tablets written in cuneiform script and dating from the first centuries of the second millennium BCE. These texts illustrate practices that highlight a key operation involved in proving, in cases where the proof concerns the correctness of a statement that unfolds in time, as that of an algorithm does. However, to understand this point, readers must apply a specific type of reading to these tablets, which Jens Høyrup was the first to advocate and which is correlated with the fact that the formulation of these texts is unexpected.

As Høyrup (2002, p. 11–13) emphasizes, the earliest translations of problems and procedures borne by a tablet such as BM 13901 shared a characteristic feature. This feature can be illustrated with the translation of its first problem published by François Thureau-Dangin in 1936, which reads as follows:

> J'ai *additionné* la surface et (le côté de) mon carré : 45'.
> Tu *poseras* 1°, l'*unité*. Tu *fractionneras* en deux 1° : 30'. Tu *multiplieras* (entre eux) [30'] et 30': 15'. Tu *ajouteras* 15' à 45': 1°. 1° *est le carré de* 1°. 30', que tu as multiplié (avec lui-même), de 1° tu *soustrairas*: 30' est le (côté du) carré. (my emphasis)

Thureau-Dangin, like other historians at the time, interpreted the problem as corresponding to the equation $x^2 + x = 45'$, and, in his view, the list of operations placed after its statement was the rule to follow to determine the value of the unknown.

The crucial feature of Thureau-Dangin's interpretation and, thus, of his translation is this: for him, the terms that I have italicized referred to arithmetical operations that had to be applied in succession, first, to the numerical values given by the statement of the problem and, also then, to those gradually determined along the text. In this way, the algorithm eventually yielded the value sought-for.

In a sense, Thureau-Dangin's interpretation reads in the text a formulation close to Hacking's example of a calculation. However, Høyrup raises an objection to this reading: if the terms italicized simply referred to arithmetical operations, why, he asks, in a given text of procedure, do we have several terms referring to the same operation? His answer to this question is this: in fact, each of these terms points out not only an arithmetical but also a geometric operation. Høyrup (2002) thus offers an interpretation of all the terms referring to operations in these texts of problems and procedures that convey both meanings. As a result, his translation of the same text in BM13901 reads as follows:

1. The surface *and* my confrontation: 45′ is it. 1, the *projection*,
2. you posit. The *moiety* of 1 you *break*, 30′ and 30′ you *make hold* each other.
3. 15′ to 45′ you *append*: by 1, 1 is the *equalside*. 30′ which you have made hold
4. in the inside of 1 you *tear out*: 30′ the confrontation. (I have emphasized the same terms as above)

Moreover, Høyrup restores the sequence of geometric operations to which the terms italicized refer as shown on Fig. 1.

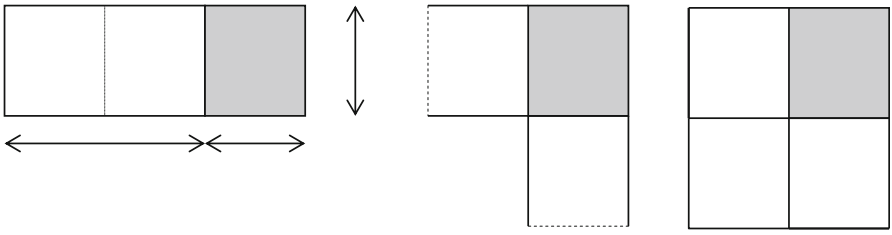

Fig. 1 "A possible geometric procedure for BM 13901 #1. Distorted proportions" (Høyrup 2002: 13)

In other words, in Høyrup's view, in the context in which BM 13901 was composed, a practitioner of mathematics read the technical texts by means of which cuneiform algorithms were written down, using a double interpretation. First, the terms referring to the operands and those prescribing operations designated, respectively, numerical values and arithmetical operations on them. Second, the same terms also indicated, respectively, a geometrical configuration and geometrical transformations that allowed the practitioner to associate a meaning with the operations carried out. This second facet of the interpretation enabled the user of the text to understand what the list of operations was carrying out and why the algorithm was correct.

The practitioner using such texts thus knew at the same time which operation to carry out and the reason why this operation was to be used. In contrast to a text of calculation such as Hacking's, for which the formulation yields no understanding, texts such as those we find on cuneiform mathematical tablets – if we adopt the reading practice restored by Høyrup –conveyed simultaneously a prescription and an understanding.

Two key points must be emphasized.

First, in such cases, the text of an algorithm delivered at the same time a procedure and the reasons of its correctness. However, for the proof of the correctness to be expressed in this way, the formulation of the algorithm had to possess the property that the list of operations could be interpreted step by step or sub-procedure by sub-procedure. I designate texts of this kind as "transparent." They imply a practice of formulating proofs that is quite specific. Below, I will consider fundamental reasons why not all texts of algorithms are transparent in this sense.

The fact is that we do find transparent texts for procedures in ancient cuneiform sources as well as in Chinese sources such as *The Nine Chapters*. In the latter case, the commentator makes explicit the meaning read in the formulation of the algorithm, and hence we can observe an ancient reader engaging with such texts precisely in this way (Chemla 1991). Interestingly, in this context, the commentator refers to the meaning of a step or a sub-procedure using the technical term of "meaning/intention *yi* 意." This actor's terminology, which points out a key dimension of the proof, designates the intention presiding over the use of an operation or a list thereof. By derivation, it also designates the global reasoning that accounts for the correctness of the procedure (Chemla 2012c).

In fact, if we return to the cuneiform tablet mentioned above, we observe that the text refers to the reasons of the correctness of an algorithm using another property of the formulation. Indeed, the terms employed for both the operands and the operations designate at the same time a computation to be carried out and the reason why it should be: This represents a second facet of the practice of proof to which these documents attest. In *The Nine Chapters*, we also find texts that use terms referring to operations in the same double way. These texts for procedures also illustrate a practice of writing down algorithms, for which the readers must apply specific reading to get from the text the specific list of operations to be applied depending on the case dealt with (Chemla 2015).

The second key point is this: in the case of the cuneiform tablet discussed above, Høyrup puts forward a hypothesis regarding the kind of device actors used to shape the meaning of the algorithm. He suggests that they used diagrams in the plane that could be transformed into other diagrams. In a sense, in the *Meno*, Socrates also makes use of a diagram of this kind: he puts together four equal squares around a point, emphasizing that the figure obtained is four times the original one. He then introduces diagonals in each of the four squares, interpreting them as cutting each square into two equal parts. Socrates can then consider the figure shaped by the four diagonals as making a space that is the double of the original figure: the evaluation of the extension proceeds by a counting that regularly requires interpretation based on the diagram.

The commentators of *The Nine Chapters* sometimes use diagrams of this kind, for instance, when they deal with the correctness of algorithms computing areas, or square roots, or else algorithms used in relation to right triangles. They also use blocks to deal with algorithms that concern volumes. Finally, as can be established by an observation of the commentaries, mathematical problems also appear to have had the key function of allowing practitioners to formulate the meaning of steps or sub-procedures of algorithms in the context of proofs of this kind (Chemla 2009). We will see an example thereof in the next section.

The foregoing analysis has borne on texts of algorithms independently of the way in which they were executed. However, seventh century subcommentaries on the Confucian classics contain descriptions of executions of arithmetical operations that also illustrate ways in which texts can weave the operations to be applied and the reasoning accounting for their correctness (Zhu 2016, 2022). To this end, the subcommentators introduced regularly geometrical interpretations of quantities, which allowed them to make the meaning of steps in the execution explicit. Interestingly, during the same decades, the mathematical canon that was taught at the Imperial University and that included *The Nine Chapters* as one of its main textbooks inculcated ways of executing the same operations in a completely different way: the execution bore on a decimal place-value numeration system and was carried out in a purely formal way – much in the same way as we carry out arithmetical operations in a written way. These two sets of texts nicely illustrate the tension that exists between the understanding of a calculation that can be acquired during its execution (the former texts) and, by contrast, the practical certainty that can be achieved through calculating formally on the basis of a symbolic notation (the latter).

2.4 Understanding and Proving as Actors' Categories

So far, we have approached the issue of understanding a computation from an observer's viewpoint. However, we have evidence attesting to the fact that actors also intended to gain understanding through proving. We will now examine a document of this kind to analyze the type of understanding actors sought in a

given context as well as what this tells us about their motivation for proving the correctness of algorithms.

The document in question is part of the commentary ascribed to Liu Hui on the algorithm given to multiply fractions. The passage of the commentary we are interested in starts with the following declaration: "If here one makes use of the formulation of a field with length and width, it is difficult to have (the procedure) *be understood with a greater generality* (*nan yi guang yu* 此田有廣從, 難以廣諭, my emphasis.)"[6]

The "formulation of a field with length and width" refers to the mathematical problem in the framework of which the multiplication of fractions is dealt with in *The Nine Chapters*, that is, a problem asking to compute the area of a rectangular field with fractional width and length (4/7 *bu* and 3/5 *bu*, respectively, to which, below, I refer as *a/b* and *c/d*). The problem is followed by a general and abstract procedure. From the commentator's perspective, this problem does not allow him to convey an "understanding" of the algorithm "with a greater generality." Indeed, this declaration is followed immediately by the statement of a sequence of three equivalent problems in the context of which the meaning of the steps of the procedure are made explicit. Let us outline how these problems are used to prove the correctness of the procedure and how we may interpret the understanding in question.[7]

The procedure under consideration reads as follows:

> Multiplying parts
> Procedure: the denominators being multiplied by one another make the divisor. The numerators being multiplied by one another make the dividend. One divides the dividend by the divisor.
> 乘分
> 術曰: 母相乘爲法, 子相乘爲實, 實如法而一。(Chemla and Guo 2004, 170–171)

In modern terms, the procedure prescribes multiplying the fractions *a/b* and *c/d* as follows:

$$\frac{a}{b}.\frac{c}{d}=\frac{ac}{bd}$$

To establish the correctness of the procedure, the commentary in which we are interested first introduces a problem solved by the last operation of the procedure (dividing *ac* by *bd*). The problem reads as follows – I insert symbolic notations between brackets for the sake of a better understanding:

[6] (Chemla and Guo 2004, 170–171). My emphasis.

[7] The connection between mathematical problems and the issue of "understanding" the algorithm through proving it also occurs in other passages of the commentary, for instance at the beginning of chapter 8, where we read: "It would be difficult to *understand* (the procedure) with abstract expressions (*kongyan*), this is *why* one deliberately linked it to (a problem of) *millet* to eliminate the obstacle. 以空言難曉, 故特繫之禾以决之。" (Chemla and Guo 2004, 947, my emphasis). On this issue, see (Chemla 2009).

> Suppose that one asks: 20 (*bc*) horses are worth 12 (*ac*) *jin* gold. If one sells 20 (*bc*) horses and if 35 (*bd*) people share this [the gain], how much does a person get? Answer: 12/35 (*ac/bd*) *jin.*
> To solve it, one must follow the "procedure for directly sharing" (NoT: division between quantities combining integers and fractions) and take 12 *jin* gold as dividend and 35 people as divisor.
> 設有問者曰, 馬二十匹, 直金十二斤。今賣馬二十匹, 三十五人分之, 人得幾何。荅曰: 三十五分斤之十二。其爲之也, 當如經分術, 以十二斤金爲實, 三十五人爲法。[8]

The commentator goes on by introducing a second problem, equivalent to the first one, but whose solution requires using all the operations of the procedure for multiplying fractions. Let me quote this problem and its solution, before commenting on them:

> Suppose that, *modifying* (the problem), one says: 5 (*b*) horses are worth 3 (*a*) *jin* gold. If one sells 4 (*c*) horses and if 7 (*d*) people share this [the gain], how much does a person get? Answer: 12/35 (*ac/bd*) *jin*.
> To solve it, one has to *homogenize* these quantities of people (*bd*) and gold (*ac*), and they (the quantities transformed) then all conform to (the quantities in) the initial problem and they are entered into the (procedure for) "directly sharing".
> 設更言馬五匹, 直金三斤。今賣四匹, 七人分之, 人得幾何。荅曰: 人得三十五分斤之十二。其爲之也, 當齊其金、人之數, 皆合初問入於經分矣。

To begin with, the commentary focuses on how the second problem can be solved. "Homogenizing," which is put into play here, is a technical term that belongs to a pair of operations: "homogenizing and equalizing," which the commentaries have introduced earlier and which recur in several proofs for crucial reasons, to which we return. What is meant here is this:

b horses are worth *a jin* gold.
c horses are sold by *d* people

hence
bc horses are worth *ac jin* gold.
bc horses are sold by *bd* people.

We thus see that horses are "equalized" to bring the two statements into communication. Accordingly, to warrant the validity of each statement, *a* is also multiplied by *c* while *d* is multiplied by *b*. These correlated transformations explain the relation between the two operations of equalization and homogenization and also the name of homogenization given to the latter. Now, as the commentary emphasizes, this global transformation reduces the problem to the first problem, and hence the sequence of

[8] For the sake of simplicity, when I translate Chinese passages from *The Nine Chapters*, I use so-called "Arabic numerals." It would be more appropriate, but also more cumbersome, to translate using English words expressing quantities. In the context of a discussion of proof, this nuance does not seem to me to matter.

the two homogenizations and of a division completely solves the second problem. However, the commentator continues:

> If this is so, "multiplying the numerators by one another to make the dividend (*ac*)", is *like homogenizing* the corresponding (quantity of) gold; "multiplying the denominators by one another to make the divisor (*bd*)" is *like homogenizing* the corresponding (quantity of) people. *Equalizing* the corresponding *denominators* makes 20 (*bc*). *But the fact that the horses are equalized plays no role. One only wants to find the homogenized (quantities) and this is all.*
> 然則分子相乘爲實者, 猶齊其金也; 母相乘爲法者, 猶齊其人也。同其母爲二十, 馬無事於同, 但欲求齊而已。(my emphasis)

Indeed, in the context of the second problem, we see that the homogenizations correspond exactly to the operations of multiplying *b* by *d* and *a* by *c,* that is, in other words, to the first two operations in the algorithm given to multiply fractions (which the commentary quotes *verbatim*). To put it differently, the complete algorithm for the multiplication of fractions thus solves this second problem, and now, the sequence of problems and related procedures allows us to see why the procedure solves this problem correctly. Finally, to conclude his commentary, the commentator points out that:

b horses are worth *a jin* gold.
c horses are sold by *d* people.
is equivalent to
1 horse is worth *a/b jin* gold.
c/d horse is sold by 1 person.

The third statement of the problem is now identical to the original problem in *The Nine Chapters.* The former problem – the second one considered, the commentator insists – is stated using integers and the latter – the third one, using fractions. Beyond the change of formulation, they amount to the same. However, looking at the operations, solving the problem with fractions from this new perspective has embedded the multiplications yielding *ac* and *bd* into a wider set of computations, which highlight their meaning as "homogenizations." As the commentator immediately stresses, the computation of *bc* is not needed to *solve* the problem. It is only required to highlight a meaning of the algorithm for the multiplication of fractions. In other words, this computation is needed not for the *solution* of the problem, but for the *proof* of the correctness of the algorithm solving it.

We see that the key point in the change of problem is precisely to enable this "equalization" to become visible. As a result, we grasp that bringing to light this additional operation is essential to the "understanding" of the algorithm as the commentator conceives of it. Moreover, we see how this understanding derives from the proof. In fact, several proofs allow the commentators to show that the same formal pattern of equalization and homogenization underlie different procedures and account for the correctness. Through highlighting the pair of operations "homogenizing and equalizing" – or similar formal strategies – in the proofs of the correctness of different algorithms, the commentaries bring to light that, beyond the

diversity of the procedures given to solve all kinds of problems, the same small number of formal strategies are put into play (Chemla 1991): these formal strategies have thus a greater generality than the algorithms themselves.

I interpret the second term that commentators use to refer to the "meaning" of a procedure, namely "*yi'* 義,"[9] as designating precisely the underlying formal strategy that accounts for its correctness and that at the same time reveals its connection with other procedures—*pace* Biot. "Homogenizing and equalizing" is one such formal strategy, and showing that it underlies the algorithm for the multiplication of fractions is what I interpret as yielding "understanding with a greater generality." We have seen the role played by the new problem to make this formal strategy visible. In the commentaries of *The Nine Chapters*, seeking to prove the correctness of the algorithms stated in the classic appears to aim primarily at finding out the fundamental formal strategies underlying them all. From this viewpoint, the connection between actors' motivation for proving and the "understanding" they seek to acquire appears clearly.

2.5 Proof as Calculation and Why Not All the Algorithms Are Transparent

The arguments developed in the previous sections have illustrated in various ways why, when proofs aim at proving the correctness of algorithms, they are entwined with computations. Our last example, in particular, has showed how it was through embedding the operations prescribed by the algorithm into a broader set of computations and through interpreting these computations in the semantic field provided by a problem that the correctness was established (Chemla 2009). However, in this case, the mathematical work put into play operations *qua* operations, and not their execution. This example makes clear why the fact that there might have been connections between proof and computation is to be distinguished from the aim of securing "practical certainty" for proving, in contrast with what has been suggested by Hacking. However, this issue calls for a deeper analysis, which I will present on the basis of a problem and an algorithm found in *The Nine Chapters*.[10]

The eleventh problem in chapter 5 of *The Nine Chapters*, titled "discussing works," and the procedure given in relation to it read as follows:

> Suppose one has a truncated pyramid with a circular base, the circumference of the lower circle of which is 3 *zhang*, the circumference of the upper circle of which is 2 *zhang*, and the height of which is 1 *zhang*. One asks how much the volume is.
>
> Answer: 527 *chi* 7/9 *chi*.

[9] I transliterate *yi'* and not *yi* to distinguish the second "meaning" from the first one discussed above.

[10] The text analyzed below is fully edited and translated in (Chemla and Guo 2004: 424–427). A much more detailed analysis than I can give here can be found in Chemla 2012c).

Procedure: The circumferences of the upper and lower circles being multiplied by one another, then multiplied each by itself, one adds these (the results); one multiplies this by the height and divides by 36.
今有圓亭, 下周三丈, 上周二丈, 高一丈。問積幾何。
荅曰: 五百二十七尺九分尺之七。
術曰: 上下周相乘, 又各自乘, 并之, 以高乘之, 三十六而一。

A commentary is appended to this procedure, and it establishes its correctness: I will highlight some of its characteristic features to illustrate aspects of the proof of the correctness of algorithms that have not yet been discussed so far, returning eventually to the issue of practical certainty.

Note that the commentator assumes that *The Nine Chapters* uses throughout the ratio of 3 to 1 for that of the circumference of a circle to its diameter. The proof of the correctness is thus given in the framework of this assumption.

If we call C_s (resp. C_i) the circumference of the upper (resp. lower) circle and h the height of the truncated pyramid, the sequence of operations given in *The Nine Chapters* to determine its volume can be represented as follows:

$$\begin{matrix} C_i \\ C_s \end{matrix} \xrightarrow[\text{Sum}]{} C_i C_s + C_i^2 + C_s^2 \xrightarrow[\text{by } h]{\text{Multiplication}} (C_i C_s + C_i^2 + C_s^2)h \xrightarrow[\text{by 36}]{\text{Division}} (C_i C_s + C_i^2 + C_s^2)h/36$$

What matters most for us here is this: the commentator's proof proceeds along three interwoven lines of argumentation. First, Liu Hui establishes an algorithm, for which he proves that it yields the desired volume, that is, the volume of the truncated pyramid with a circular base. However, this algorithm differs from the one given in *The Nine Chapters*, whose correctness needs to be established. This is where the second and third lines of argumentation are put into play. The commentator's second line of argumentation is the main focus of this section: Liu Hui transforms this algorithm *as such* into the algorithm the correctness of which is to be proved. For this, Liu Hui applies valid transformations to the algorithm taken as a list of operations, thereby modifying it progressively into other lists of operations, without affecting its result. In the following, we shall make clear what such transformations can be. Thirdly, in doing so, the commentator simultaneously accounts for the form of the algorithm as found in *The Nine Chapters*, by making explicit the motivations he lends to its author for not stating the algorithm as he or she most probably first obtained it, but instead changing it: we refer to this facet of his proof as the third line of argumentation. This whole process provides an analysis of the reasons underlying the correctness of the algorithm.

Let us concentrate on the parts of the commentary under consideration that matter to us in this section.

The first step in Liu Hui's reasoning is to make use of an algorithm for which the correctness was established in relation to the problem placed immediately before the one under examination. This algorithm provides the means to compute the volume of a truncated pyramid with a square base when one knows the sides of the upper square (D_s) and lower square (D_i) as well as the height h. It can be represented as follows:

Multiplications Division
Sum by 3
Multiplication by h

$$\begin{matrix} D_i \\ D_s \end{matrix} \longrightarrow (D_i D_s + D_i^2 + D_s^2)h \longrightarrow (D_i D_s + D_i^2 + D_s^2)h/3$$

On this basis, Liu Hui states a first algorithm (algorithm 1) which determines the volume of the truncated pyramid with a square base circumscribed to the truncated pyramid with a circular base which is considered. To do this, given the fact that the value of π lent to *The Nine Chapters* is 3, it suffices to divide by 3 the upper and lower circumferences of the truncated pyramid with a circular base to get the related diameters, which are the sides of the upper and lower circumscribed squares. From a syntactic viewpoint, the only transformation needed to make use of the algorithm above in this new context is thus to begin with the upper and lower circumferences and to prefix the text of the algorithm with two divisions by 3. These operations change the given circumferences into the corresponding diameters, the lengths of which are respectively equal to the lengths of the sides of the upper and lower circumscribed squares. This is how Liu Hui starts shaping an algorithm that will eventually compute the volume of the truncated pyramid with a circular base: this belongs to what I have called above the "first line of argumentation." This first algorithm (Algorithm 1) can hence be represented as follows:

Divisions by 3 Multiplications, sum, Division by 3
Multiplication by h

$$\begin{matrix} C_i \\ C_s \end{matrix} \longrightarrow \begin{matrix} D_i = C_i/3 \\ D_s = C_s/3 \end{matrix} \longrightarrow [\tfrac{C_i}{3}.\tfrac{C_s}{3} + (\tfrac{C_i}{3})^2 + (\tfrac{C_s}{3})^2]h \longrightarrow [\tfrac{C_i}{3}.\tfrac{C_s}{3} + (\tfrac{C_i}{3})^2 + (\tfrac{C_s}{3})^2]h/3$$

Liu Hui can assert the "meaning *yi*" of the result – as the volume of the truncated pyramid with square basis circumscribed to the pyramid under consideration – using the previous problem and algorithm as well as the numerical values employed by *The Nine Chapters* as corresponding to a value of π. This is precisely the virtue of the "first line of argumentation" in Liu Hui's proof of the correctness of the investigated algorithm. However, the next step in the proof belongs rather to both the second and the third lines. Indeed, Liu Hui will transform the algorithm whose meaning is established, *qua* list of operations, into another algorithm that yields the same magnitude and the same numerical value, but follows a different sequence of operations. This step makes us encounter the aspect of proof that is the main focus of the present section.

Indeed, the division of C_i and C_s by 3, which give respectively D_i and D_s, yields as a rule numerical results under the form of an integer (resp., a_i and a_s) increased by a fraction (resp., $b_i/3$ and $b_s/3$). In algorithm 1, these quantities subsequently enter into three multiplications, in the context of which they are multiplied by each other. These operations imply inserting at this point the algorithm that *The Nine chapters* gave for multiplying integers with fractions, the correctness of which has been

previously established. The first step of the inserted algorithm consists of transforming the said quantities into, respectively, $(3a_i + b_i)/3$ and $(3a_s + b_s)/3$ and then, as we have seen in the previous section, to multiply the numerators by each other, the denominators by each other, and finally to divide the result of the former by the result of the latter.

The key observation is this: dividing the circumferences by 3 gave numerical values corresponding to the sides of the circumscribed squares. Entering these numerical values into the inserted algorithm meant, to begin with, computing numerators through a multiplication by 3. From a numerical viewpoint, the multiplication by 3 cancels the effect of the division by 3 – precisely because the results of division are given as exact. The numerators computed therefore return in fact to the values of the circumference. Multiplying the numerators with each other is strictly identical to multiplying the circumferences with each other. Restoring the division by 3 and the opposed multiplication allows the practitioner to understand the meaning of the computation. Deleting these two operations makes the computation more straightforward. As long as one postfixes a division by 9, one can thus eliminate the first two operations of algorithm 1 and compute exactly the same magnitude (the volume of the circumscribed truncated pyramid with a square base) and its numerical value using algorithm 2, which can be represented as follows:

	Multiplications Sum Multiplication by h		Division by 9		Division by 3	
C_i C_s	———>	$(C_i\,C_s+C_i^2+C_s^2)h$	———>	$(C_i\,C_s+\,C_i^2+C_s^2)h/9$	——>[	$(C_i\,C_s+\,C_i^2+C_s^2)h/9]/3$

Algorithm 1 enabled the practitioner to determine the meaning *yi* 意 of the result: this is what is at issue in restoring in the first place the division by 3 and the opposed multiplication. However, when one computes, these operations are useless, and they can be deleted. Algorithm 2 derives from algorithm 1 by rewriting the list of operations in a formal way (this is typical of the second line of argumentation on which I lay stress here). The fact that this rewriting gives the algorithm the property that the computation becomes more direct belongs to the justification Liu Hui gives to explain why the algorithm was rewritten – I have referred to this part of the reasoning as the third line of argumentation. Note that the formulation of algorithm 2 implies that other transformations of the list of operations *qua* list of operations have been carried out on algorithm 1. One such transformation was swapping the multiplication by the height and the division by 9: this is again typical of the second line of argumentation. Elsewhere, Liu Hui accounts for the correctness of this transformation by reference to the fact that the results of the division are exact. In addition, Liu Hui makes clear that this avoids getting fractions as results and then computing with fractions (third line of argumentation).

To transform an algorithm computing the volume of the circumscribed truncated pyramid with a square base, such as algorithm 2, into one that computes the volume of the truncated pyramid with a circular base, one needs to append to the list of

operations a multiplication by 3 – which is assumed to be the value for π used in *The Nine Chapters* – and a division by 4. Doing this, we obtain algorithm 3, which performs the task to be fulfilled, namely, computing the volume of the truncated pyramid with a circular base (first line of argumentation). Algorithm 3 can be represented as follows:

Multiplications Sum Multiplication by h — Division by 9 — Division by 3 — **Multiplication by 3**

C_i C_s ——> $(C_i\,C_s+C_i^2+C_s^2)h$ —> $[(C_i\,C_s+C_i^2+C_s^2)h/9]/3$ —> $[[(C_i\,C_s+C_i^2+C_s^2)h/9]/3].3$

Division by 4

—> $[[[(C_i\,C_s+C_i^2+C_s^2)h/9]/3].3]/4$

The "meaning *yi*" of the result of Algorithm 3 is clear. However, if one used it to compute, computations would be cumbersome. This is why, once again, Liu Hui relies on the list of operations to transform it in a formal way into an equivalent list, more straightforward with respect to the computations prescribed. In doing so, the goal, from this point onwards, will be to transform this algorithm, *qua algorithm*, into the one for which the correctness is to be established, that is, the one provided by *The Nine Chapters* for the volume of the truncated pyramid with a circular base.

Here, Liu Hui hence resumes reasoning along the second line of argumentation. Considering the list of operations obtained by the last transformation, he remarks that the algorithm yielding the circumscribed truncated pyramid with a square base ended by a division by 3, whereas the transformation first appended to it a multiplication by 3. Once again, these two operations hence cancel each other out. This transforms algorithm 3 into algorithm 4, as follows:

Multiplications Sum Multiplication by h — Division by 9 — ~~**Division by 3**~~ — ~~**Multiplication by 3**~~

C_i C_s ——> $(C_i\,C_s+C_i^2+C_s^2)$h —> $[(C_i\,C_s+C_i^2+C_s^2)$h/9$]$~~/3 —> $[[(C_i\,C_s+C_i^2+C_s^2)h/9]/3].3$~~

Division by 4

—> $[(C_i\,C_s+C_i^2+C_s^2)h/9]/4$

The commentator clearly considers the operations that follow each other as a *list* and carries out a transformation of this list as such. The correctness of this operation, which is applied to a list of operations to produce another list that is equivalent to it, depends on the fact that the results of the division are exact – a point the commentator emphasizes (Chemla 1997/1998, 2012c). The latter transformation modifies the list of operations without altering the meaning or the value of the result. We meet here with the same phenomenon as above. Bringing to light the opposed multiplication and division was crucial to interpreting the meaning (*yi*) of the result. However, when viewing the list of operations as a means for computing, the two

operations appear unnecessary. This is how Liu Hui progressively accounts for the shape of the algorithm found in the Classic.

Exactly the same remarks apply to the subsequent transformation, which continues along the second line of argumentation, while applying a different operation to algorithm 4. Indeed, instead of carrying out the divisions by 9 and then by 4 in succession, the final transformation suggests "dividing in combination" (*lianchu*). This implies transforming the end of algorithm 4 into the multiplication of the two divisors by each other and dividing by the product. With the expression of "dividing in combination," we meet with a technical term that recurs regularly in the commentaries but is not to be found in *The Nine Chapters*. We may account for this by noting that it is a designation of the division typical of the mode of proving the correctness of algorithms on which this section concentrates.

Two successive divisions were accounted for, each being shown to be necessary for their own reasons. As above, Liu Hui had to dissociate them to bring to light the meaning of the result of the algorithm he shaped. However, viewing the list of operations as a means for computing leads to modifying the way of carrying out the computation and transforming the end of the algorithm. Liu Hui thereby accounts for the form of the algorithm given by *The Nine Chapters*, by highlighting that the two operations were grouped into a unique division. The technical term chosen for this division refers to the motivation of the effected transformation. As a consequence, algorithm 4

$$C_i, C_s \text{—} \text{—} > \left(C_i\, C_s + {C_i}^2 + {C_s}^2\right)h \text{—} > \left(C_i\, C_s + {C_i}^2 + {C_s}^2\right)h/9 \text{—} > \left[\left(C_i\, C_s + {C_i}^2 + {C_s}^2\right)h/9\right]/4$$

is transformed into the algorithm

$$C_i, C_s \text{—} \text{—} > \left(C_i\, C_s + {C_i}^2 + {C_s}^2\right)h \text{—} > \left(C_i\, C_s + {C_i}^2 + {C_s}^2\right)h/36$$

which is equivalent to it and identical to the desired algorithm. This was what was to be obtained: the correctness of the procedure provided by *The Nine Chapters* is established. The way in which the proof was conducted shows clearly how the activities of shaping an algorithm and proving the correctness are intertwined.

However, there is more. The algorithm obtained following the first line of argumentation is transparent in the sense put forward in Sect. 2.3. If the final algorithm no longer has this property, the reason is clear: the transparent list of operations was rewritten *qua* list of operations, in order to improve the convenience of the computation.[11] We hence meet here for a fundamental reason why not all algorithms manifest this property of transparency.

I have suggested to designate the type of proof illustrated in this section as "algebraic proof in an algorithmic context." Proofs of this kind are characterized by the articulation of the three lines of argumentation I have distinguished. However,

[11] On the transformations that can be applied to a list of operations, and how the commentators of *The Nine Chapters* account for their correctness, see (Chemla 2012c).

clearly, the second line of argumentation is the part of the proof that is specific to algebraic proofs.

The designation of this proof as algebraic can be understood by comparison with a modern rewriting of it, which would read as follows:

$$V = \frac{\left[\frac{C_i}{3}.\frac{C_s}{3} + \left(\frac{C_i}{3}\right)^2 + \left(\frac{C_s}{3}\right)^2\right].h}{3}.\frac{3}{4}$$

$$= \frac{\frac{\left[C_i.C_s + {C_i}^2 + {C_s}^2\right].h}{9}}{3}.\frac{3}{4}$$

$$= \frac{\left[C_i.C_s + {C_i}^2 + {C_s}^2\right].h}{9}.\frac{1}{4}$$

$$= \frac{\left[C_i.C_s + {C_i}^2 + {C_s}^2\right].h}{36}$$

The modern rewriting of the proof has replaced lists of operations formulated discursively, as we find them in *The Nine Chapters* and its commentaries, with lists of operations written as formulas. Notwithstanding this new way of representing lists of operations, in this proof, like in the proof analyzed above, lists of operations are rewritten into other lists to yield eventually the formula sought-for. Both types of proof further share the same fundamental reason for their correctness: the fact that divisions (and in other cases, root extractions) are given exact results. These are the two key reasons to consider them as similar. For these two types of reason, computation is central to proofs of this kind.

However, the precision that in the case of the commentaries on *The Nine Chapters*, the "algebraic proof" is carried out "in an algorithmic context" points to a key difference between the two. Indeed, the commentators draw on lists of operations formulated under a discursive form and carry out their rewriting in a discursive way. This is precisely the point where we can return to the issue of "practical certainty." Indeed, the introduction of notations of the type illustrated by the modern rewriting of our proof allowed practitioners to transform operations carried out discursively into operations that were performed on a notation comparable to the inscription of numbers using a decimal place-value notation. On these supports, their transformations only required "manipulating signs" and "transform[ing]" them.

The proof by the commentator highlighted a first link between proof and computation, since proofs proceeded through producing an algorithm executing a task and rewriting lists of operations carrying out this task formally. Now, the reformulations of lists of operations into formulas highlight a new connection between proof and computation. Indeed, in this change in the practice of proving, proofs have become manipulations of signs using rules similar to the execution of an operation relying on, e.g., a decimal place-value notation of number. So now the link

between proof and computation is established at the level of computation *qua* execution. The latter practice sheds light on *how* proof gains practical certainty. However, this dimension should not overshadow the multiple other ways in which proofs are tied with computation. Indeed, this change represented only the establishment of a new relationship grafted on an older practice in which proof and computation already had intimate links.

3 Conclusion

To conclude, *pace* Biot, Whewell, and Hacking, the ancient sources on which we have dwelled in this chapter shed light on several facets of the relationship between proof and computation that, so far, have not been discussed widely. It is probably not by chance that the ancient sources that proved useful for our project dealt with proofs of the correctness of algorithms. However, the conclusions they have allowed us to draw appear to be valid beyond this context.

First, proofs have appeared to be related to computations by the mere fact that some of them make use of computations. Second, we have seen that for some actors, proofs of this kind yielded understanding, however, in specific ways. Indeed, in some contexts, we have seen that proofs seek to highlight formal strategies that are more general patterns of computation. In the eyes of these actors, such a practice is what yields understanding. Gaining deeper understanding is a complex endeavor that actors undertake, and we might expect that a historical approach to this endeavor would be useful to interpret it in a nuanced way. However, for us, these remarks also raise the more specific question of how computations contribute to understanding – a question that we leave open for the moment. Finally, we have seen that proofs present ties with computation in at least two ways, depending on the facet of computation considered: computation as transforming magnitudes through operations and computation as producing a numerical value for a magnitude through the execution of these operations. Interestingly, numbers are involved in different ways in each of these facets: giving exact results to division and root extraction – more generally, drawing on the algebraic structure of field to which the numbers dealt with belong – is essential for some key operations on lists of operations carried out in the former sense of computation to be valid, while how one notates numbers and defines rules of rewriting on the notations is crucial to the second. This opens on a research program in the history of mathematics that would broaden these views and also inquire in a historical fashion into how these ties were established.

Abstract

This very short introduction will first outline how ontological investigations and questions of practice go together. The second section will bring in the next pole of this entire book, history of mathematics. How do ontology, practice, and history go together? Is this a forced marriage or one born in true love? That is, do these three belong together in some very basic way? One chapter in the section argues that the philosophy of mathematical practice intersects with the history of mathematics essentially. If the first section of this introduction is persuasive that will also show that the history of mathematics intersects with ontological questions as well, specifically, that historical questions are very much about the ontological commitments of past mathematicians. The last section will take up what might seem a very different theme, namely, how these things matter to mathematics education. This section is connected closely to the second section since mathematics education has taken an interest in the role of history of mathematics in mathematics education, and much insight can be gained by seeing the issues in relation to the ontology-practice-history triad. The question of education is also important since teachers must consider what it is exactly that they are teaching, or, to adapt the title of

Reuben Hersh's well-known book, "What is mathematics really about?" And the "aboutness" of mathematics is really the ontological question.

Keywords

Ontology · Ontological commitment · Practice · History of mathematics · Mathematics education

1 Introduction

The chapters that make up this section are, on the face of it, quite diverse in focus. For many readers, it may not be evident that all belong together in a section called "ontology." This diversity owes partly to the broad spread of ontological investigations in general and partly to the wide range of meanings and manifestations of mathematical practice. As for the latter, this entire work amply demonstrates just how much is subsumed under the name "practice" and how these many forms of practice contribute to what we call "mathematics." Such are not only those forms of practice arising directly from a socio-institutional world where one must do things to get promoted at a university, to get published by leading journals, and, generally, to gain recognition. As important and relevant those forms of practice may be, mathematical practices, as has been shown in this volume, also include the devices we employ to persuade one another. Questions of proof are thus also questions of practice, for example, whether proof uses forms of algorithms to convince other practitioners or not (see Azzouni's chapter below). Even what one might deem purely logical reasoning can be viewed in terms of mathematical practice (e.g., the use of counterfactuals in reasoning discussed in Baker's chapter below). So, from the start, one should expect a great variety of topics and focuses in each part of this entire work.

But this still does not explain what these might have to do with ontology – and, here, just as with practice, the problem is only complicated by the range of questions and themes subsumed under the name "ontology." I should say a word about that. The most basic motives of modern ontological investigations still exist as they did for Aristotle, even though Aristotle did not use the Greek-inspired word "ontology" and even though we do not necessarily accept his own ontological conclusions. Those motives are rooted in the questions of what is and of the categories that apply to what is. But the *way* one pursues these questions depends much on what one imagines one is looking for in the first place. This is no less true in the circumscribed field of mathematics nor is the point particularly modern. The treatment of mathematical ontology in the Platonic tradition, for example, where mathematical objects – triangles, spheres, and numbers – were universal things existing apart from anything that happened to be triangular or spherical or a pair, albeit, on the scale of being, intermediate between the objects which are the source of images and the pure ideas, the *eidē*, naturally gave its distinctive color to ontological investigations. And as one

moves through the spectrum, through nominalism which denies universal objects altogether, to a kind of physicalism, like that of Mill where mathematical statements refer to physical things and mathematical concepts are derived from perceptible experience, mathematical ontology becomes a different kind of investigation altogether. And there are others, for example, ontological investigations inspired by structural semiotics (see Roy Wagner's contribution in this volume). But despite all this diversity, we can say this. Adapting the title of Reuben Hersh's well-known book (Hersh 1998), what an ontological investigation has always asked, now and in the past, is what is it that mathematics is *really* about?

In answering that question, what distinguishes many modern investigations of ontology (and what made Hersh's book so interesting to so many) is precisely their emphasis on forms of practice, that is, on *what mathematicians actually do*. In other words, for the philosophy of practice, the question of what mathematics is about is precisely the question what is it that mathematicians are doing when they do those things one designates as mathematical. Contrary to the emphasis in the past, the philosophy of practice thus ostensibly shifts the question away from the question of mathematical objects as the main subject of ontological inquiry. But it is more subtle than that, for our very practice may require us to make ontological assumptions of the old type, make assumptions, among other things, about mathematical objects and their objecthood. On the other hand, it may still be true that the theories driving our practices are accepted because we make assumptions about the nature of mathematical entities. So, we cannot simply remove ontology from practice as a different can of worms. The two are entwined.

This very short introduction, accordingly, must say a bit more about how ontological investigations and questions of practice go together. We will give our direct attention to this in the first section. In the second section, we will bring in the next pole of this entire handbook, history of mathematics. How do ontology, practice, and history go together? Is theirs a forced marriage or one born in true love? That is, do they belong together in some very basic way? One main theme in Marco Panza's chapter is that, indeed, the philosophy of mathematical practice intersects with the history of mathematics *essentially*. And if the first section is persuasive that will also show that the history of mathematics intersects with ontological questions as well, specifically, that historical questions are very much about the ontological commitments of past mathematicians. Finally, in the last section, we will take up what might seem a very different theme, namely, how these things matter to mathematics education. This section is connected closely to the second section since mathematics education has taken an interest in the role of history of mathematics in mathematics education, and much insight can be gained by seeing the issues in relation to the ontology-practice-history triad. More generally, however, the discussion of education brings us back again to our leitmotif inspired by the title of Hersh's book, for how we teach mathematics and what we expect students to know are unavoidably connected to how we answer the questions what mathematics is really about and what it is we hope students will do when they really do mathematics.

2 Ontology and Mathematical Practice

If one accepts a Platonic position regarding mathematical ontology in its usual form (see Panza for a *less* usual version), or just that of a hardcore realist, the general connection between ontology and practice is not all that difficult to state. For since mathematical objects, according to this view, exist in a form that is wholly fixed and unchanging, mathematical practice must only be adapted to the task of drawing out their equally fixed and unchanging properties. Practice, in this setting, can change of course: it can expand, become more refined, or even change direction. However, such changes are governed, and their effectiveness is measured by the presumed unchanging character of mathematical objects. For example, the power of using complex analysis in number theory was established when it yielded a proof of the prime number theorem, that is, when it could be shown to shed light on a fundamental fact about the distribution of fundamental mathematical objects, prime numbers. This, granted, is in many ways an oversimplification: for example, one can wonder about the sense in which Hadamard and Vallée Poussin's proofs were viewed as deep precisely because they used complex numbers and Erdos and Selberg's later elementary proof, precisely because it did not. Still, the point is only that when objects like prime numbers and their properties are thought to be given and fixed, *practice is subordinated to object*.

Interestingly enough, one can argue that the view traditionally *opposing* Platonism, nominalism, also puts objects before practice in its own way. For just as Platonism takes universal abstract objects – the kinds of things we usually think of as mathematical objects – as real existing things, nominalism takes only the individual concrete objects before us as real – the kind of things we usually think of as things. But since nominalism does commit to these individual concrete objects, once again our practice becomes measured by what it does with respect to *these* things. Once again, there is a standard to which practice is subordinated. But, of course, nominalism as a philosophy of mathematics has great difficulties, and not the least because it is hard to say what mathematical practice really is about: what does it mean to say that a practice is mathematical when the best you can do to identify a mathematical thing as mathematical is by putting one's finger on a certain similarity between concrete individual objects (which is not too far from what Mill did)? It is very hard to avoid slipping into a kind of Platonism after all.

It must be pointed out that there are variants of nominalism in the philosophy of mathematics (see Bueno 2020). One comes out of the thought of Jody Azzouni (though it is not the main thrust of his chapter in this volume) and has come to be known as deflationary nominalism (2004). This does take mathematical discourse seriously, that is, it does not question that mathematical practice is about something. In particular, the claim is that one can use quantifiers such as $\forall$ and $\exists$ without insisting that they say "For all such [existing] things" or "There exists a such or such," that is, without committing oneself to a set of existing mathematical objects that one then surveys to see whether something is true or all of them or just some of them. In a way, the claim is saying that one can speak seriously of "all" or "some" without the addition of "of them." It must be said, however, that whether deflationary

nominalism truly does allow us to speak about mathematical truths literally without committing ourselves to the existence of real mathematical objects has been debated (see, for example, Kovacs 2019).

The general tenor of these arguments comes close to another variant of nominalism, one that also rejects the existence of abstract universal mathematical objects but accepts that it makes sense to speak mathematics. This is fictionalism. Fictionalism, faithful to its name, treats mathematics like a work of fiction. This does not mean that mathematics, according to this view, is something frivolous – a work of mathematics is as serious to the mathematician as *King Lear* is to a reader of Shakespeare. Just as "true" and serious things can be said about the fictional Lear, "true" and serious things can be said about sets, functions, and categories. Taking mathematical truths literally means, then, precisely that, *literally* as in literature. But even in literature, one does wonder how it is that fictions tell us something "true." Is it not because while the characters are invented they somehow address aspects of real people? Is there a parallel to mathematical fictions? That is to say, is there in fact a hidden commitment to an ontological claim about real objects or real relations that, in the end, makes the fiction true and useful to us? Distinguishing fictionalism from nominalism, where abstractions are also just convenient words having no ontological status, Bueno (2009) says:

> . . .fictionalism is an *agnostic* view; it doesn't state that mathematical objects don't exist. Rather, the issue of their existence is left open. Perhaps these objects exist, perhaps they don't. But, according to the fictionalist, we need not settle the issue to make sense of mathematics and mathematical practice. (p.63)

Bueno's point that fictionalism does not take an ontological stand one way or another goes farther than simply making ontology inessential for mathematical practice to proceed: by allowing mathematical practice to be free from an ontological domination, we can now shift our attention to mathematical practice as *primary* or at least be on an equal standing with ontology. This may not be the central issue for fictionalism as such, but it opens the way to a different kind of relationship between practice and ontology.

As we already remarked in the opening of this introduction, the shift towards practice as primary or at least not secondary in mathematical philosophy allows for a much richer relationship between what mathematicians do, the practice of mathematics, and the existence, characteristics, and properties of mathematical objects, that is, mathematical ontology. Rather than being subordinate to ontology or, alternatively, unaffected by ontology, practice now may have an active role in shaping an ontology or at least in choosing an ontology. One can think of this in terms of Quine's ontological commitment (e.g., Quine 1953) which makes our ontology in mathematics dependent on the requirements of a mathematical theory. Although, granted, Quine's original formulation of this emphasized more the ontology our use of logical quantifiers committed us to, we can look at the commitment in a more active way, that is, what we assume to be the case to *do* mathematics according to theory we have adopted – and we always do mathematics according

to *some* theoretical position. Those assumptions, however, may again be about what is a mathematical object. The difference is that we come to the question *from the position* of working according to a particular theory or according to a set of procedures that we view as valuable, fruitful, or conducive to knowledge – itself partly determined by our theoretical position. With regards to practice, the two important points are: (1) that adherence to a theory – as opposed to, say, belief in a theory – is part of what we mean by adherence to a set of practices and (2) adherence and commitment are actions rather than consequences of discovery, something we do, not something that has come to us in some way (though, admittedly, if it is something we have been taught, it may not strike us as subject to adherence or commitment).

Taking our commitments and ways of doing mathematics as formative of a mathematical ontology rather than simply the result of it, naturally, raises the problem of the objectivity of mathematics – what has always been thought of as the hallmark of mathematics. Objectivity is unambiguous from a Platonist perspective where mathematical objects exist unchanging in some extra-human world and are universally intelligible. But once they are placed squarely in a human world, must one write "true" with quotation marks as we did in our description of fictionalism above? That may be the case. Yet, "true" still does have some meaning as "true," albeit with a somewhat weaker sense than it does in a Platonist view. Byers' term "weak objectivity," which he discusses in his chapter below, is useful in this regard. He grants that "objectivity" requires independence from anything "merely subjective," personal prejudice or extra-mathematical cultural forces, religion, race, politics, etc. "Of course," he goes on to say, "some people consider mathematics itself to be a culture but within mathematics the criterion of independence from arbitrary opinion might serve as a minimal way to differentiate subjectivity and objectivity – we could call this *weak objectivity*" (Byers, in this volume, section 13). Weak objectivity allows mathematics both to be dependent on human thought and practice, thus weak, and yet not arbitrary, thus objective.

3 History of Mathematics, Practice, and Ontology

Granting that what mathematics is about is dependent on human thought and practice means that mathematics, in this sense, not only has a history, a chronology of discoveries and historical figures, but is itself also a historical subject. Understanding what mathematics is is understanding different modes of thought and different forms of practice. The idea of practice, in fact, embodies thought. This is made clear by Kitcher's definition of practice, which sees practice as a complex of five components: L – the language of the practice; M – the set of metamathematical views; Q – the set of accepted questions; R – accepted reasonings; and S – accepted statements (Kitcher 1984, pp.163–4). More than specific mathematical techniques or modes of argument that we simply use, we begin to see how mathematical practice also entails what we accept as legitimate ways in which we can *speak* about ideas in mathematics or about mathematics itself and, ultimately, how we *think* about mathematics. And since that changes and develops, mathematics is necessarily, to that

extent, a historical phenomenon. With practice understood this way, Kitcher goes on to say that "Mathematical knowledge develops through the rational modification of the mathematical practices" (p.165). But of course such modification happens from the inside, that is, within the context of practice. This is perhaps why Panza in his chapter below says that "More than having a history, mathematical activity *is (or generates)* a history [emphasis added]." Arguing for the essential connection between philosophy and history of mathematics (as did Kitcher), Panza accordingly says trenchantly that "the philosophy of mathematical practice is. . .the philosophy of an historical fact."

This essential connection, notwithstanding, one should not *identify* philosophy of mathematical practice and history of mathematics. This is particularly important with respect to ontology and mathematical practice. In their attempt to understand the mathematical practice of the past, which we now see includes mathematical thinking of the past, historians of mathematics must engage, as it were, in the very ontological commitments made by their historical subjects. Unlike philosophers of mathematics, they cannot stand outside those commitments. In order to understand Euclid, historians need to try and think like Euclid; in order to understand Monge or Möbius, historians must try and think like Monge or Möbius.

This is really the idea of *reenactment* which Collingwood identifies as distinguishing historical thought from other forms of scientific thought (see Collingwood 1992, part V). The nexus that leads Collingwood to this begins with the simple observation that the field of history, the occupation of historians, concerns the history of human affairs. From here, he points out that unlike natural sciences (even natural *history*!), the history of human affairs has an outside and an inside. The outside is observable and physical, the external facts of an event. "By the inside of an event," he says, "I mean that in it which can only be described in terms of thought" (Collingwood 1992, p.213). Collingwood certainly appreciates the outside and recognizes that that aspect of historical events is essential, but he emphasizes,

> [The historian's] work may begin by discovering the outside of an event, but it can never end there; he must always remember that the event was an action, and that his main task is to think himself into this action, to discern the thought of its agent. (p.213)

It is here (though not only here) that Collingwood says famously that "All history is the history of thought" (p.215). And so the job of historians is to rethink the thoughts of historical figures in the historians' own mind. Needless to say, Collingwood's idea of reenactment has been criticized on several fronts as a way of interpreting historical events. In the case of intellectual history, like the history of mathematics, rethinking the thoughts of the historical mathematician is also problematic, partly because our own ways of thinking, our own prejudices, as Gadamer would say, cannot be entirely put aside. That said, in intellectual history, thinking the thoughts of our subject is certainly what one must *try* to do. At very least, one must assume that our subjects' thoughts are different from ours so that we must suspend as much as possible thoughts that clearly belong to our own time; it may not be entirely possible, but it is also not impossible. To the extent that it is not impossible, we are able to learn

from history, and what we learn, according to Collingwood, is thus something about the powers and limitations of our own minds (see Collingwood 1992, p.218).

Whether or not we can truly understand the mathematics of the past, we can seriously *mis*understand the past if we do not enter into the ontological commitments of past mathematicians and suspending our own. It should be emphasized that misunderstanding the past is not the same as making claims that are "wrong," as if one were speaking only of "facts," for example, whether or not there was a red house on the corner 10 years ago or not. The whole question of "rightness" or "wrongness" is one very much connected to one's ontological commitment, for it depends very much on *what* one is truly talking *about*. To make this more concrete, let us consider a historical example in some detail: let us consider the place of ontological commitment and thus also of mathematical practice in reading a historical work, the *Conics* of Apollonius of Perga.

In a classic book on the history of mathematics, one that in many ways I like and find useful, Carl Boyer (1985) writes:

> Apollonius, like his predecessors, derived his curves from a cone in three-dimensional space, but he dispensed with the cone as promptly as possible. (p.164)
>
> . . .
>
> After Apollonius had derived from a stereometric consideration of the cone the basic relationships between what we should now call the plane coordinates of a point on the curve—given by the three equations $y^2=lx-b^2x^2/a^2$, $y^2=lx$, and $y^2=lx+b^2x^2/a^2$—he derived further properties from the plane equations without reference to the cone. (p.165)
>
> . . .
>
> . . .whereas today we invariably refer a conic to a pair of mutually perpendicular lines or axes, Apollonius generally used a pair of conjugate diameters as equivalents of oblique coordinate axes. (p.166).

Are these statements *wrong*? Suppose a student who understands conic sections and other curves to be defined by their equations came to her mathematics teacher and said, "I have found a wonderful geometrical visualization for the conic sections" or even "a geometric derivation of the curves and their properties" and then presented her teacher with something like Apollonius's *Conics*. What would we say? Would we say that, in fact, she got it wrong? We would have to check. We would first establish some basic rules: length is a number, or a symbol for a number, x or y; a rectangle or an area is a product of such numbers or symbols, xy or x^2 or y^2; an area taken a certain number of times, say, m, is mxy; a ratio is a fraction, x/y, and so on. One would have to look at the geometry, see that it is correct, and, with these rules at hand, that the geometrical statements lead to some form of the familiar equations and relations. One would have to admit that, in this sense, it is not "wrong" to say that the geometric picture is truly a visualization or derivation of the "true" relations.

What we want to say is that it is anachronistic, historically wrong. But what is the content of the anachronism? Surely it is not just that our student is, presumably, writing in English or, in any case, not in ancient Greek. Nor, allowing that she is writing in English, that she puts things in her own words, in her own forms of

English expression. But is she putting things in her own terms? For her, it may be that the algebraic expression xy is no different than the "rectangle contained by segments AB and BC." For her, these may well be perfectly acceptable statements, perfectly within the bounds of acceptable metamathematical assumptions, and so on. For her. But, for Apollonius – and, one assumes, for those with whom he shares his thoughts – in his own inner view of conic sections, our student's way of seeing conic sections may be utterly foreign and foreign because of the kinds of ontological commitments they respectively adopt.

The primacy of magnitude or number and the primacy of relation and the unhesitating willingness to see $x, y, xy, x^2 + ay^3$ as genuine objects to be manipulated no differently than 3, 4,and 5 – these are marks of mathematical practice since algebra assumed its place at the heart of the subject. In this regard, what Descartes writes towards the end of his 1628 *Regulae* (Descartes 1970) signals the revolution of analytic geometry as pointedly, if not more, than what he writes in *La Géométrie* written almost a decade later, namely, that the product ab can be written as a line or some extended magnitude and can be multiplied by another magnitude c to produce another magnitude, and, conversely, that a magnitude given as a line can be written as an area (Rule XVIII). Whether x is a line or an area is, for him, *only a matter of interpretation*. The shift away from what x and y are is even clearer earlier in the same work (Rule IV) where Descartes shows that the kind of mathematics he aims for, the *mathesis universalis*, considers only order and measurement (i.e., relation and magnitude) and "that it make no difference whether it be in numbers, figures, stars, sounds or any other object that the question of measurement arises" (Descartes 1970, p.13). For him – and for us – mathematics is not about those objects as such but about pure relations between magnitudes, the latter are, for us, the "true" relations.

The ancient mathematicians certainly did care whether one is speaking of numbers or figures or stars. Mathematics, for them, is about such things. In at least one instance, namely, in Diophantus's *Arithmetica*, there are symbols; however, they serve as placeholders – unknowns, "blanks to be fill" – or word abbreviations of operations or number combinations. This is not to belittle what Diophantus did. I only want to stress that he is still focused on concrete numbers rather than, to use Viète's expression, operations on "species of numbers" where x or y may be treated as "things" in themselves. The ancient mathematicians could not speak about an x or a y without saying what they were speaking about – a line, an area, a number. Even in the most abstract book of Euclid's *Elements*, Book V, about ratio and proportion, one always reasons about lines taken as magnitudes. Symbols, what there are of them, are never taken as objects. For this reason, J. Klein saw the concerns of the ancients as being explicitly ontological while those of the moderns (i.e., since Viète, roughly) are symbolic. Indeed, he goes farther and says: "From now on [i.e. after Viète] the fundamental *ontological* science of the ancients is replaced by a *symbolic* discipline whose ontological presuppositions are left unclarified" (Klein 1968, p.184, emphasis in the original).

The ontological status of the conic sections, for Apollonius, is in their being sections of a cone. Even if, as Boyer correctly points out, the cone largely vanishes

after Book I of Apollonius's *Conics*, that does not mean that the cone was somehow inessential in light of the "equations" that he "derives" from it. First of all, he does not dispense with the cone altogether: it reappears at the end of Book I and at the end of Book VI. Its reappearance at the end of Book I is significant for there he uses it to show how to construct a conic section, for it is not enough to say that the points satisfy a certain relation but that the curve arises from a cone. So the cone is there implicitly even when it does not appear explicitly. Indeed, it is for this reason that the entire work begins with the definition of a conic surface and cone and then launches into a "mini-treatise" on the cone and how it is sectioned (see Fried and Unguru 2001 for more details). Writers such as Boyer and Heath do not forget Apollonius's cone, but they trivialize it, for their own ontological commitment does not require that a curve come from a geometric situation but only that it represents an algebraic relation. Their misunderstanding of Apollonius is not a misunderstanding of the relations that they can derive from his geometry but of his own ontological commitments. And these commitments are part and parcel of his geometric way of doing mathematics. To understand historically is to see clearly that the way mathematicians have done mathematics in the past was not a matter of mere style or peculiarity of language but an expression of what mathematics was about for them: their practice – Apollonius's sectioning cones, for example – and their sense of mathematical ontology are inseparable components of their mathematical thinking.

4 Ontology, Practice, and Mathematics Education

Let us conclude this introduction to the section on ontology in the history and philosophy of mathematical practice by saying a few words about mathematics education. Indeed, should any of this matter to mathematics educators? I think it should. As mentioned at the outset, mathematics educators do have to ask themselves the ontological question: what is it that mathematics is about? After all, this is also a question that students ask. Students rarely understand the complexity of the question, and, sometimes this is so of their teachers as well.

On the other side, situating our own discussions about practice and ontology in an educational setting can put our own questions in a new light. In that connection, one recalls Dewey's remark towards the end of *Democracy and Education* (2004) that, "Education is the laboratory in which philosophical distinctions become concrete and are tested" (p.316). It is thus not by accident that Byers' discussion below about mathematics as process and creative rationality revolves around the learning of mathematics, that is, the coming to know mathematics.

For him, though, coming to know mathematics is not a purely epistemological issue but an ontological one: what mathematics is about, as he sees it, arises out of our doing mathematics and the subsequent reification of our activity. In other words, learning mathematics is creating mathematics; it is not merely having students adapt themselves to an already crystalized body of knowledge. Students make mathematics as mathematicians do, and that insight, Byers stresses, provides a common ground for educators and people who think about mathematics, mathematicians, to shed light on one another's concerns. As he puts it in part 4 of his paper:

> Though mathematicians and math educators do not normally communicate with one another because they live in different disciplinary compartments, educators are well placed to understand the difference between being content or process oriented. Educators and teachers need to focus on process because it is evident that learning is a process. Today, influenced by a view of knowledge as mere data, there is a tendency to think of learning as the accumulation of facts and techniques. But this is not what I mean by learning or doing mathematics and has little to do with becoming fluent with a particular mathematical world.

In a way, what Byers says about the focus on process and the way doing and creating mathematics run hand-in-hand is very much along the lines of what was known and much talked about in the 1990s in educational theory as radical constructivism – and, needless to say, mathematics education research was particularly influenced by it. Radical constructivism, according to Ernst von Glasersfeld (1989), whose name is associated with it, is grounded in Piaget's constructivist thought which, like Byers, sees process and particularly operations as primary. More distantly but surely, it is, he says rooted in Vico's eighteenth century thought which held that what we know is what we have made – and, for Vico, mathematics is no exception to this: "Geometrica demonstramus, quia facimus" ("We demonstrate geometry because we make it"), as Vico said in his address, *On the Study Methods of Our Time* (Vico, (1708)1990, p. 23), significantly a work reflecting Vico's philosophy in thoughts about education. Von Glasersfeld's reference to Vico, as his epigraph taken from Piaget and Garcia's *Psychogenesis and the History of Science* (1983), is telling, for Vico's idea that what we know is what we have made necessarily raises history to a high level as a form of knowledge, and Vico did just that. Byers too recognizes that reframing mathematics in terms of process, *doing* mathematics, makes considerations of history essential for understanding mathematics and the learning of mathematics.

Conversely, in trying to clarify what it meant to have an historical understanding of mathematics above, I too resorted to an educational context where a student presents an Apollonian geometrical development of conic sections to her teacher. The point was to show that the close interrelationship between practice and ontology and the kinds of ontological commitments that arise from it make statements about "rightness" and "wrongness" problematic when they refer to historical mathematics: one must take into consideration both the practices, for example, geometrical or algebraic practices, and the ontological commitments of the historical mathematicians. In a way, the lesson that ontology and practice cannot be separated is just a realization of the standard wisdom in all historical work that content cannot be separated from form.

5 Conclusion

Viewing mathematics from the perspective of practice and ontology – and, therefore, history – can certainly enlighten teachers and others who deal with mathematics as to what mathematics is "really about." This provides also a solid justification for bringing history of mathematics into the mathematics classroom (see Fried 2014

for the general issues involved). More often than not, however (luckily not always!), the justification is vitiated by the tendency to see history is only something to be *used* (Fried 2001), or, as Jankvist put it, treat history as a tool rather than a goal (2009). The problem with seeing history as a tool only is that when one asks what it is a tool for, one comes to a rather static view of mathematics with an unproblematized ontology: one has to teach the subject of quadratic equations in two unknowns – taken as an almost Platonic category – and then looks for any historical context which can be construed to be about this, for example, Apollonius's *Conics*. There are no equations in the *Conics*, but one can say they are there, *mutatis mutandis*. Using history in this way makes form independent of content, and it fails to recognize how practice is interconnected with ontological commitments: it certainly does not take into account ontological commitments of the past. This makes it bad history, but more importantly, by not taking into account ontological commitments of the past, we and our students may not be fully aware of our own ontological commitments and how those are interacting with our own mathematical practice. Taking history quite seriously, as Byers and Panza do in their essays, that is, *not* merely as a tool for something else but as an opportunity to explore the process of mathematics and what says about mathematical ontology, can inform mathematics education in ways that would make it deeper. Thinking about mathematics education and about what messages about mathematics we convey to students is also, as I have said, allows us a way of confronting the philosophy of mathematical practice and mathematical ontology.

Abstract

A new approach to informal rigorous mathematical proof is offered. To this end, algorithmic devices are characterized and their central role in mathematical proof delineated. It is then shown how all the puzzling aspects of mathematical proof, including its peculiar capacity to convince its practitioners, are explained by algorithmic devices. Diagrammatic reasoning is also characterized in terms of algorithmic devices, and the algorithmic device view of mathematical proof is compared to alternative construals of informal proof to show its superiority.

1 Mathematics Is Strange

A mere couple thousand years ago, mathematics seemed innocent enough. (At first glance, anyway.) You sketched out some fairly simple diagrams, and you talked them up in ancient Greek. You said things like, "look over here," "look at that," and then you drew a conclusion or two (Plato 1963). Somehow, nevertheless, it all amounted to something like nothing else we do – like nothing else we do *on Earth.* The conclusions drawn had an exactness impossible even by careful measurements (interior angles of triangles were proved to be *exactly* 180° – nothing slightly more or less, which is what always happened if, instead, the angles of a triangle were measured directly)[1]; furthermore, the results shown this way seemed to be necessarily true (they *couldn't be* otherwise), and so the process ("reasoning") by which these results were achieved seemed independent of our usual tools for learning about things – our senses. Equally odd was that these conclusions were often unexpected and sometimes undesirable. Many of them were results no one saw coming; some of them were even results that no one *liked* after they arrived – for example, the famous (and scandalous) fact that the length of the diagonal of a triangle isn't a ratio of the lengths of the adjacent sides of that triangle … from which it can be shown that $\sqrt{2}$ isn't rational.[2] Call this *the epistemic strangeness of mathematical proof.*

Philosophy was born, perhaps, from the desire to explain the weird and bizarre – less melodramatically, from the need to explain *odd cases.* This used to be called *wonder*, a "what on Earth is going on *here*?" Shortening a long descriptive history of (very ingenious) explanations of the epistemology of mathematical proof, many of them *supernatural* – such as mathematical proof being our recollection of eternal entities that we perceived directly in a previous life, or as involving innate ideas that have been stamped conveniently into our souls by God, or proofs being sequences of thoughts true by virtue of their conceptual structure alone (syllogistic sequences, "analytic truths"), or proofs as involving the addition of content from "intuition" ("synthetic a priori truths"), or proofs being lists of sentences true by the meanings of the words within them, etc. – a post-mid-twentieth-century conceptual revisiting of the artificial ("formal") languages that were invented by Frege (1879) at the end of

[1] Also *very* striking was that these exact results arise from methods applied to diagrams – compass and straightedge – that themselves don't intrinsically involve exact measurements: no ruler is used, for example.

[2] A rumor passed down from ancient Greek times is that the person who discovered this was *murdered.*

the nineteenth century seemed to *finally* offer a conclusive explanation. Derivations in such *artificial* languages are effectively recognizable patterns of reasoning.[3]

That is (and here's one sort of explanation gestured at in the last sentence above), if the many mathematical proofs in natural languages just *are* (disguised) derivations in artificial languages – if they're abbreviations of such derivations, for example – then this can explain all the odd epistemic qualities mathematical proofs in natural languages have. It can explain, for example, the impression of necessity: Our senses play only as much of a role as they seem to with ancient Greek diagrams (only enough to enable us to manipulate the language entities involved, and nothing more), and the results aren't necessary or eternal, but only as necessarily true as the premises the proofs start from. If logical inference is to be characterized as formal derivation in these artificial languages, then the epistemic qualities of mathematical proof become purely matters of logic. In particular, the strange unchanging and perfect eternal entities that Plato used to explain the apparent properties of mathematical results (exactness and necessity) are no longer needed: If an argument that mathematical entities exist is to be given, it can no longer arise via an inference to the best explanation for the epistemic qualities of mathematical proof; instead, it must result from the requirement, when applying mathematics to empirical science, that one necessarily uses phrases like "there are numbers. . .," coupled with the linguistic claim that such a phrase commits us to the existence of numbers.[4]

Call a *derivational account of informal rigorous mathematical proof*, any account that takes the epistemic qualities of ordinary mathematical proof to derive from a relationship (of some sort) between ordinary mathematical proofs and formal derivations in one or another (or a family) of artificial languages.

[3]I'm condensing some intellectual history here. "Effective recognizability" as relevant to an explanation for the epistemic strangeness of ordinary mathematical proof emerged after the discovery of formal languages (it emerged, perhaps, even some *decades* after the Church/Turing/Kleene discovery of the mathematical characterization of effective recognizability). The possible explanation Fregean languages initially seemed to offer for epistemic strangeness was instead a development of a much earlier view (one already in, to some extent, Descartes, and certainly in Leibniz) that mathematics is just "logic" *once all the missing inferential steps are explicitly given ("filled in") in the corresponding derivations.* There still is an issue, of course, about the epistemology of logical inference: how challenging this issue is corresponds to how much apparent mathematical content has been pressed into the "logical" principles. In any case, the explanation doesn't work because it has the same problems faced by *any* explanation of the epistemic properties of ordinary mathematical proofs in terms of their relations to derivations in artificial formalisms (see Sect. 3 below).

[4]That is, I'm describing proponents of what have come to be called *indispensability arguments.* There is a large contemporary literature on these arguments. For the version of them that influenced their recent application to mathematics, see Quine (1953). See Azzouni (2009a) for an indispensability argument with weak premises that establishes only the truth of applied mathematics and not the existence of mathematical *objects*; see Panza and Sereni (2015) for a categorization of the whole family of indispensability arguments according to the strength of the premises used in those arguments, and for a survey of this literature as of that date.

2 Effective Recognition Procedures

Before discussing the drawbacks of derivational accounts of mathematical proof, I should first discuss in more detail why formal derivations of formal languages seemed and continue to seem so illuminating about (or, at least relevant to) the epistemic properties of informal rigorous mathematical proof. The key point is that formal derivations come with *effective syntactic recognition procedures.* That is, anyone (including computers or mechanical calculating devices) can acquire a set of rules by which she or he or it can determine after a finite amount of time, *whether or not* a sequence of strings of vocabulary items is a proof. In describing these recognition procedures as "syntactic," I'm pointing out that a person can execute such a procedure successfully without knowing what the sentences "mean"; indeed, such syntactic recognition procedures don't require knowledge that what's being recognized are "sentences" of a language. So far, I've only mentioned well-known truisms about formal languages. I now compare natural languages with formal languages, and how they differ on the recognition procedures they come with. What I say next isn't quite as truistic; some of it is even controversial.

Natural languages also have recognition procedures. What's required of *every* language to begin with (ones we can *use*, anyway – one way or another) is that there be recognition procedures that enable the sorting of vocabulary tokens (the "alphabet") into type-classes. Vocabulary types are sensorily accessible classes of physical items, for example, the type of items, "e," that include those that occur in the paper you're reading. These may be electronically composed of pixels or instead they may be chemical stains on a background medium. We idealize these type-classes of *physical* vocabulary items by assuming that there is a decision procedure (looking "by eye"[5]) that determines what type-class *any* candidate physical item belongs to. Implicitly excluded (call these *exclusion idealizations*), therefore, are all those many physical tokens that can't be decided by eye because (among other things), they're too blurry or badly shaped. The very coherence of physically executing *any* algorithm (by humans, computers. . .) *requires* exclusion idealizations.[6]

Both natural languages and many formal languages – not all formal ones – have recognition procedures for primitive vocabulary. Consider now the recognition procedures for syntactic classes of items other than primitive vocabulary items – in particular, for sentences. The recognition procedures available for these syntactic classes of items of formal languages go beyond those of natural languages in two ways.

[5]"By eye" is metaphor; other human (or nonhuman) senses can be used instead of vision.

[6]This is true of physically real Turing machines: a written symbol in a cell that a Turing-machine head "scans" can't be so lightly printed that the Turing-machine head is unable to tell whether or not the cell is blank. At least when it comes to humans, these recognition procedures are extremely complex, neurophysiologically speaking. If one physically built such a thing, scanning could be designed to be mechanically quite simple, as it isn't for us. Even so, there would still be cases where the physical device failed to scan a cell successfully; this is a fact about any Turing machine that exists in space and time. Indeed, this is true of any actual calculating device whatsoever: there will always be "mishaps."

First, although we *can* assume that those competent in natural languages have (and use) recognition procedures for the sentences of those languages, we can't state these procedures explicitly.[7] We *can* state in mathematically precise ways the recognition procedures for the sentences of many formal languages – in particular, Frege's original language, and the many formal languages currently studied, including the first-order predicate calculus.[8] We can describe and mathematically study, of course, many formal languages – some with infinitely long sentences, but not those alone – that don't have recognition procedures for their sentences or even, say, for their primitive vocabulary (because the set of types of primitive vocabulary in a formal language can be infinite too).

Many formal languages have a second property that's often treated as a constitutive element of those languages. They can have syntactic-transition rules from sentences (of such-and-such syntactic forms) to sentences (of so-and-so forms), as well as *axioms*.[9] Consider the set of finite sequences of sentences of a formal language, where each sentence is either an *axiom* or follows from earlier sentences in the sequence by the application of a syntactic-transition rule to those earlier sentences. Call this a *derivation.* If there is a recognition procedure for the syntactic-transition rules, and for sentences, then there is a recognition procedure for the set of derivations. Call an *interpretation* of a formal language a function that takes all the sentences of a language to truth values (true or false), where the axioms are mapped to true, and so that the syntactic-transition rules take true sentences to true sentences.[10] A formal language (individuated to include axioms and syntactic-transition rules) is *consistent* if it has an interpretation; the foregoing stipulates soundness as a requirement of an interpretation.

The formal languages I've just finished describing are special insofar as the derivations in them have been characterized purely syntactically. This isn't the only possibility. The "semantics" of such languages – what the sentences mean – has been restricted to truth values that are assigned to sentences; but of course richer semantic characterizations of the sentences (and syntactic characterizations of other items of formal languages – predicates and names for example) can be given. The now-traditional way of doing so for classical languages is to supply a Tarskian model for a formal language, in which a domain of objects is assigned as the ranges of the

[7]It seems, and this is a typical assumption of Chomsky-influenced linguists, that competence in a natural language simply *is* the possession of a recognition procedure for its grammatically correct sentences. What such recognition procedures look like is a contested empirical question; it's clear, in any case, that we neither have conscious access to them – as individual users of natural languages (but only to, at best, some of their results when candidate sentences are presented to us) – nor do we, as a matter of linguistic science, know much about their properties (let alone what they are).

[8]Indeed, the grammars (syntax) of most of these languages are extremely simple – stated by a handful of easily understood rules.

[9]It's possible to drop axioms altogether; replace them with syntactic-transition rules from the empty set to sentences.

[10]I momentarily consider interpretations that are richer than the mere assignment of truth values to sentences – so this isn't a *definition* of "interpretation."

quantifiers, individuals from that domain are assigned to individual constants (names), and classes of *n*-tuples of objects from the domain are assigned to *n*-place predicates (Tarski 1933).[11] This isn't, of course, the only way to assign semantic properties to the sentences of formal languages. Regardless, semantic-transition rules can be formulated for formal languages (given one or another characterization of the semantic properties for the sentences of such a language), and a resulting notion of a derivation can depend on semantic properties of sentences instead of (or in addition to) the syntactic properties of such sentences. The resulting set of derivations will have a recognition procedure (or not) depending in part on whether there is a recognition procedure for the relevant semantic properties assigned to sentences.

It *seems*, as I mentioned, that semantic properties (of *some* sort) are intrinsically involved in informal rigorous mathematical proof. This empirical question is entangled in part with the broader empirical question of whether reasoning in natural languages is (purely) syntactic or not. Syllogisms are long-known examples of *bits* of natural-language reasoning that can be characterized syntactically. Nevertheless, it's not obvious that when nonprofessionals reason syllogistically that they are reasoning syntactically (i.e., independently of the perceived content of the sentences in such syllogisms).[12] It's also not obvious that reasoning doesn't occur purely syntactically in cases where it doesn't appear to: that depends on exactly what the grammar of natural languages turns out to be – what aspects of what (pretheoretically speaking) seem to be meaning properties of items of natural languages turn out to be such and which don't (anaphora, e.g., seems to be a syntactic matter in natural languages; so seem aspects of noun/verb agreement). In this respect, informal rigorous mathematical proof – inference steps in informal proofs – couched as they are in natural language, may also (or not) turn out to be based (at least some of the time) on meanings.

Regardless, we can now characterize the family of derivational accounts of informal rigorous mathematical proof with a little more precision. The idea is this: Informal rigorous mathematical proofs have the epistemic properties they have because there is a family of formal languages, where each informal proof is associated with a derivation or (possibly) a class of derivations (which may be from more than one formal language), and where the epistemic properties of informal rigorous mathematical proofs are explained by this association. For example (and, again, this crude example can't be right, but it illustrates the idea), any informal rigorous mathematical proof is an abbreviation of a particular derivation, and mathematicians (subconsciously) appreciate this fact.

[11]In nonclassical settings – for example, paraconsistent ones – generalizations of the Tarskian approach to model theory have been developed. So too, for intuitionism, multivalued logics, and other "logics."

[12]For reasons from the psychological literature to think otherwise, see Thompson et al. (2011).

3 Why Derivational Accounts of Mathematical Proof Don't Work

Mathematical proofs were expressed for centuries in natural languages – long before Frege's invention of artificial ones. And, despite the fertile infusion of formal tools into mathematics during the twentieth century – both as methods of proof but almost more importantly, as subject matters *of* mathematical study – mathematical practice continued and continues to occur in natural language.[13] We can ask why; and one straightforward answer places a heavy burden on derivational accounts of mathematical proof. This is that it's proofs, after all, in *natural languages* that convince mathematicians of the theorems that are established by these proofs. Furthermore, and this is an important datum too, it's *not* that mathematicians are convinced (finally) when these proofs are explicitly transliterated into their formal cousins. That, pretty much, never happens: "Oh wow, *now* I see why this is true." There would be no issue if the word "abbreviation" that I used in Sect. 1 was literal – that the version of the derivational account that worked was one where informal rigorous mathematical proofs were abbreviations of formal items – but if that were the case, then Frege's invention would not have been the original and amazingly creative invention it was.

It's important to realize that when I describe Frege's invention as that of an *artificial* language, I'm not exaggerating: he didn't (as a superficial glance might imply) lift out a couple of ordinary-language words or phrases, the German words or phrases for "and," "or," "there is," for example, along with a couple of syntactic rules of German and exhibit *them* as his invention. The syntax (and the semantics) of these artificial languages (i.e., what currently passes for "logic" in contemporary studies) is nothing like that of *any* natural language. Mathematical proof seems epistemically strange; but we can't explain that strangeness by treating mathematical practice as *actually occurring* in languages *that didn't exist* until (about) 1879. Explanations of mathematical practice have long trafficked in inferences to the best explanation of it being our sensitivity to supernatural entities of one sort of another – but perhaps this is really taking things too far.

[13]There is no book, no article, of mathematics that's entirely written in one or another formal language – not one in first-order logic, not one in any higher-order logic, not one in any of the numerous modal logics, etc. The proofs that occur in mathematical articles and books are rarely completely or even partially formalized; even in *logic* books and textbooks, completely formalized proofs occur only as *examples.* Frege, on the other hand, really intended his invention to replace then current mathematical *proof practices.* He saw ordinary language as flawed in a way that he took to create serious problems for mathematical proof. As the subsequent failure of mathematicians to adopt his formalism, or anyway, to switch to one or another formal language when doing mathematics shows, this is wrong. Exactly why it's wrong is one topic of this chapter.

Call *Phenomenology* the requirement that any derivational account explain why formal transcriptions of informal rigorous mathematical proofs don't ever have a property that the original informal rigorous mathematical proofs sometimes have: the property of inducing an experience of recognizing that this is a good proof – based (partially or sometimes entirely) on what the sentences of the proof *say.* It's important not to overstate the datum *Phenomenology* labels. The experience of (pretty much) any informal rigorous mathematical proof is that of *heterogeneous reasoning*: some inferential steps involve an "aha"-epiphany (Feferman 2012) that's one probable source of early modern philosophical views about the a priori; some, however, involve complex semantically obscure mechanical manipulations ("calculations") that are recognized to be valid manipulations because they follow rules that have been shown to be truth preserving (or that we've assumed are); some are taken on the authority of the author or as understood-to-be-background assumptions in the field; some involve significant and rich inferential moves (although this is often tacit, unexplored, and sometimes unrecognized); some are, strictly speaking, meta-proof considerations (e.g., "the other cases are the same"; "the indices on these operators are countable"). A new notion is required to enable the analysis of the heterogeneous nature of reasoning in ordinary rigorous mathematical proof – that of an *algorithmic device* (see Sect. 6 and later sections for discussion).[14]

Leaving the option of abbreviation aside, it wouldn't help if we instead hypothesized that natural-language proofs function successfully as epistemic guides for mathematicians by providing semantic or syntactic directions – "indications" of the corresponding formal proof – where such guidance is posited to be the psychological machinery (conscious or unconscious) by which mathematicians become convinced of theorems by the informal proofs they give. For, unfortunately for derivational accounts, nothing like this looks right either.[15] The initially slow evolution of specialized terminology in mathematics (the invention of place-holder Arabic numerals, algebraic notation, scientific notation, etc.), simultaneously accompanied with an evolving notion of "rigor," can give the impression that mathematical language slowly crawled over the eons toward an artificial-language endstate; Frege's "genius" was just to speed up the process by jump-starting the first of subsequently many such artificial languages in which the heretofore buried structure of mathematical proof could be finally fully exposed.

[14]A terminological conflict: Barwise (1993) uses the phrase "heterogeneous reasoning" to label formal-reasoning systems with both language-based inference patterns and diagrammatic ones. This usage has become influential in this literature. My usage (Azzouni 2017a, Sect. 9) describes something different: the character of typical informal rigorous mathematical proofs, as I describe them in the passage this footnote is appended to.

[15]What follows in the rest of this section is distilled from many discussions about mathematical proof over the past 20 years or so. Among the relevant papers and books are: Hersh (1997), Rav (1999), Azzouni (2006), Rav (2007), Azzouni (2009a, b), Lavor (2012), Tanswell (2015), and many others. Avigad (2019) and Hamami (2019), however, are recent attempts to defend derivational accounts. I discuss these a little in Sect. 15.

Several considerations, however, undercut this view of the terminological evolution of mathematics. There is, most importantly, that the phenomenology of mathematical proof – our experience of validity – doesn't accord with this picture. Mathematicians, pretty uniformly, learn to become convinced of the validity of mathematical proofs in ordinary language, by being trained to appreciate a certain degree of rigor in these proofs – *as they stand.* Such training does involve acquiring a facility with specialized terminology – a terminology that changes over time. Nevertheless, it's clear that the recognition of the validity of proofs often (but not always) involves the earlier mentioned "aha"-epiphany of recognizing that a certain result follows from others. This experience, as I've mentioned, *isn't* preserved when such proofs are transliterated into their purely formal versions but it does occur outside of mathematical practice; it's one we all feel with *certain* items of valid reasoning – for example, with (certain) instances of modus ponens, or when we see that from "All dogs are good pets," and "All good pets are creatures with large carbon footprints," it follows that "All dogs are creatures with large carbon footprints."[16]

That is, this "aha"-epiphany – among all of us – seems to *depend on the perceived meanings of the sentences in question and not on the syntactic properties of those sentences*; it doesn't occur when someone, applying rules, recognizes that a string of symbols follows by those rules from an earlier set of strings of symbols. This is why the formalization of an informal rigorous mathematical proof lacks the epistemic qualities that such proofs (sometimes) possess in ordinary language.[17] We no longer rely on our appreciation – whatever it comes to – of the meanings of the words and sentences we're using. We've switched to the mechanical manipulation of strings according to preassigned rules.

Phenomenology isn't the only challenging aspect of informal rigorous mathematical proof that derivational accounts face. Tanswell (2015, 297–298) requires of any derivational account that it explain (or at least be compatible with) five aspects of informal rigorous mathematical proof as it occurs in natural languages – what he calls *Rigor*, *Correctness*, *Agreement*, *Content*, and *Techniques*.

[16]This validity-experience, however, is frailer (at least in some cases) than many philosophers realize. It can be interfered with by our appreciation of the *content* of sentences – for example, by the conclusion striking us as implausible (see, e.g., Thompson et al. (2011), for studies that show this). I hypothesize that we need to consciously *learn* to distinguish intuitions of validity from intuitions of soundness – something that officially happens in classes on "critical thinking." The distinction, that is, isn't naturally made when we evaluate (in real time) arguments in day-to-day living: we're usually just interested in whether we should believe the conclusion on the basis of what we've heard.

[17]This will turn out to be an *overstatement.* More carefully: formalizations *sometimes* lack the epistemic qualities of the informal proofs they correspond to. They don't if they're *phenomenologically faithful.* See Sect. 13.

- *Rigor*: Informal mathematical proofs must meet conditions of rigor that (implicitly and explicitly) hold of informal proofs. This "rigor" seems different from the rigor exhibited by derivations (the latter is only that the derivation be fully written out according to formal rules). Notably, informal conditions on rigor change over time.
- *Correctness*: Mathematicians, perusing informal proofs, recognize them to be correct and incorrect intrinsically – "intrinsically" is understood here only in the sense that mathematicians don't recognize these properties of proofs by comparing them to formal transliterations.
- *Agreement*: Mathematicians, upon perusing candidate informal rigorous proofs, largely agree with one another about whether the proofs are suitably rigorous and on whether these proofs are correct or incorrect. Strikingly, mathematicians from different proof-practice backgrounds (e.g., classical as opposed to intuitionistic ones), and who understand the respective proof practices, agree on this as well. As noted earlier, this doesn't seem to occur by a process of recognizing the derivations (valid or invalid) that these proofs are associated with.
- *Content:* Any derivational explanation must explain how the perceived content of an informal rigorous mathematical proof – what the sentences of that proof are experienced to *say* – determines which formal proof(s) it indicates.
- *Techniques*: Any derivational account must explain the role of informal techniques of proof that aren't obvious transcriptions of formally licensed inference steps in a way that's compatible with the posited epistemic role of formal derivations.

Coupled with *Phenomenology*, these legitimate demands on any derivational explanation are a high bar to meet. I'm going to assume – within the framework of this chapter – that a derivational account that meets all of these demands adequately isn't possible.[18] I'm hardly alone in drawing this conclusion, of course; most of those philosophers who have studied informal rigorous mathematical proof agree. If so, epistemically speaking, informal rigorous mathematical proof is sui generis in one sense: we can't explain its epistemic properties in terms of formal derivations in

[18]See Azzouni (2017a) for discussion of how well various derivational accounts fare in meeting these demands – better than one might expect. I draw the conclusion, nevertheless, that (at the end of the day) they can't be met by such accounts. It's here, however, that issues about the large size of formal transcriptions (as compared to the original informal proofs) arise; this poses a challenge, for example, to the derivational account being able to explain *Agreement.* It's also here that issues arise about the explicit rules governing derivations (including ones of logic) needing to be treated as only tacitly available to ordinary mathematicians – and *essentially* tacit until the emergence of Frege's explicit characterization of logic.

artificial languages that the informal proofs supposedly correspond to.[19] We must look elsewhere for an explanation. I'll start my particular take on this by noting an historical irony. If I'm right about what I claim in the rest of this chapter, then Frege's invention is a garden path (or rabbit hole) – at least as far as the epistemology of mathematical proof is concerned. Formal languages, it turns out, have nothing directly to do with the epistemology of informal rigorous mathematical proof. Formal derivations play no more of a role in explaining the properties of ordinary mathematical proofs – implicitly or explicitly – than strange Platonic objects do.

4 Algorithms

I slightly overstated things in the concluding paragraph of the last section. The study of formal languages *isn't* a garden path or rabbit hole – not with respect to resolving the puzzles of informal rigorous mathematical proof (although it's still true, I'll argue, that formal languages – *directly* – play no role in the epistemology of mathematical proof). What turns out to be extremely important to resolving the puzzle of the epistemic strangeness of ordinary mathematical proof is something that the progenitors of formal logic (Frege, Russell, Hilbert,. . .) didn't anticipate. This is that the study of formal languages would directly lead, in the course of hardly more than a half century, to Gödel's incompleteness theorem (Gödel 1931), which, in turn, would enable (provably equivalent) characterizations of the crucial notion of an algorithm (Church 1936; Kleene 1936; Turing 1936). My claim: it's algorithms – and not formal languages (of any sort) – that are the key to understanding the

[19] I use a qualifier here ("in one sense") and earlier when characterizing Tanswell's correctness condition ("only in the sense that . . .") not to foreclose on the view, held by many of these philosophers (but not me) that sociological vectors explain *Agreement* among mathematicians – more generally, that what we may describe as conformity among mathematicians about mathematical proof is to be explained along the same lines that conformity in other areas (e.g., dietary practices) is to be explained. Although I think such sociological vectors do play a role in what mathematicians write down (for example) in giving an informal proof because what they assume as known by their colleagues shifts over time, or because of inertial effects in styles of proof, I don't think these factors play a very large role otherwise. Indeed, the centuries-long perception that mathematical reasoning is special in a way atypical of reasoning, generally, is a perception of its evident stability vis-à-vis social factors *in contrast to* reasoning elsewhere. (Manders (2008, 67) writes that "Euclid . . . Apollonius and Archimedes, are virtually without error: their every result has a counterpart in modern mathematics, even if subsumed in patterns of claims and proofs recognized much later." Absence of "error" is code for: successfully resists sociological intrusions.) In the course of this chapter I'll invoke intuitively effective recognition procedures that are available for (much of) informal rigorous mathematical proof to explain this. See what follows in the rest of this chapter.

epistemic strangeness of informal rigorous mathematical proof. Seeing exactly what the role of algorithms is in that practice will solve this ancient philosophical problem.[20]

I'll start with a brief description of Turing's well-known characterization of algorithms via what have come to be called (deterministic) *Turing machines*.[21] A Turing machine is an idealized rule-governed writing device – a Turing-machine head – located on an infinitely long tape that's divided into linearly ordered adjacent cells. Each cell is either blank ("□") or has a squiggle ("~") written on it. The Turing-machine head occupies one cell at a time; and it's governed by a finite number of rules which dictate all its possible actions and nonactions, depending on (a) what

[20]A *lecture*: Following the rhetorical lead of Lewis (1991, 57–59), many philosophers, for example, Burgess and Rosen (1997, 34) glibly laugh (or otherwise engage in something that's an approximation of laughter) at the idea that philosophers of mathematics can provide insights that might have an impact on the practice of mathematics or even yield something of interest to mathematicians. This purported laughter is silly. To make the first obvious point: philosophical concerns needn't be mathematical concerns. Sometimes, as with the philosophical puzzle of the epistemic strangeness of mathematical proof, this is because the philosophical wonder is *occasioned* by a specific practice, in this case, mathematical proof. What makes mathematical proof an occasion of philosophical concern is a *contrast fact:* mathematical proofs seem different from arguments in other areas of discourse as I indicated in the opening paragraphs of this chapter. Because the professional mathematician needn't be concerned with what arguments look like in other areas of discourse, and because she needn't be concerned with what it is that makes mathematical proofs different, these concerns, strictly speaking, aren't *mathematical* ones. So too, issues about mathematical ontology are philosophical concerns, not because the mathematicians' use of "there is" in their own practice should be challenged in some way, but because (again) it's a usage that offers puzzles across *all* discourses. (It can turn out for purely linguistic reasons that the mathematicians' use of "there is" is metaphor or a terminological extension of the ordinary phrase; discovering this and publicizing it isn't, by virtue of that, to necessarily recommend a revision in mathematical practice.) Recognizing philosophical puzzles and what's making them *philosophical* puzzles isn't easy – not even (apparently) for people who are officially philosophers.

But a rather more straightforward observation should be made, especially after noting one of Lewis' remarks, mentioned in the last paragraph (59) – italics his: "I'm moved to laughter at the thought of how *presumptuous* it would be to reject mathematics for philosophical reasons. . . . If [mathematicians] challenge [a philosopher's] credentials, will you boast of philosophy's other great discoveries: [and now Lewis gives a list of purportedly bizarre claims made by one philosopher or another]?" Response to Lewis: Classical physical theories of solar combustion were refutable in the late nineteenth century on the basis of the fossil record and other geological evidence: the Earth was clearly more long-lived – by a large magnitude of order – than the Sun could possibly be, given the then contemporary physics. Imagine a Lewis-style physicist snobbily turning his nose up at an argument (by a geologist, say) against classical physics *solely because* she's some upstart from outside a "genuine science" who dares challenge accepted physical theory. Alas (for such hierarchical views of knowledge gathering), that's how confirmation *works:* evidence for something can come from *anywhere* – even (dare I say it) from philosophy.

[21]Turing (1936, 118) uses the word "automatic." I should note that my presentation of Turing machines will be slightly eccentric in several ways – one of which is that I'll use meaningless symbols instead of the usual numerals "1" and/or "0." I do this to accentuate certain philosophical points about the interpretation of Turing formalisms that I subsequently make. Standard presentations of Turing machines, incidentally, are everywhere (especially in numerous textbooks) – if the reader wants or needs a (standard) refresher course in Turing-machine formalisms.

state S_i the machine head is in, and (b) what's written on the cell the machine head is located at. The machine head is capable of triple-actions. First, it erases/writes-in (or doesn't) the cell it's at, then it moves to the left/right (or doesn't), and then it shifts to a new state (or doesn't); what it does at any cell is dictated by the "state" it's currently in. Call the finite list of rules that describe what a Turing-machine head does, given the states $S_1, \ldots, S_n$ it's in, the *machine table* of that Turing-machine head. Let R mean, "move right," L mean "move left," and B mean "stay in place." Here is a sample machine table for a Turing-machine head with three states:

$$(S_1, \square) \hookrightarrow (\sim,L,S_1); (S_1, \sim) \hookrightarrow (\square,R,S_2);$$

$$(S_2, \square) \hookrightarrow (\sim,L,S_1); (S_2, \sim) \hookrightarrow (\sim,B,S_3)$$

This fully describes what this machine head will do, given its location on any cell, and it's being in any state. (I'll now individuate machine heads by the machine tables they obey.) The machine table reveals that if the machine head is in state S_1, and it's on a cell which is blank, it will write a "~" on that cell, move the left adjacent cell, and remain in S_1.[22] If this machine head is in state S_2 on a cell on which a "~" is written, it will leave the "~" in place, not move, and change from the state, S_2 to the state, S_3. There are no instructions for this machine head when it's in S_3; thus, the machine head will, as it's described, "halt."

Call any tape with a distribution of "~"s in its cells a *configuration.* Given a machine head located on a particular cell of that tape (what can be called a *Turing-head configuration*), call an *input* the configuration before the machine head initiates a finite sequence of actions; call the *output* the configuration that results after the machine head has completed a finite sequence of actions. Consider a set of Turing-head configurations, where the configurations are all different. Call this an *algorithmic operation* – that is, an algorithmic operation is a set of differing configurations, each of which has a Turing-machine head (with the same machine table) located on one cell of that configuration. Call the resulting modification by the actions of the machine head after a finite set of steps an *algorithmic calculation.* If the machine head halts, that's an *implementation* of the algorithmic operation.

I've deliberately described the operations of Turing machines as manipulating *meaningless* marks on tapes; consequently, the algorithmic operations (as just defined) are meaningless as well. They're open of course to being interpreted – and it's how widely they can be interpreted that makes the Turing-machine formalism so fundamental to our notion of calculational/effective processes (and, in particular, to the effective recognition procedures of formal languages that I described in earlier sections of this chapter). Let's make the (various) interpretations of Turing machines explicit. Consider a set of Turing-head configurations (consider, that is, an algorithmic operation). An *interpretation* of this algorithmic operation is a

[22]Sometimes, as I illustrated earlier, the machine head is described as "scanning" the cell it's located on. But this talk implicitly builds more machinery into the machine head than is needed.

mapping of its configurations to configurations of objects *along with* a mapping of its machine-head actions to corresponding actions on the corresponding configurations of objects.

Example: Identify "~" as the numeral "1" (interpret "~" as standing for the number 1). Next, single out a set of configurations that can, using this identification, represent the counting numbers (e.g., "~~~" is 3; "~~~~~~" is 6); indeed, single out a set of configurations that represent pairs of such counting numbers (e.g., "~~~□~~~~~~"). Consider the set of Turing-head configurations, where the Turing-machine head is located on the blank cell between strings of "~"s that represent these pairs of counting numbers. We can design a machine table (that halts with respect to these pairs) that can be proven to generate a single representation of a counting number that's the sum of any pair of numbers (represented by an initial pair of represented numbers in this set of Turing-head configurations); we can design a more complex machine table (that also halts with respect to these pairs) that can be proven to generate a single representation of a counting number that's the product of a pair of counting numbers represented by a Turing-head configuration in this set. These are typical exercises in any textbook on (or with chapters on) Turing machines.

Second example: Now consider a mapping of the same set of Turing-head configurations, not to numbers and operations on numbers (as just illustrated), but instead to bead configurations on a physical abacus,[23] and to (certain) physical operations of moving those beads. This is an interpretation of that set of Turing-head configurations too. For that matter, so is any mapping of that set of Turing-head configurations to any numerical representation of numbers (and manipulations of those representations). Interpretations of Turing-head configurations, that is, can be to notational objects or to worldly objects; correspondingly, the actions of a Turing-machine head can be interpreted as manipulations of Platonic *abstracta*, idealized operations on notional objects, or as (also idealized) physical actions on real objects.

The Turing-machine formalism (along with all interpretations of it) is unexpectedly robust along *several* dimensions. I'll discuss this in the rest of this section.

To begin with, describe as *Turing-machine formalisms,* a certain class of variations of the above description of Turing machines. For example, consider Turing-machine heads that scan more than one cell at a time – finitely many, let's say, or ones that can recognize more than one symbol in a cell, finitely many, let's say (or even countably many).[24] And now call *mechanical procedures* those sets of operations (on any collection of objects) that (as above) a Turing-machine formalism can be interpreted as. It has been proven, strikingly, that increasing the powers of a Turing machine in the above ways doesn't lead to an increase in the set of mechanical procedures that Turing machines (under an interpretation) can execute: these remain the same. It's furthermore quite striking what kinds of powers machine heads

[23]I'm going to be fairly spotty in describing abacuses; it's easy to find out about these things in articles in print and on the web.

[24]Consider, in particular, Gandy machines (see Gandy 1980).

must be granted in order to enable the class of mechanical procedures to become strictly larger than what can be managed by Turing machines. If, for example (Abramson 1971), "extended Turing machines" are stipulated that are able to write and read uncountably many symbols, the resulting class of mechanical procedures is strictly larger than those executable by conventional Turing machines. The class of mechanical procedures a "mechanical" device is capable of is strictly larger as well, if, unlike Turing-machine heads, it can complete infinitely many actions in finite amounts of time.[25] It appears that the notion of Turing-machine computability isn't only an upper limit on *human* computation (as Turing originally meant it to be) but also an upper limit on designed-machine (e.g., computer) computation – at least if the physical processes of our universe are what they appear to be.[26]

To continue the discussion of the robustness of the Turing-machine formalism, let's now (temporarily) restrict ourselves to interpretations of Turing-machine algorithms as computing operations on counting numbers. These numerical algorithms can be characterized in other mathematical ways – in terms of being definable from certain classes of functions for example.[27] These various characterizations have been proven to be equivalent to the set of Turing-machine algorithms (as defined above). With a little bit of argument (turning partly on the fact that any interpretation of a set of Turing-head configurations can be routed through an intermediate interpretation in terms of numbers), the same set of mechanical procedures is picked out by all of these characterizations.

Second, consider Church's thesis. (Or, alternatively described, the Church-Turing or the Turing-Church thesis.) A preliminary "intuitive" notion: call a function of the natural numbers an *intuitively effective function* if it's one that can be carried out by human(s) using pencil and paper. Church's thesis is: A function of the natural numbers can be calculated by an intuitively effective method if and only if it is computable by a Turing machine (subject to the above interpretations). "Intuitively effective," so described, *really is* an "intuitive" notion. The use of "intuitive" means various things to various philosophers and logicians[28] – but for current purposes it can be taken to indicate a hand-waving (unanalyzed and nonmathematical) characterization of an open-ended class of what strikes us as humanly possible calculations.

[25]See Copeland (2019) for further discussion and citations of the growing literature on this.

[26]All bets about this are off, of course, if the study of gravitational singularities and the like, where time – in particular – seems to have unexpected properties, allows the design (at least in principle) of devices that can complete infinitely many calculations in what amounts to finite amounts of time.

[27]In particular, the early publicized characterizations in terms of lambda-definable and recursive functions have been joined by further (provably equivalent) characterizations in terms of register machines, canonical and normal systems, combinatory definability, Markov algorithms, and others.

[28]Turing (1936, 135), notably, uses the word "intuition" in relation to his statement of the thesis, writing, that "no attempt has yet been made to show that the 'computable' numbers include all numbers which would naturally be regarded as computable. All arguments which can be given are bound to be, fundamentally, appeals to intuition, and for this reason rather unsatisfactory mathematically." Warning: "intuition," as used here – following Turing's usage – can be misleading. See the parenthetical remarks in footnote 114.

In mathematical practice (specifically, in the study of recursive functions and effective computability), Church's thesis is often used as a proof-shortcut, to avoid the tedium of exhibiting a Turing-computable function for an intuitively effectively calculable numerical function, for example, in Rogers (1967) where a numerical operation is described (or recognized) as humanly calculable and then via Church's thesis that operation is deduced to be Turing computable. The intuitive notion of an effective procedure is idealized in various ways. In particular, we imagine the humans doing these calculations as having sufficient time, tenacity, tools (pencils and paper), and abilities to continue the task (without errors) as long as needed for the particular algorithmic calculations involved. Call this a *persistence idealization*.[29]

A way of attempting to *prove* – in the (informal rigorous mathematical sense) Church's thesis is to argue that the hand-waving ("intuitive") description of an intuitively effective procedure can be characterized by (is coextensive with) a mathematical characterization (of some sort), and then use that characterization to prove Church's thesis. There are several versions of this strategy. Kripke's (2013) version relies on "Hilbert's thesis":

> Every (human) computation can be formalized as a valid deduction couched in the language of first-order predicate calculus with identity.

"Human computation," however, as used here, is every bit an intuitive notion as "intuitively effective method"; thus, crucially, Hilbert's thesis relies (as Church's thesis does) on an identification of an "intuitive" notion with a mathematically precise notion – namely (using my terminology) an identification of "humanly computational" with "derivable in the language of the first-order predicate calculus with identity." The reason that these empirical theses are needed is because a branch of (pure) mathematics, algorithm theory, is being applied empirically to human (and machine) computation. It's *always* an empirical question (a "thesis," if you will)

[29]Here's a generalization of "intuitively effective numerical function" – beyond cases of numerical functions – to any method whatsoever (I'm borrowing this formulation from Copeland (2019)):
M is an intuitively effective method if:

1. *M* is set out in terms of a finite number of exact instructions (each instruction is expressed in a finite number of symbols);
2. *M* will, if carried out without error, produce the desired result in a finite number of steps;
3. *M* can (in practice or in principle) be carried out by a human being unaided by any machinery except pencil and paper;
4. *M* demands no insight, intuition, or ingenuity, on the part of the human being carrying out the method.

I treat the above description as allowing that the instructions in question can be written in a natural language. I also take it to be topic-neutral: *M* can be a method that's applied to anything whatsoever. (I'm not claiming this is intended – or not intended – by Copeland.) I'll take up the topic neutrality of the intuitive notion explicitly in Sect. 5.

whether or not a branch of pure mathematics can be applied successfully to the entirety of an empirical domain that we try to apply it to.[30]

In any case, there is a related family of equally intuitive theses sometimes described as Church's thesis, and sometimes distinguished from it (see Copeland (2019) on this). Consider, in particular, the "maximality thesis": All functions that can be generated by machines (working in accordance with a finite program of instructions) are computable by intuitively effective methods (Gandy 1980). An argument deriving this thesis about "machines" is, in my view, possible along the lines I indicated in the material footnote 26 is appended to; I won't pursue this any further now. In any case, evidence for Church's thesis (and its relatives) continues to accrue by the explicit exhibition of particular Turing algorithms (directly or through equivalences) as able to execute specific intuitively effective procedures and those that machines (of various sorts) carry out. This, as I indicated, is a different dimension along which the applications of Turing-machine formalisms are robust.

There is yet a third dimension, along which Turing-machine formalisms, treated as characterizations of mechanical calculability, have proven strikingly robust. It's one already indicated by a central aspect of the proof of Gödel's incompleteness theorem – that it turns on a reinterpretation of computable functions of number theory as functions of the syntax of a language. This *hints* of the vast potentiality for the interpretations of algorithmic operations – a vast potentiality that's being executed (as I write) by developments in computer technology. For intuitively effective procedures are undertaken by humans on all sorts of objects (real and unreal) in all sorts of ways that are only slowly being interpreted in what amounts to Turing-machine formalisms – for example, a robotic hand picking up a paper cup without crushing it, or all the numerous (and increasingly realistic) video and virtual-reality games and films.

5 Recognition Procedures in Games

I turn now to developing a point I made in footnote 29 – that intuitively effective methods can be stated in ordinary language. Indeed, this is why Hilbert's and Church's theses are "intuitive" theses: ordinary reasoning and ordinary effective methods are invariably couched in natural language – and transliterating such to a formal setting is precisely to apply a branch of pure mathematics to these natural-language activities (as I indicated at the end of the last section). Coupling this point with the observations in the last section about interpreting algorithmic operations allows us to see how ubiquitous intuitively effective methods are in our lives. Let's start with a discussion of games. Many games (although not all games) essentially involve elements and configurations of elements with recognition procedures that players (and observers) of those games rely on. Chess, and other board games, are

[30] I return to a discussion of Church's thesis, generalizations of Hilbert's thesis and formal systems, in Sect. 15.

obvious cases (and so are card games). Recognition procedures are required to distinguish chess pieces, the squares on the board (and the spatial properties of those squares, e.g., adjacency relations), and to recognize admissible moves. Other games, despite involving "luck," are similar. In many board games, the pieces are moved along designed paths after throwing dice (to determine the acceptable number of steps a piece can take). Without appropriately designed intuitively effective recognition procedures, these games would be impossible to play – we'd be fighting over whether an *appropriate* move had been made; we'd even be fighting over what move, exactly, we were fighting over.[31]

Central to the Turing-machine formalism seems to be – to use a commonly used distinction – that the algorithms it describes are digital and not analog. Mechanically recognizable operations are required to be step-by-step ones, where each step is clearly distinguishable from every other step. Turing (1936, 136) makes this point explicitly:

> We may suppose that there is a bound B to the number of symbols or squares which the computer [human calculator] can observe at one moment. If he wishes to observe more, he must use successive observations. We will also suppose that the number of states of mind which need be taken into account is finite. The reasons for this are of the same character as those which restrict the number of symbols. If we admitted an infinity of states of mind, some of them will be "arbitrarily close" and will be confused.[32]

And yet, many games, unlike the board games I've just described, seem to be intrinsically analog: they take place physically, and continuously, in space and time. Such games, baseball for example, appear nevertheless to have intuitively effective recognition procedures. One is inclined (at first glance) to say, of any set of admissible moves in this game – hitting a pitcher's throw appropriately with a bat – that it's an *infinite* set of possible moves. After all, the variations of possible movements in space and time are infinite. How then can a game like baseball – and any game that similarly takes place continuously in space and time – be amenable to an application of the Turing formalism?

There are at least two mistakes involved in this line of thought. The first is that a certain kind of idealization – central to all algorithms that humans actually carry out but eliminated (usually) from presentations of such algorithms – is being

[31]It's been claimed against me (more than once) that games are at best analogous to Turing-definable algorithms because games have rules that are underspecified or even inconsistent. Tanswell (forthcoming) thinks these defects "are ironed out by social features of game-playing." It's, however, a ubiquitous feature of algorithms that there is no general test for "bugs" (there is no general test for inconsistency): they must be *spot-corrected* when discovered. In no significant sense does this introduce "social determinants" into practices, like games, that are governed by algorithms.

[32]Notice that the generalizations of Turing's apparatus (e.g., in Abramson 1971) mentioned in Sect. 3 are ones that shift to an essentially transhuman framework in exactly the ways that Turing rules out. For example, that the purported human can distinguish uncountably many symbols or that the purported human can complete an infinite number of discrete actions in a finite amount of time.

misdescribed. Consider the symbol "~" that I characterized all Turing-machine heads as using. Were an actual machine involved, the tokens of this symbol would be a somewhat ill-defined set of physical items – ill-defined because no matter how we designed Turing-machine heads, they will fail to sort *every* otherwise scannable physical token into one or the other class. In the same way, a chess piece can be placed on a chess board so that it's unclear (to the humans playing the game) which of two neighboring squares it's on. For that matter, the borders between squares on a chess board can be fuzzy, or badly designed chess pieces are possible where humans easily confuse the pawns with kings. We idealize the items and configurations of the items in a game (using what I called in Sect. 2 "exclusion idealization") by simply treating such confusing items as not occurring in the game. A last example is the intuitively effective recognition procedures associated with the derivations of formal languages: these too, when the derivations in such formal languages are actual ones that people (or computers) are constructing, involve exclusion idealizations so that by assumption there are no tokens so badly written that the recognition procedure for those derivations can't be executed.

The second mistake is to take the apparent analogness of our experience of space and time (and, in particular, our actions and perceptions of such actions) at face value. Given a finite amount of space and time, and a possible action across that space (and in that time), such as waving a hand – despite the impression otherwise, we *cannot* distinguish infinitely many variations of movements. What we are capable of seeing, and distinguishing, are only finitely many such movements. This is true of anything we can do in space and time. The analog appearance of our own behavior (or its appearance in the behavior of others), consequently, is an illusion.[33]

This shows that that the appearance of analog practices in such games doesn't belie an application of a generalized Church-Turing thesis to them: The intuitively effective recognition procedures that such games exhibit can be taken to be ones amenable to the Turing notion of algorithmic calculations.

The other crucial point that games illustrate in abundance are intuitively effective recognition procedures that are written in *natural* languages. We can use Hilbert's thesis, if we wish, to draw the conclusion that these can be formalized – indeed, to draw the conclusion that these games, in their entirety, can be formalized. And by this, I mean, transliterations to language-based formal systems.[34] Several connected points must be made about this, however. Our grasp of the intuitively effective recognition procedures used in such games – intuitively effective recognition procedures that children grasp – are ones *grasped directly,* and not via an implicit

[33]See Azzouni (2017a), especially Sect. 3, on this. To show the amenability of these games to Turing formalisms, in my view, it must be shown that the intuitively effective recognition procedures at work in these cases involve an unseen grid-structure as the field against which the admissible moves in these games are being evaluated. The details are in the article just cited.

[34]"Formal" systems, as I illustrate in Sect. 8, can be diagrammatic as well as language based.

(psychological) application of Hilbert's thesis. The neurophysiological/psychological facts that underlie these capacities are ones to be explained (that *are* being explained) in terms of visual-system capacities, saliencies, and the like. Our abilities to physically navigate our world are what underwrite the intuitively effective recognition procedures used in games. This is one reason, among others, why these recognition procedures are only partially described by the "rules" that officially govern such games. Usually taken for granted, and left unmentioned, are the physical details of the elements of such games (e.g., baseballs) that are often only partially specified in terms that explain the successful use of recognition procedures during these games; usually, tokens of them are simply exhibited. The same is true of the primitive alphabet for formal systems. These are, in practice, just listed – that is, the intuitively effective recognition procedures are *assumed* – using tokens, for example: the constants, a_1, a_2, a_3..., the individual variables, x_1, x_2,..., etc. I'll label these, in Sect. 13, *embodied algorithms*, and say a bit more about them then.

When, however, such games are transliterated entirely to language-based systems, the idealized physical properties of the objects and configurations of them that are *used* by the intuitively effective recognition procedures associated with those games must be treated as part of the subject matter to be described; they must be explicitly characterized and treated axiomatically. This is because language-based formal systems use only intuitively effective recognition procedures for distinguishing items of an alphabet: we're required only to see (by "eye") linear concatenation relations between tokens, to be able to distinguish the distinct primitive vocabulary tokens, one from another, and to be able to recognize which they belong to.[35] So, since the other intuitively effective recognition procedures, the ones that enable us to recognize the relations among the chess-board squares, are set aside, these relations must be explicitly described by terms that are axiomatized and treated as governing the "pieces on squares." (I'll say more about this in the next section.)

I turn now to making points about ordinary rigorous mathematical proof that are analogous to those that I've just made about games. Just like a certain subfamily of games, ordinary rigorous mathematical proof involves numerous intuitively effective recognition procedures that mathematicians grasp directly and not via formal transcriptions of those procedures into the medium of formal languages. This is why the derivations occurring in the family of artificial languages that are studied by logicians are irrelevant to the epistemic properties of ordinary mathematical proof. In going forward, I assume a generalized version of the Church-Turing thesis: I assume that all intuitively effective procedures *are* Turing computable.

[35]The other sorts of linear syntactic-relation patterns we – or some of us, anyway – "just see" are helpful but not required by most linear alphabet formal systems we study.

6 Language-Based Algorithmic Systems and Algorithmic Devices

Straightforward examples of language-based algorithmic systems are *axiom systems.* These have been studied extensively. A primitive vocabulary is given and syntactic rules for constructing well-formed expressions, including sentences, are defined. On this basis, in turn, a subset of the sentences are singled out as axioms, the finite sequences of sentences that are *acceptable derivations* are defined, and finally, the theorems (the sentences that appear on any line of an acceptable derivation) are defined as well. All of these have intuitively effective recognition procedures in the ways described earlier – the definitions I've just alluded to are designed to enable these intuitively effective recognition procedures to piggyback on earlier ones (e.g., the intuitively effective recognition procedure for theorems is designed on the basis of the one for acceptable derivations). Intuitively effective recognition procedures in formal systems are nested on one another in the way that the intuitively effective recognition procedures for primitive vocabulary, sentences, acceptable derivations, and theorems are nested here.

Example (Church's P_1)[36]: The primitive vocabulary are parentheses, (,), a two-place sentential connective, $\supset$, a one-place sentential connective, $\neg$, and an infinite list of sentential variables, p, q, r, s, p_1, q_1, r_1, s_1, p_2, q_2, ….[37] All and only the sentences are defined like so: the sentential variables are sentences; if P and Q are sentences, then $\neg$P and (P $\supset$ Q) are sentences. The axioms are: $(p \supset (q \supset p))$, $((s \supset (p \supset q)) \supset ((s \supset p) \supset (s \supset q)))$, and $(\neg\neg p \supset p)$. The syntactic-transition rules are two (I use the symbol "$\vdash$" to indicate syntactic transitions): For all sentences, P and Q, P, (P $\supset$ Q) $\vdash$ Q; if b is a sentential variable that appears in P and if P* is the sentence that results from the substitution everywhere in P by a sentence Q, then P $\vdash$ P*. A derivation is a finite sequence of sentences where each sentence is either an axiom or follows from earlier sentences in the sequence by a syntactic-transition rule.[38]

There are two ways to think about syntactic-transition rules. One is to think of them as structuring every *acceptable derivation:* each sentence in an acceptable derivation is either an axiom or follows from earlier sentences in that derivation by a syntactic-transition rule. The other is to think of them as methods of generating acceptable derivations from other acceptable derivations. Given any acceptable derivation, we can generate a new (augmented) acceptable derivation by introducing a new last sentence that is either an axiom or a sentence that follows from sentences in the original derivation by a syntactic-transition rule.

[36]From Church (1956, 78), I've modified P_1 by introducing an abbreviation that Church (1956, 78) gives later.

[37]Notice that there is an implicit intuitively effective recognition procedure in place for these, turning on an antecedent intuitively effective recognition procedure that's available for numerals.

[38]This apparently austere system is equivalent (via definitions) to the full two-valued classical sentential calculus with all definable (two-valued) connectives.

The point I want to stress about the intuitively effective recognition procedure for derivations in this example (and this is typical of many axiom systems) is that this recognition procedure directly operates in terms of the intuitively effective recognition procedures for whole sentences and not via any intuitively effective recognition procedures on the elements that such sentences are composed of. The intuitively effective recognition procedure for whole sentences of course depends on intuitively effective recognition procedures for the primitive alphabet – as I noted earlier. I'm here stressing a different point, however: Syntactic-transition rules are possible that rely not on whole sentences but instead directly rely on certain expressions *in* those whole sentences. Consider the alternative algorithmic formal system in the next example.

Second example: Same as the previous example, except that there are no axioms, and in addition to the two syntactic-transition rules given in that example, we have three additional syntactic-transition rules. For any sentences P and Q,

$$Q \vdash (P \supset Q);$$
$$(S \supset (P \supset Q)) \vdash ((S \supset P) \supset (S \supset Q))$$
$$\neg\neg P \vdash P.$$

The first two syntactic-transition rules are focused on the connective, $\supset$; the third focuses on the connective $\neg$; it's the occurrence of these connectives in certain syntactically indicated locations in sentences that license these syntactic transitions. In this sense these syntactic-transition rules are centered on a particular syntactic element and not on the sentence the element occurs in. For any expression e, call such syntactic-transition rules *e-centered syntactic-transition rules.* This characterization can be generalized to families of expressions E. Consider, for example, those Peano syntactic-transition rules that are E-centered on the constant 0 and the successor function′.[39]

Now consider an expression e and a language (*any* language, natural or otherwise) in which e appears. I call any set of e-centered syntactic-transition rules an *algorithmic device.*

The individuation conditions on algorithmic devices are importantly weak. Apart from the fact that the above definition allows algorithmic devices to be nested within one another, it's not required of an expression e governed by a set of e-centered syntactic-transition rules that constitutes an algorithmic device A that it be *fully* governed by those syntactic-transition rules. In the second example, just above, both $\neg$ and $\supset$ are governed by the original two syntactic-transition rules as well as by the new ones I then introduced. So too, an expression e, in a formal system, can be governed both by e-centered syntactic-transition rules and other syntactic-transitions rules (e.g., axioms) which aren't e-centered.

[39]For that matter, consider Church's P_1. This is an E-centered algorithmic device, where $E = \{\supset, \neg\}$.

The conditions on something being an algorithmic device are weak in a second sense. Although I've introduced the notion with respect to language-based formal systems, such devices can (and do) occur elsewhere. They show up, specifically, in natural languages and, indeed, they show up everywhere in mathematical practice, as it occurs in natural languages (as I'll indicate in the sections to follow). But, for the moment, consider the old philosophical example, "bachelor," where the meaning of this word is stipulated to mean: unmarried male. We have, according to this aspect of the meaning of the word, the following syntactic-transition rule P |- P*, where P* results from P by zero or more replacements of "bachelor" with "unmarried male."[40] More generally, the meanings of words can be taken (in some cases) to license syntactic-transition rules in arguments. This is compatible with those meanings being governed by other conditions – sufficient-condition application rules of some sort (for example) – which don't involve syntactic-transition rules.

So notice: consider any expression that seems governed by a small set of meaning-transitions (or meaning postulates) that enable the recognition of a class of truths or inferences containing that expression. Such a set of meaning-transitions is a kind of algorithmic device – not by any means the only kind of algorithmic device, of course. And notice, as well, that any expression that's so governed is usually governed by all sorts of other conditions too – both generalizations that involve many other words, and more restricted conditions that govern that expression along with others. The last point to stress is that it's come to be recognized that natural-language expressions – that we otherwise understand the meanings of – don't usually have definitions (necessary and sufficient conditions in terms of other expressions). They have, at best, some necessary conditions and some sufficient conditions. Some of these are encapsulated in the conditions of an algorithmic device; but others may be an implicit (or explicit) understanding of patterns of things we apply such expressions to (e.g., all blue things).

One thing – when studying logic – that makes "Gentzen" or "natural deduction" rules more user-friendly than axiom systems is that in this respect they're modeled on our impression of the meanings of natural-language expressions. We experience the natural-language meanings of expressions as localized to (and due to) those very expressions. This is why, say, a characterization of the "meaning" of the truth-function "&" like so:

$$p\&q \vdash p,$$
$$p, q \vdash p\&q,$$

seems to capture via the *meaning* of "&" the logical properties of "&" – as it operates in derivations of sentences from other sentences.

[40]The syntactic rule must be finessed to avoid counterexamples involving expressions like "Bachelor Buttons," which is the name of a flower. (Sadly, "Unmarried Male Buttons" isn't the name of that flower – or, I think, any flower.) I skip this.

For current purposes, the importance of algorithmic devices is that such items – focused on new expressions or, as it were, modifications of devices already governing old expressions – can be added to any language (formal or otherwise, one that already has one or another proof or derivation system, or one without) so long as the expressions the added devices are focused on (still) syntactically fit in with that language. For example, natural languages have noun phrases, verb phrases, and the like. If the new terms an algorithmic device is focused on are actual noun phrases or verb phrases, all that's required of them is that they operate syntactically (outside the confines of the application of the algorithmic device itself) like other noun or verb phrases already in the language – in particular, as these occur in natural-language sentences.[41]

7 Some Observations About Algorithmic Devices, Conceptual Engineering, Synchronistic Effects, and Imperatives

Imagine a natural language in which we have in place intuitively effective procedures for recognizing some instances of "Q follows from P" facts. Or, imagine that the methods we have aren't intuitively effective. The introduction of algorithmic devices can augment, make easier, or even introduce (to begin with, that is) an intuitively effective recognition procedure for a class of "Q follows from P" facts. Some algorithmic devices (or, sometimes, some transitions of configurations licensed by the device – see Sect. 9) should be seen, essentially, as "black boxes": sentences P, Q, and R (say) are transformed (by an algorithmic procedure) into notational or physical items that the device can operate on; after it does so, the resulting item(s) are transformed (by another algorithmic procedure) back into a sentence, S say. We then draw the conclusion, on the basis of this, that: "S follows from P, Q and R." In other cases, the connections between natural-language words – nouns and verb phrases, etc. – and the inner workings of the algorithmic device are more intimate (as it were). We can describe the transitions of the device in terms of transitions between sentences. The algorithmic devices I'll go on to discuss later will exemplify these differences.

A familiar first illustration: consider the numeral expressions of a natural language ("one," "two," . . ., "eleven," "twelve," . . .). These appear in natural-language sentences as both noun phrases ("one is less than two") and adjectivally ("There are six apples in Granok's basket"). Consider the introduction of a notational calculational device that provides shortcuts – indeed a *method* – for adding (Arabic notation

[41]This introduction of terminology into natural language – grafted from an algorithmic device – needn't be restricted to nouns and verb phrases. Whole sentences possessing what otherwise amounts to an alien grammar are introduced as *idioms* – whole syntactically-unparseable blocks with meanings. This is how – for example – those interpreted sentences of a formal language, untranslatable into natural language, are nevertheless expressed there. (Consider, e.g., those first-order sentences with long sequences of quantifiers that have no syntactic cousins in natural language.) I can't get any further into this now.

and the tableau layout for addition that utilizes, e.g., the base 10 properties of that notation). The inference of "There are seventeen apples in both Mordesh's basket and Granok's basket" from "There are seven apples in Mordesh's basket" and "There are ten apples in Granok's basket" is licensed by this calculational device.

In cases where there is already an antecedent proof or derivation practice, augmenting that practice with an algorithmic device in this way can induce far-reaching global effects on what can be proved or derived. A melodramatic example is when the supplementation of an already in-place derivation system with a new algorithmic device renders the augmented class of derivations trivial: *everything* can then be shown. But, there are many less melodramatic, indeed *routine,* cases.

Describe the introduction of an algorithmic device A into a language – formal or otherwise – with an already-present derivation/proof practice as *syntactically conservative* if, given an augmented derivation/proof D* of a sentence S, there is an antecedent derivation/proof D of S.[42] Often – very often – the addition of an algorithmic device into an already-present proof practice *isn't* syntactically conservative.[43] Failures of syntactic conservativeness – which, with regard to proof, are *successes* not failures – are nevertheless surprising because of our (always in place) local expectations about the noneffects of words (and the rules governing those words) on sentences in which those words don't appear. We don't expect that the introduction of a set of concepts that aren't "about" a subject area can induce new implications that are *purely* about that subject area.

An illustratively surprising result of this sort (Harris 1982) in a purely logical setting is that if we have an antecedent formal language governed by intuitionistic connectives, and we add classical negation (without placing syntactic restrictions on where that negation can appear), so that the system now has both syntactically unrestricted intuitionistic and classical negations, all the *other* connectives become classical. In particular, results like $(((p \supset q) \supset p) \supset p)$ – Peirce's law – and $((p \supset q) \vee (q \supset p))$, as well as (in the predicate calculus – here, let "$(p \Leftrightarrow q)$" stand for "$(p \supset q)$ & $(q \supset p)$"), $((\mathrm{F} \vee \forall x\mathrm{G}x) \Leftrightarrow \forall x(\mathrm{F} \vee \mathrm{G}x))$ and $((\mathrm{F} \supset \exists x\mathrm{G}x) \Leftrightarrow \exists x(\mathrm{F} \supset \mathrm{G}x))$ can now be shown. None of these are intuitionistically valid. This happens *precisely* because these results can be shown via the newly introduced classical negation and they suffice to render "$\supset$," and the other heretofore intuitionistic connectives, classical. This phenomenon is *typical* in

[42]Notice that built into this definition is that the sentence S doesn't contain any *new* terminology. Not required (and in fact rarely available) is that, given a syntactically conservative augmented derivation/proof of a result, a derivation/proof of that result using the original methods can be *easily* shown. In practice, mathematicians are drawn to augmenting their methods when that enables them to easily show new results – regardless of whether those results can be shown with great difficulty or at all by methods they already have. (Indeed, the question of whether or not innovations are conservative or not in the above sense was rarely entertained until modern times. I say "rarely" because, actually, I know of no cases where it *was* entertained – but I hesitate to be definitive about this. In the case of complex numbers or infinitesimals, the worries were ontological, not proof-theoretical – for example, are these weird numbers real or *imaginary?*)

[43]Or, more commonly, no one knows.

mathematics – it's one reason why pure mathematics is so interesting: new concepts introduced into a subject area yield surprising and unexpected results about the antecedent concepts that don't (or don't seem to) follow from reasoning about the antecedent concepts alone.[44] The phenomenon, I should stress, shows up in natural languages too – even in those cases where our concepts are governed (rather weakly) by meaning conditions alone.[45] Call these *synchronistic effects*. Lesson: synchronistic effects are everywhere in mathematics, and, as well, everywhere in our inference practices *outside* mathematics.[46]

Algorithmic devices, as I've described them, are very flexible in two senses. Consider a device that's centered on a set of concepts (terms), c_1, c_2, etc. – for example, a set of natural-language numerals (finite or not). The scope and effects of any such algorithmic device centered on $\{c_1, c_2, \ldots\}$ can be changed by (i) supplementing or changing its rules directly, and apart from this (ii) by introducing other algorithmic devices that are also centered on $\{c_1, c_2, \ldots\}$, on different terms, or both. The usual (informal) impression that there are specific concepts (e.g., the counting numbers) associated with these terms, and that they have certain fixed meanings is usually unaffected by these supplementations of and to algorithmic devices (again, consider the case of counting numbers) which aren't seen as changing their meanings.[47] Strikingly, as I mentioned earlier, the distinction between such

[44]See Azzouni (2000), where I discuss this phenomenon in relation to "relevance intuitions" and recommend it as a crucial element of the intrinsic interestingness of (pure) mathematics.

[45]Example? Consider a natural language in which the set of natural-language numerals is finite.

[46]The label "synchronistic" in "synchronistic effects" is meant to stress not so much simultaneous impact as (apparently) unrelated impact. Field-style nominalist programs, incidentally, are motivated by the (false) belief that the impact of applied mathematics to empirical topic areas can be shorn of synchronistic effects – and that, indeed, this is a *virtue* of mathematical applications. It's neither a virtue nor is it even possible. Because of synchronistic effects, the introduction of new mathematics to an antecedent subject area (mathematical or otherwise) always yields *surprises* – ones in the empirical case that are open to empirical refutation. That is, we can learn that a branch of mathematics should *not* be so-applied empirically. See Detlefsen (2008) for a discussion of the historically long and influential requirement – proponents include notables such as Aristotle and Bolzano – that epistemically good mathematical proofs should be pure (not involve alien or incongruous notions). See the discussion of the work of the mathematician Brunfiel, in Hafner and Mancosu (2008), who insists on pure proofs, and the discussion of Hilbert's analysis of Desargue's theorem in Hallett (2008). Notice what the purity requirement entails, with respect to incomplete axiomatizations. We must replace the proofs using the "alien" vocabulary with ones totally in the language of the unaugmented system. Why assume that the new axioms – in the familiar vocabulary – will be easy to find or that the resulting proofs will be particularly attractive – in *any* sense, other than in the sense of the sheer absence of alien vocabulary?

[47]One source (perhaps *the* source) of the relative insensitivity of meaning intuitions to changes in what I shortly call inferential scope is that such intuitions – especially in the mathematical case – are ontologically focused: the number words, for example, are experienced as referring to particular objects with such and such properties. Therefore, the embedding of such number-words (and rules governing them) into a context with other words (governed by different rules) is seen as simply the putting of numbers – counting numbers, say – into a context with other objects (e.g., rational numbers) which leaves the properties of the counting numbers unchanged. This (falsely – by means of a kind of use/mention error coupled with some sort of intrinsic-property confusion) gives the impression that doing so will be (inferentially) conservative.

supplementations enabling easier and/or quicker proofs (e.g., calculations) and those supplementations introducing new results that can't be shown otherwise, wasn't made – until modern times – except insofar as it was recognized that a change to an algorithmic device or the introduction of a new one into a practice could render the whole thing inconsistent.

Call the *inferential scope* of an expression, or of the concept associated with that expression, the set of truths *intuitive-effectively* determinable by the collection of inferential tools available to practitioners at a time (by "inferential tools," I mean, for example, licenses to infer based on meanings, such as "B is a brown house" implies "the outside of B is brown," logical principles, if any, algorithmic devices, if any, etc.).[48]

The heart and soul (as it were) of *conceptual engineering* in mathematics occurs via the development and/or supplementation of informal rigorous algorithmic devices. One important lesson: Most of the literature on conceptual engineering focuses on meaning and meaning change, and on issues of definition.[49] But "meaning" so-called and definitions – even in mathematics – are (largely) red herrings. I've already explained in the last few previous paragraphs why meaning is a red herring. Here's why definitions are too. Definitions are *local* in the following sense: they provide necessary and sufficient conditions for an expression *in terms of other expressions*.[50] In this way the inferential scope of a defined expression is linked to the inferential scopes of the other expressions occurring in the definition. But these, as I've illustrated, are always directly open to shifts in referential scope – even by the introduction of new expressions governed by new algorithmic devices, and so *that's* where the engineering action is.

Let me summarize this way: The contours of our concepts are always inferentially specified by our actual (intuitively effective) inferential tools; that is, the scopes of these concepts change as we change the tools we use to determine the truths that the expressions corresponding to these concepts occur in. *This* is conceptual engineering. Much of it is invisible to us because we understand our concepts and corresponding expressions *not* to change in their meanings even when the actual contours of their inferential scopes shift drastically.

I turn now to an important symptom of the presence of algorithmic devices in informal rigorous mathematical proof. Tanswell (forthcoming) has noticed that

[48]I do *not* mean, notably, *intuitive-ineffective* semantic determinations of classes of truths, such as "intended models" or intuitively ineffective "tools" such as validity defined in second-order terms using "standard semantics" – these truths are *not* intuitively effectively determinable.

[49]See, e.g., Cappellan (2018), Tanswell (2018). My work on this topic doesn't so focus. See, e.g., Azzouni (2006).

[50]Thus, definitions can range from the apparently trivial ("a triangle is anything that's a triangle") to the relatively "deep" – where the impression of depth arises from how significant or illuminating the expressions being used in the definition appear to be: in every case, trivial or not, a definition gives "necessary and sufficient conditions."

imperatives occur a lot in mathematics.[51] Indeed, the form of many informal rigorous mathematical proofs is that of *recipe-instructions,* of the form: Do *U*; do *V*; notice *W*; and then notice *X*.[52] Often, imperatives occur seamlessly with indicatives in a proof, as in the example of a proof from Rudin (1970, 357) that Tanswell (forthcoming) quotes (I've changed some of the lettering in what follows):

> Theorem: If A is a commutative complex algebra with unit, every proper ideal of A is contained in a maximal ideal. If, in addition, A is a Banach algebra, every maximal ideal of A is closed.
>
> Proof: The first part is an almost immediate consequence of the Hausdorff maximality principle (and holds in any commutative ring with unit). Let I be a proper ideal of A. Partially order the collection $\mathfrak{R}$ of all proper ideals of A which contain I (by set inclusion), and let M be the union of the ideals in some maximal linearly ordered subcollection $\wp$ of $\mathfrak{R}$. Then M is an ideal (being the union of a linearly ordered collection of ideals), $I \supset M$, and $M \neq A$, since no member of $\mathfrak{R}$ contains the unit of A. The maximality of $\wp$ implies that M is a maximal ideal of A.

Tanswell (forthcoming) suggests that the practice of using imperatives is *so* ubiquitous – especially in the context of diagrammatic proofs – that it requires a view of mathematics that centralizes imperatives. (He calls it the *recipe model of proofs*.) The first point to make is that – syntactically speaking, at least – the presence of imperatives is a relatively shallow matter. They can always be replaced with "if . . . then" indicative-locutions. This can be seen already in the above quotation, in which the imperatives may be naturally rewritten like so:

> If the collection $\mathfrak{R}$ of all proper ideals of A which contain I (by set inclusion), is partially ordered, and if M is the union of the ideals in some maximal linearly ordered subcollection $\wp$ of $\mathfrak{R}$, then M is an ideal (being the union of a linearly ordered collection of ideals), $I \subset M$, and $M \neq A$, since no member of $\mathfrak{R}$ contains the unit of A.

I described imperative-to-indicative translations as relatively shallow (grammatical) matters. Someone may resist this characterization for the following reason. Consider a (cooking) recipe Tanswell (forthcoming) gives:

1. Preheat the oven to 170°/gas.
2. Peel the bananas and lay them in a snug-fitting heatproof dish. Finely grate the orange zest and put aside, then halve and squeeze over the [bananas the] juice of 1½ oranges.
3. Drizzle with the honey and sprinkle over 2 teaspoons of the cinnamon, then roast in the oven for around 20 minutes, or until golden and soft, then set aside to cool.
4. Place the bananas and their syrup in a blender, then blitz with the milk and yoghurt.

[51] Indeed, several philosophers of mathematics have noticed and stressed the use of action terminology in mathematics. Larvor (2012) and De Toffoli and Giardino (2015) are three. They think its presence is significant for philosophically understanding informal rigorous mathematical proof. I disagree – what follows indicates why.

[52] Permissions seem to come up as well. See the discussion of the postulates of Euclidean geometry forthcoming in Sect. 11.

5. Add in a handful of the zest, the juice of the remaining orange half, a pinch of sea salt and the rest of the cinnamon, then churn in an ice-cream machine. If you don't have one, freeze the mixture in a suitable container for about 3 hours; every hour, take it out, whip with a whisk, then return to the freezer.
6. Serve in bowls with a scattering of orange zest and a fine grating of dark chocolate.

This can be rewritten, letting "(*n*)" stand for what follows each numeral *n* in the above list of commands:

If you (1), you (2), you (3), you (4), you (5), then you can (6).

Or we can introduce a stylized list (corresponding to how recipes are given):
If you:

(1),
(2),
(3),
(4),
(5),
then you can (6).

Rewriting Tanswell's recipe in indicatives, that is, reads as naturally as a list of commands does, but comes across a bit long-winded because (grammatically speaking), we can give ("bark out") commands, one after the other, in single sentences, just as in recipes; but we can't do the same with the list of "if" conditions followed by a "then" conclusion. The use of commands in recipes, however, is a mere stylistic fact about how recipes are given in cookbooks; it may even be due to the fact that a complex set of conditions are more easily surveyable if they're broken up into single sentences, and so one naturally puts them into command-form even though in no real sense is a recipe a list of *commands*. One can certainly imagine a different recipe-tradition, where recipes are instead given as predictions of what will happen under certain circumstances. In such cases, "if" conditions would be written, stylistically, as single sentences. Indeed, it can be argued, as I just have, that – semantically – that's what recipes actually are: they're predictions. (Consider the old organized-crime joke: *B*: Do this or a horse's head in your bed tomorrow morning. *C*: You're telling me what to do. *B*: No, I'm not; I'm predicting the future here.)

This point aside, algorithms (as I indicated in Sect. 4) are very naturally couched in terms of commands; machine tables look like lists of commands. It should be no surprise, therefore, that if an algorithmic device is (implicitly or explicitly) present, that presence will be usually – if not invariably – syntactically marked by imperatives.[53]

[53]That said, as Transwell's quotation from Rudin (1970) shows, and as many of the examples from De Toffoli and Giardino (2015) also illustrate, sometimes instructions on how to manipulate notation are ontologically disguised as descriptions of actions on *abstracta*. Again, a motivation for this may be that it's easier to understand single sentences (in command form) than it is to understand long "if, if, . . . if, then" sentences. In addition, it should be noted, this is an illustration of the ubiquitous use/mention conflations that occur everywhere in mathematics – right from Euclid's work on, as I illustrate in Sect. 11.

We do many things with the sentences of the natural languages we speak; in particular (and perhaps fundamentally), we express our thoughts and describe states of affairs; neither of these uses of language directly involve inference or inferential devices. The focus in this chapter is what we do with language entities by the machinery of intuitively effective inferential tools: these license the expression (speaking, writing) of certain language entities given the expression of other language entities – often sentences from sentences, but this isn't just a matter of sentences. In any case, we carry out such inferences in ways that (sometimes) phenomenologically appear rule-governed. Central examples – the ones under study here – are some of the cases where the process of inferring one sentence from another is seen as the antecedents semantically implying the consequents. These goings from one item of language to others are syntactic *functions* (their *domains* are pieces of language which they map to other pieces of language – what's described as their *ranges*). There are, of course, many ways we go from one sentence (or piece of language, words, for example) to others – other than by inference. In any case, in the foregoing, I've been focusing on syntactic functions – and in particular, on syntactic functions from sentences to sentences that have intuitively effective recognition procedures. Call these *syntactic algorithmic functions*; call the particular syntactic algorithmic functions that (at least in part) govern inference *inferential algorithmic functions*.

It should be obvious by this point in the chapter that an inferential algorithmic function can occur in a language or context that hasn't (or doesn't appear to have) other inferential algorithmic functions. Indeed, it's possible for there to be an E-centered algorithmic device in a language that has no other inferential algorithmic functions. Return, for example, to the case of categorical syllogisms, and consider the expressions, "all," "no," "not," etc. that occur in such syllogisms; let these expressions be our family E, and let the syntactic method(s) of recognizing valid syllogisms be the algorithmic device in question. Recall that I mentioned (in Sect. 2, footnote 12) that – empirically speaking – we don't know whether natural-language reasoners actually use the intuitively effective syntactic recognition procedures (that are in principle) available to determine when they're faced with a valid syllogism. Imagine, however, natural-language reasoners who *do* use an intuitively effective recognition procedure for categorical syllogisms, but who are otherwise unable to reason effectively. Imagine, that is, that these language users have no intuitively effective recognition procedures for inference patterns *other than* the one they use for categorical syllogisms. Such language-users – even if they have languages that otherwise are as rich as natural languages – can't *reason* except via categorical syllogisms. I hypothesize that such reasoners would strike us as strangely unable to grasp certain things that strike the rest of us as "obvious."[54]

[54]This is because, as we now understand, syllogistic reasoning is quite restricted in its inferential scope. However, an important cost in understanding "logic" more broadly is the loss of something that was (tacitly) assumed about reasoning until modern times – that there are *decision* procedures for recognizing validities and contradictions, and indeed (this was believed by Hume), except for issues of length, they're trivial ones.

I define an *algorithmic inferential system* as one in which *all* the inferential functions have intuitively effective syntactic recognition procedures. A first-order language which is Gödel-complete is one where the *semantic* implication function for the sentences of that language is coextensive with an intuitively effective syntactic recognition inference procedure. A higher-order language, with a model theory (an interpretation), according to which its syntactic deduction rules are Gödel-complete (Henkin models, as they're called), also has a semantic implication function that's coextensive with an intuitively effective syntactic recognition procedure. A higher-order language, however, which (relative to what's described as "standard model theory") is Gödel-incomplete, is one where the implication relation lacks *any* intuitively effective recognition procedure, let alone a syntactic one.[55]

8 Diagram-Based Formal Systems; Shin's Venn-II

As the discussion of games in Sect. 5 illustrated, just as we manipulate pieces of language (using intuitively effective recognition procedures), we can manipulate pieces of *anything* using intuitively effective recognition procedures. And similarly, there are functions, and indeed algorithmic functions, with domains (and ranges) governing some of the ways that we manipulate *things* – be those things baseballs, chess pieces, robotic hand-movements, items of notation, etc. Call a *context* the set of objects (and configurations of objects) that a set of algorithmic functions is defined on. A context can be the context of an algorithmic system or of an algorithmic device.

Diagram-tokens are a kind of object and so diagrammatic algorithmic systems and diagrammatic algorithmic devices are subcollections of object-based algorithmic systems and object-based algorithmic devices.[56] Examples of diagrammatic devices are Euler and Venn diagrams (as introduced originally by Euler and Venn), Euclidean diagrams, as practiced by ancient Greek mathematicians, and so on; examples of object-based algorithmic devices are physical tools like abacuses, various mechanical calculating devices, etc.

The "formal" in "formal language-based algorithmic system" conveys that the system in question is mathematically *fully-explicit* – in particular, the primitive vocabulary is given, and the rest of its syntax is explicitly defined on that basis (regardless of

[55]See Van Benthem and Doets (1983) for details. Notice that the absence of intuitively effective recognition procedures for sentence-functions turns on those functions being characterized in some other manner – as I suggested, for example, semantically. This will be significant for the later discussion of mathematics because, unlike games, the items in mathematics – ordinary-language sentences, sentences containing specialized terminology, and algorithmic devices (diagrammatic and otherwise) – are usually (explicitly and implicitly) interpreted. See what follows on this, but especially Sect. 10.

[56]Actually, all notation-tokens are, in this sense, objects (or, in the case of utterances, events). Nevertheless, I'll continue to distinguish between algorithmic devices using what I call objects – and here I'll be alluding to devices like abacuses (but also computers) – and those based in notation that we manipulate, such as diagrams.

whether certain kinds of syntactic items, like sentences, are, as a result, intuitive-effectively recognizable). Call a *language-based formal system* one that defines all syntactic objects in terms of the primitive vocabulary and (one-dimensional) concatenation alone. Nothing, in principle, prevents *equally formal* systems being based on syntactic constructions *other than* one-dimensional concatenation, for example, adjacency constructions in two or three dimensions (what we might call "higher-dimensional concatenation").[57] Call such systems *formal diagrammatic systems.* As with language-based formal systems, some of these formal diagrammatic systems are algorithmic and some aren't. [58]

My use of the distinction between one and higher-dimensional syntactic (concatenation) relations to distinguish non-diagrammatic from diagrammatic formal systems may seem obviously wrong – especially to those who are familiar with Shin's (1994, chap. 6) discussion of the distinction between diagrammatic and non-diagrammatic representation, as well as Giaquinto's (2007) discussion of this. Giaquinto focuses on whether conventions or resemblances are being utilized to determine interpretations – and to what degree; Shin focuses on whether new syntactic devices are introduced by a system of representation – ones that require conventions to use.

Apart from this, it may seem clear (to the reader) that a representation of individuals sitting between one another in space by locating their names one-dimensionally on a line, so as to imitate their relative spatial locations, is diagrammatic (Shin (1994, 156) – despite being one-dimensional – and it may seem, by contrast that the integral notation of the calculus, for example:

[57]I claim, but won't argue here – see Azzouni (2017a) – that if the resulting syntactic classes of items (sentences or admissible diagrams, and syntactically defined parts of these) are to be intuitive-effectively recognizable then there must be an implicit grid – in one, two or three dimensions – that the primitive items appear in; the syntactically defined items must be various (intuitive-effectively recognizable) classes of distributions of the primitive vocabulary across the grid. One approach to this places a lower-limit on the size of the areas of the cells of the grid; in one-dimensional concatenation systems (the ones we are most familiar with – alphabet systems), this is done, typically, by choosing a specific *font* for (all of) the primitive vocabulary items that appear in the (implicitly present and implicitly sized) cells. Underlying grid-frameworks aren't always explicit – they're not in Miller's (2007) Euclidean diagrammatic system FG, but they're made explicit in Mumma's Euclidean system Eu by means of arrays, which are the official backgrounds against which diagrams appear (see, e.g., Mumma 2010). I discuss these two formal diagrammatic systems in more detail in Sect. 11.

[58]I claim (see my comments on Feferman (2012) in Sect. 5 of Azzouni 2017a) that there are *two* diagrammatic systems in play in the proof of the Schröder-Bernstein theorem. One isn't algorithmic because one diagram that's alluded to in the proof is *actually* infinite. This diagram isn't *used* by mathematicians but only referred to. There is another diagram – a series of diagrams, actually – that are unbounded in size (although none of them are actually infinite). A finite number of these *are* used in the proof, and the pertinent properties of these diagrams are intuitive-effectively recognizable. There are many such examples of what should be called two-tiered diagrammatic proofs (the proof used to show what's called "Koch's snowflake" is another), ones which induce a structured semantics where the diagrams actually used by mathematicians belong to an algorithmic system but such diagrams are interpreted as referring to actually infinite diagrams in a system that isn't algorithmic; in turn, these actually infinite diagrams are interpreted as standing for functions (and sets) of various sorts. I can't get any further into this now.

$$\left[\int_0^{2\pi}\int_0^{\infty} e^{-r^2} r\, dr\, d\theta\right]^{1/2}$$

isn't diagrammatic, despite being two-dimensional (neither, one might think, is Frege's two-dimensional notation diagrammatic).[59] I'm tabling further discussion of this until Sects. 13 and 14 because it involves subtle complications involving the interpretation of diagrams; both Shin and Giaquinto's approaches to the diagrammatic/language-based distinction, that is, involve interpretations of diagrams and sentences. Restricting myself solely to dimensional considerations as they play out syntactically yields a rough-and-ready distinction between notations it's important to explore. (Whether it tracks the actual intuitive distinction between diagrams and items that aren't diagrams is relatively unimportant.) I'll consider – at the end of Sect. 14 – whether a principled distinction is available that's more in accord with intuitions about when a representational system is diagrammatic or not diagrammatic. I'll there suggest that the question isn't semantic as it, perhaps, appears to be, but is best taken to be a psychological one that requires empirical study to resolve.

In the rest of this section, meanwhile, I'll illustrate a fully-explicit formal diagrammatic algorithmic system: Shin's (1994) algorithmic system Venn-II. "Fully-explicit" means here that the diagrammatic system is as syntactically explicit (as mathematically explicit) as any typical interpreted language-based formal language. In the section that follows, I'll consider what stands in (in informal settings) for the semantic apparatus that's used to characterize formal systems – for example, model theory. After that, I'll consider some specific cases of algorithmic devices that don't occur in formal algorithmic systems – although they can be embedded in them (this is described in Sect. 12); included among these cases are those where algorithmic devices occur in natural languages; this is what happens in ordinary mathematical practice. One important case is the (ancient) use of Euclidean diagrams – where the details of the practice are somewhat controversial and complicated.

Venn-II, as Shin's choice of nomenclature partially indicates, is a formalization of Euler/Venn/Pierce diagrams.[60] The primitive vocabulary (Shin (1994, 115) calls them "primitive objects") are closed curves, rectangles, complete shadings of

[59]Interestingly, Giaquinto (2008a, 39) suggests matrices provide "a significant example of visual operations on symbol displays. . .." These strike me, on the contrary, as involving "visual operations" to exactly the same extent that one-dimensional catenation systems do – that is, only adjacency is involved and nothing more (e.g., part/whole spatial perceptions *aren't* involved, nor do other perceptual powers for recognizing two-dimensional visual patterns – that don't directly involve adjacency – seem involved: recall how one multiplies and add matrices). In any case, the difference between one and two dimensions looks significant to other philosophers even if (according to me) they misdescribe its import.

[60]Shin (1994) presents two formal diagram systems. Venn-I corresponds to categorical-syllogism reasoning; Venn-II is an expansion of Venn-I to a formal diagrammatic system that she proves is equivalent in expressive strength to a version of first-order monadic logic (one in which the empty set can be a model). There are other formalizations of these diagrams and various formalizations of extensions of them as well. One interesting extension are "spider diagrams" – see Howse et al. (2005) and, more recently, Stapleton et al. (2013), where there are references to earlier work.

(certain) spatial regions, and the diagrammatic elements, ⊗ and —, that appear within those regions. Well-formed diagrams are defined in terms of these elements (116), and persistence and exclusion idealizations are introduced so that we're presumed able to intuitive-effectively recognize (distinguish between) distinct diagrams containing any finite number of closed curves $C_1, \ldots, C_n$ contained properly within any number of rectangles (connected by lines), where, for any rectangle, containing a subset of these curves, $C_{i+1}, \ldots, C_{i+m}$, their intersections in the diagrams, and whether or not the symbols, ⊗ and —, appear in the regions defined by these curves, are also intuitive-effectively recognizable.[61]

The next step is to provide intuitive-effectively recognizable *diagram-transformations* (121–124): these are acceptable (intuitive-effectively recognizable) transformations of diagrams into other diagrams. The intuitively effective recognition procedure for diagram-transformations is based on the well-formed-diagram conditions, which in turn are based on the recognition procedures for the primitive vocabulary. The "obtainability" relation of a diagram from a set of diagrams ("⊢") is defined via diagram-transformations (125). This obtaining relation is an intuitively effective syntactic one; it corresponds to the derivation-relationship of sentences from other sentences definable in formal language-based algorithmic systems.

As I mentioned before, unlike games (or most games, anyway), diagrammatic algorithmic systems and diagrammatic algorithmic devices usually have interpretations. This is one aspect of such diagrams that enable them to have such a significant role in mathematical practice. In the case of Shin's Venn-II, one particular interpretation is pretty natural.[62] It's a model theory where sets are assigned to rectangles, and subsets of those sets are assigned to the closed curves in the rectangles.[63] Using

[61]Shin (1994, 60, footnote 7) here relies on Polythress and Sun (1972) for the result that, given any arbitrary number of closed curves, a configuration exists (an "atomic diagram") in which for every subset of these closed curves, there is a visible region generated by the intersection of all and only the curves in that subset. Assuming a lower bound on the (tacit) cells that such curves are drawn across, this means that such configurations (and the curves themselves) are arbitrarily large. The evident implausibility of these diagrams being intuitive-effectively recognizable (we surely can't "recognize" such diagrams of arbitrary complexity – not even those containing only a small number of such closed curves) involves exactly the same sort of persistence idealizations that are invoked to allow that people, with pencils and paper, can continue a computation in time as long as needed. We are, in this case, idealizing the intuitively effective recognition procedures by allowing arbitrarily large diagrams that a person "scans" progressively (while retaining in her memory what she has seen). Exclusion idealizations are also at work when, for example, Shin (1994, 82) rejects diagrams containing partial shadings as "ill-formed."

[62]Interpretations for algorithmic systems, however, are never uniquely determined – no matter how "natural" any specific interpretation may be. This is equally true of diagrammatic systems; and so this can be confusing (especially where certain interpretations seem natural because of "resemblances," e.g., the supposed resemblances between drawn triangles and real triangles). I'll discuss this later, in Sect. 13, when I turn to debates about the "rigor" of diagrams in mathematical practice.

[63]I'm omitting niceties in describing how Shin uses this model theory to interpret the diagrams and their elements of Venn-I and Venn-II; among such niceties are ones that involve identifications of the sets that a model assigns to rectangles and curves in different atomic diagrams that are connected to one another by lines; this is needed, for example, to enable to Venn-II to express (some) disjunctive expressions.

this model theory, a notion of a diagram "being true in a model," can be defined, and via that, a notion of implication ($\models$) between diagrams can be defined as well (one collection of diagrams implies another diagram if every model that every diagram in the collection is true in, is one that the second diagram is true in as well); in terms of these notions of implication and obtainability, soundness and completeness are shown (i.e., for all diagrams D_1 and D_2, $D_1 \models D_2$ iff $D_1 \vdash D_2$).[64]

As the above model theory indicates, the diagrams of Venn-II can be associated one-to-one with the sentences in a formal language, specifically a first-order monadic language L.[65] In particular, the formal language-based system L and the formal diagrammatic system Venn-II have exactly the same metalogical properties with respect to the model theory they share.[66] Furthermore, as I indicated, this isomorphism between the diagrams of Venn-I and Venn-II and the sentences of L is intuitively effective. That is, we have an intuitively effective (decision) procedure for reading off from any diagram of Venn-I or Venn-II a sentence of one or another (interpreted) formal language L which "says" (in terms of the interpretations of both the language and the diagrammatic system) what the diagram "says." We can similarly depict what any sentence of the formal language L says with a diagram that captures its "content" exactly.

The model theory for L – traditionally understood – provides interpretations for all the sentences of L. That is, the model theory for L indicates what the sentences of L say. Further, given a specific model M of L, we can speak of the sentences of L being true or false relative to M. The same is true for the diagrams of Venn-II. Each diagram, using the same model theory, says something, and what it says (relative to a specified model M) is either true or false. The model theory for Venn-II and for

[64]See Shin (1994, chap. 5). The fully-general result, in terms of infinite collections of diagrams, that enables a compactness result for the implication relation of models, is given by Hammer and Danner (1996).

[65]Again, avoiding certain niceties, that the procedure of associating sentences with diagrams is intuitively effective turns on how the interpretation for a diagram (in terms of sets) is given – this yields a normal-form theorem: each atomic diagram corresponds to a conjunction of existential and negations of existential sentences describing the (finite) intersections of the sets corresponding to all the closed curves in a diagram, and a diagram (composed of atomic diagrams connected by lines) corresponds to a disjunction of these conjunctions. The reverse procedure turns on giving an intuitively effective method of transforming any sentence of the language to its normal-form equivalent. I stress that these procedures are decidable.

[66]On this, see Shin (1994, specifically Chap. 5), Hammer (1994), and Hammer and Danner (1996). One metalogical property the two systems (naturally) share: the theorems of both systems are decidable and not merely effectively enumerable.

Venn-I (for that matter) thus provides interpretations for the elements of the diagrams that also, as I indicated, yields a notion of truth-in-a-model for the diagrams.[67]

Relations between sentences and diagrams when formal systems like the above are in play are not only decidable, but involve metalogical properties such as completeness. Relations between sentences and diagrams are useful in mathematical contexts – and generally – even when such metalogical properties are missing, as they usually are when algorithmic devices are employed in natural-language contexts. Here, usually, model theory is absent as well – and so model theory *isn't* the tool by which mathematicians interpret diagrams. Nevertheless, we can (and do) legitimately speak of interpreted diagrams or, more generally, of interpreted configurations of objects (a certain sequence of executed movements on an abacus, say) as being true or false – or as being implied by later interpreted configurations. The interpretations in question, however, are ones given by specified sentences of natural language – or sentences in a natural language augmented with (technical and specialized) vocabulary items that nevertheless respect the natural-language syntax this vocabulary occurs in. I turn to developing this important point in the next section.

If we combine Shin's diagrammatic formal system together with a language-based formal system, the result is an example of a *formal* system of "heterogeneous reasoning" in Barwise's (1993) sense (Shin 1994, 188–189; Hammer 1994): a *formal* algorithmic system that has both diagrammatic and language-based elements. Although this kind of combination of systems – diagrammatic tokens along with language-based tokens – is atypical of most formal systems currently studied, the heterogeneity it exhibits is endemic in informal rigorous mathematics. I turn to attempting a description of how similarly "heterogeneous reasoning" works in informal settings.[68]

9 Informal Reasoning by Means of Algorithmic Devices

Consider the use of an algorithmic device **A** in a natural language context. As I indicated above, informal versions of the semantic/syntactic tools in play in formal systems like Venn-I and Venn-II arise here too, although notably they don't have all

[67]For example, Shin (1994, 118) gives a definition of a set assignment (a mapping of sets to the rectangles and closed curves of a diagram) *satisfying* a well-formed diagram. Well-formed diagrams, however, correspond to *sentences*; there is nothing in her definition of satisfaction involving variables as they occur in the formal language-based systems (e.g., those studied in Tarski (1933)). Atomic diagrams are given interpretations by mapping the curves to subsets of the domain of the model, and mapping the elements to the sets in question being empty or nonempty (see Shin 1994, Sect. 3.31). These correspond to sentential relations between sets, for example, *The intersection of A and B is empty*; *the intersection of A and B is nonempty*. The additional compositional facts – about diagrams – that Shin's definition of the satisfaction relation turns on involves the linking of atomic diagrams by lines (which corresponds to the disjunction of what the atomic diagrams represent).

[68]See Sects. 8 and 9 of Azzouni (2017a). I there described algorithmic reasoning as occurring on the "surface" of informal rigorous mathematical practice. This is a metaphor that I'm explicating here in terms of algorithmic devices.

the properties that their formal cousins have. I here sketch out what things look like in the informal setting.

Start with the observation that a natural-language algorithmic device **A**, as in formal settings, allows the intuitively effectively recognition of well-formed diagrams D_i.[69] As before, there is an intuitively effective, recognizable obtainability relation, $\vdash$, that **A** licenses between its diagrams. In addition, there are intuitively effective recognition methods of reading ordinary sentences *off of* the diagrams of **A**, $D_i \rightrightarrows S_j$, and reading sentences *into* diagrams of **A**, $S_j \rightarrow D_i$. Specifically, given a diagram D_i and a sentence S_j (from a certain set of designated sentences), we can often change that diagram into another D_j, where for all sentences S_n, we can recognize that if $D_i \rightrightarrows S_n$, then $D_j \rightrightarrows S_n$, and furthermore, we can recognize that $D_j \rightrightarrows S_j$. I'll call $\rightrightarrows$ and $\rightarrow$, respectively, "reading-out" and "reading-into" procedures.

These procedures may help themselves to language-elements that are contained in diagrams (e.g., letters that appear in the diagrams and that label diagrammatic elements of it) but they needn't. It also needn't be the case that, generally, one can mechanically generate all the sentences that can be read off of a diagram – although that's true of a lot of algorithmic devices (e.g., Shin's Venn-I and Venn-II, and, I think, the informal Euclidean-diagram practice). What's assumed here is just that it's mechanically recognizable for any sentence S_i and diagram D_j, whether or not $D_i \rightrightarrows S_j$ or $S_j \rightarrow D_i$.[70]

Here is the first important contrast with Shin's formal diagrammatic system – and with formal diagrammatic systems generally: there is no assumption of uniqueness in the reading-off and reading-into relations – nor need there be "normal-form" sentences that can be described as what captures (uniquely) what the diagrams of an algorithmic system **A** "say." That is, given a diagram D_i, there can be many different sentences, S_j, S_k, ..., with appreciatively different (although compatible) contents, such that $D_i \rightrightarrows S_j$, $D_i \rightrightarrows S_k$, ... Similarly, given a sentence S_i, there can be many diagrams D_j, D_k, ... (also with appreciatively different contents), where $S_i \rightarrow D_j$, $S_i \rightarrow D_k$, ... All that's assumed is that the reading-into and reading-off relations have intuitively effective procedures. In many cases, these reading-into and reading-off relations are additional decision procedures available to diagram users: given S_i and D_j, it can be determined whether, or not, $S_i \rightarrow D_j$ or $D_j \rightrightarrows S_i$.

[69]For ease of exposition, I'm describing all algorithmic devices as if they're diagrammatic, rather than more general object-based devices. What I say here can be applied easily to the broader case, although I won't (systematically) do that explicitly.

[70]Notice that we can often intuitive-effectively recognize, of two diagrams, D_i and D_j that if $D_i \rightrightarrows S_n$, then $D_j \rightrightarrows S_n$, without necessarily being able to recognize all the sentences S_j of which it's true that $D_i \rightrightarrows S_n$ and $D_j \rightrightarrows S_n$. For example, D_j might result from D_i by the addition of a single diagrammatic element to D_i (e.g., a line or cross) so that it's easy to tell how D_i and D_j differ in their sentential contents.

Define the *content* of a diagram to be all the sentences S_n such that $D_i \rightrightarrows S_n$. (I'll notationally indicate the content of a diagram D_i as Content (D_i).) As noted already, that a given sentence is in the content of a given diagram is intuitively effectively recognizable.[71]

The content of a diagram, importantly, can sometimes look *empty.* In certain standard language-based formal derivation systems, for example, this happens because syntactic-transition rules allow transitions of formal sentences to well-formed expressions with free variables – that don't strictly speaking, say anything – and back again. In the case of mechanical devices that enable calculations, this can happen because certain machine-state transitions can be to and from states that don't nicely correspond to sentences (natural-language or otherwise). Diagrammatic algorithmic devices can operate similarly. Call such syntactic-transitions between diagrams *semantically null* transitions. The algorithmic systems we'll be concerned with will be ones in which any such diagram has, nevertheless, an interpretation – a content; this will be imposed on it by syntactic-transition rules that generate such diagrams from earlier ones. (See the description of soundness results, immediately below.)

The content of a diagram is treated as the *interpretation* of a diagram. This is usually taken to be due to antecedent interpretations of the elements of the diagram, for example, that diagrams of triangles represent triangles, closed curves represent sets, and the interpretation of their syntactic locations in the diagram – for example, that a point-element within a triangle-element represents the presence of a point topologically within a triangle. That is, the interpretation of the diagram is taken to result compositionally from the syntactic placing of these elements in the diagram. There is much more to say about this which I can't do here.

In any case, we usually have the following important *soundness* results that hold of algorithmic devices **A** that are under study in this chapter:

For all diagrams D_i and D_j in **A**, D_i, $\vdash D_j$ only if

(a) For all $S_n \in$ Content (D_i), $S_n \in$ Content (D_j),
(b) For all $S_n \in$ Content (D_j), Content (D_i) $\models S_n$,
(c) for any semantically null transition from D_i to D_j (D_i, $\vdash D_j$), Content (D_i) = Content (D_j).

[71] Contents of diagrams here are sets of sentences. This isn't the only option. We may want to treat the contents instead as "what the sentences say": in other words, the sets of configurations of elements that the sentences are about. Doing it this way or my way doesn't matter, except insofar as the approach indicated in this footnote generalizes straightforwardly to model-theory – whereas my approach involves extra steps. The reader who impatiently wants to get past *sentences* to items that the sentences are about can substitute configurations of elements for sentences in my above definition of content. This is fine except that it introduces extra expository steps in my forthcoming discussion of how practitioners shift from diagrams to natural-language results that such diagrams are taken to show, for example, in the case of Euclidean geometry, Proposition 1 in Book I, that an equilateral triangle exists that has a given straight line as one of its sides.

Some comments about the algorithmic devices these soundness results hold of.

First, as I said, this is a *soundness result* for the proofs generated by the algorithmic device **A**, coupled with the reading-into and reading-off procedures. Unsurprisingly, for algorithmic devices in informal rigorous mathematical contexts generally, we don't have completeness results. These come up – when they're available – when such devices and the informal mathematics they occur in are embedded in one or another formal algorithmic system that's formally interpreted as well (e.g., in relation to a model theory).[72] I'll say more about this in Sect. 12.

Second, I don't think (and so I don't assume) that such soundness results were *shown* in informal settings before modern times. Rather, they were empirically established (or, perhaps more accurately, assumed). In addition (but related to this), practitioners tacitly employed reading-into and reading-off procedures without recognizing much about the properties of these procedures. They recognized that there were potential issues with these procedures only insofar as they grappled with unwarranted-generalization problems. These amount to (ancient and modern) questions about what the elements in a diagram can be taken for stand for (which, exactly, mathematical triangles diagrammatic triangles in a Euclidean diagram can be taken to stand for; what mathematical functions diagrammatic curves can be taken to stand for; etc.); related to this, what the reasoning with specific diagrams can be taken to have shown, generally. (I discuss this in further detail in Sect. 10.) Apart from this, with physically instantiated algorithmic devices, empirical assumptions are needed to show soundness results. This is because persistence and exclusion idealizations must be assumed as successfully operative when these devices are used.

Third (as I've already implicated in the second remark just made), the reading-in and reading-off procedures are crucial to the use of algorithmic devices in informal rigorous mathematical proof. This is because the theorems shown by any execution of an algorithmic device **A**, is read off of the "final state" of that device. In general, any theorem yielded from a diagram by a reading-off procedure is of the form, $S_1, \ldots, S_m \models S_n$, where $S_1, \ldots, S_m$ have been read-into the sequence of diagrams at various earlier points; and S_n is read-out from the final diagram.

Fourth (as I indicated in the discussion in Sect. 7, and especially in footnote 41), the natural-language that the reading-in and -out procedures rely on is invariably terminology-enriched.

This is already obvious in the later Euclidean tradition where "triangle," "line," and so on refer to abstracta, and not to irregularly shaped physical items, that the original Greek words surely referred to. The sentences read off of a diagram can also be, syntactically speaking, "whole cloth" items: alien jargon that functions idiomatically vis-à-vis natural language (i.e., items that are unparceable as far as natural language is concerned).

[72]Of course, completeness results – relative to certain given model theories – may not be possible, as Miller (2012, 34–35) indicates is the case with Euclidean diagrammatic formal systems and certain (intended) models.

Because of the crucial role of reading-into and reading-out procedures in these proofs, there is an important generalization of the notion of "heterogeneous reasoning" beyond cases of formal systems to cases where algorithmic devices occur in informal rigorous mathematics proof (to cases of mathematics, that is, that occur in natural languages). I'll call this *informal heterogeneous reasoning*.[73] The idea is straightforward. Suppose we have an algorithmic system **A** that licenses transitions among diagrams D_i; suppose also that we have ways of recognizing implications ($\models$) between sentences of natural language (be those sentences natural-language ones or sentences composed – in part – of supplementary and specialized mathematical vocabulary). A proof (relying in part on an algorithmic device) can look something like this:

$$S_i \models S_j, S_j \rightarrow D_k, D_k \vdash D_l, D_l \rightrightarrows S_m, S_m \models S_n,$$

where we take, as a result, $S_i \models S_n$.[74] This is justified by a soundness result, of the above form, for **A**.

Example: Suppose the relevant sentences of a natural language are ones like "ten plus seventeen is twenty-seven." Let D_i be the configurations of an object-based or language-based algorithm **A**, such as an abacus, or an (Arabic) numeral system for addition or multiplication. The elements of D_i are interpreted in natural language, say by the assignment of the elements of a diagram, "1," "2," etc. to the natural-language numerals, "one," "two," etc. or instead, by, say, configurations of the elements of a physical algorithmic device (bead patterns in an abacus, for example) being assigned to natural-language numerals. And we (consequently) interpret the diagrams, and (possibly) certain subconfigurations of those diagrams, as having truth values as a result.

Consider an *abacus.* Here are some typical "word problems" we can solve using it:

The auditorium has 75 normal chairs and 20 high chairs. How many chairs does the auditorium have in total?

A bricklayer stacks bricks in two rows with ten bricks in each row. On top of each row, there is a stack of six bricks. How many bricks are there in total?

Serena buys two packs of tennis balls for $12 in total. All together there are six tennis balls. How much does a pack of tennis balls cost? How much does one tennis ball cost?

In each case, we extract an implicit arithmetical question that the word problem poses, and then, using a reading-in procedure, we generate a (finite) sequence of configurations of abacus beads; in the first word problem, for example, the arithmetical statement to be shown is: "Seventy-five chairs plus twenty chairs is X chairs," where X answers the question, and thus the word problem. Call the

[73] I'm here generalizing Barwise's (1993) use of the phrase to algorithmic devices in natural language. See footnote 14 above.

[74] In general, of course, many sentences occur, both as antecedents, and in the stages where sentences are read into diagrams.

antecedent description the calculation, and call the substitution of a natural-language numeral for "X" in "X chairs," "X bricks," etc. *the result*.[75] The calculation is coded into the algorithmic device as a sequence of configurations of abacus beads, and the result is read off from the final configuration. Introducing the usual exclusion and persistence idealizations, we imagine that abacus devices can be arbitrarily large in size (and yet humans can still execute operations on them). There is an intuitively effective recognizable class of arithmetical statements (involving the ordinary-language addition, subtraction, multiplication, and division), where the calculation can be intuitive-effectively coded as a sequence of configurations of an abacus, and where the last configuration corresponds to the result. This, therefore, is an example of heterogeneous informal reasoning, where there are both language-based inferences (of, for example, word-problem statements into arithmetical statements) and abacus inferences. The abacus results, in this way, are returned to an ordinary-language arithmetic practice (such as it is).

We can imagine, instead, that the algorithmic devices in question are notational (short division, multiplication, etc.). Notice the result: Via the reading-in and reading-off procedures, algorithmic devices of all sorts can easily augment a sentence-based informal mathematical practice. In particular, the invention of a new notation (that provides an algorithmic device – or several) can be easily added to an already existing mathematical practice in natural language with preexisting algorithmic devices. It's then empirically established that the new algorithmic devices both enable the proofs of apparent new results or they introduce ease in yielding theorems that are already accessible otherwise. That the algorithmic device doesn't render the practice trivial by yielding inconsistent results (either internally or in relation to results established by other means) is also – and must be – empirically established.[76]

I need a label for the characterization I've just given: that informal rigorous mathematical practice involves the use of algorithmic devices (either language-based or not) along with reading-in and reading-out procedures. Call this the "algorithmic-device interpretation of informal rigorous mathematical proof," or (for short) the *device view.*

10 The Generality Problem

The diagrams we make, look at, and study are tokens of syntactic objects (of types) – that is, they're tokens of types of *physical* items (sketches on paper, in sand, fleeting utterance-events, etc.). Call *the generality problem* the question what interpretation

[75]Often, natural language is supplemented, for example, in this case with new numerals, so that the reading-out procedures are still ones into natural language – although now supplemented.

[76]I mean "empirically established," not in the sense that a mathematical proof can't be given for this; I mean it in the sense that we don't have a decision procedure for discovering things like this: not having unearthed an inconsistency *so far* doesn't mean an inconsistency isn't there to be unearthed.

is to be given to the elements of the diagram, and thus, compositionally, to the diagram itself. In the case of formal algorithmic systems, this is the question of what model or set of models the diagrammatic or language-based formal system is to be interpreted in terms of. *The straightforward solution* to the generality problem in the formal context takes Gödel *completeness* results to be the guide to answering this: Choose a model theory to interpret a formal system **A** where the validities and the theorems match.

This, when philosophers study formal languages, usually *isn't* taken to be an acceptable solution to the generality problem. On the one hand, there is *the uniqueness problem.* There are many "unintended" models for any formal theory – models of "nonstandard arithmetic" for first-order Peano arithmetic or the many unintended models for first-order ZFC, for example. It's felt by many practitioners that, despite our having no syntactic grip on any specific model in these cases, there nevertheless *is* an intended model – that is, there is a unique model that we (somehow) *intend* the axioms we write down to capture.[77] But, not only do the syntactic consequences of first-order Peano arithmetic fall short of extending over all the validities (theorems) of this intended model, any augmentation of Peano arithmetic that has an effective syntactically characterizable consequence relation falls short the same way (Gödel's incompleteness theorem).[78] Relatedly, it's felt by many proponents of certain logical systems – for example, higher-order logics – that a model theory vis-à-vis which their syntactically specified theorems are complete doesn't capture the intended meanings of the terms in those systems. According to the "intended" meanings of the quantifiers of such systems, for example, any effectively specified set of syntactically characterized theorems are incomplete.[79]

[77]This model, in the case of Peano arithmetic, is called "the standard model" – for example, by Kaye (1991).

[78]For the record, I'm skeptical there is genuine content to "intended model" in any case in which characterizing it outruns our syntactic resources. I can't get further into this now; see, instead, Azzouni (2018) for discussion of the case of arithmetic – which is a case where intended-model intuitions are especially strong. Notice what the problem is. We feel we understand – grasp the meaning of – the intended extension of a notion when it's given by negating a term whose extension we *do* grasp, for example, the consistent formulas of first-order logic (which are all those which *aren't* first-order validities or contradictions). On the other hand, there is certainly a sense in which we don't understand – don't grasp the meaning of – the extension of a notion if it isn't recursively enumerable. I omit further discussion of this very delicate matter except to observe that it's connected to the discussion – in Sect. 7 – of how our intuitions of meaning are insensitive to what I there called inferential scope.

[79]Nomenclature: I think, for the reasons just given, that the generality problem should be called, instead, the intended-model problem. The latter label more sharply focuses what's at issue, both in formal and informal settings. But the "generality problem" is the label Mumma and other philosophers in this literature use – so I'm sticking with it instead.

I intend to focus on that version of the generality problem faced by a specific informal diagrammatic system: the generality problem of ancient Euclidean diagrammatic practice. This version of the generality problem gets a lot of attention, both now and over the centuries. But it's important to indicate first that it's something of an illusion that a rather different form of interpretation is at work in formal settings – where models are supposed to be used to interpret formal languages – than in the case of informal mathematical practices with algorithmic devices, where, according to my characterization of them, reading-in and reading-off procedures into natural language are used instead.

The reason is one that was made clear long ago by Davidson's (1986) characterization of how Tarski's theory of truth is supposed to be used in interpreting languages: The semantics for any language – logical or otherwise (i.e., one in which there is a nonlogical vocabulary that's allowed to vary across models, or one in which there isn't any such nonlogical vocabulary) – occurs in an *interpreted* metalanguage.[80] That means that the meanings of the elements of sentences and diagrams, and the meanings of the syntactically composed sentences and diagrams occur via transliterations of them into the antecedently meaningful language of the metalanguage. And *that* means that an interpretation of a formal algorithmic system, specifically, a formal diagrammatic system, is – strictly speaking – a formalization of what I described in the last section as the reading-in and reading-off procedures that are applied to algorithmic devices.

More precisely, the formalization in question is accompanied by an interpretation of the algorithmic system that's a transliteration of a bit of informal mathematics – diagrammatic or otherwise – and including some algorithmic devices, reading-in and reading-off procedures, as well as (usually) some accompanying informal natural-language reasoning. The algorithmic system and its interpretation is specified in ordinary language (as always happens in informal rigorous mathematics) that has

[80]That the interpreting language be, strictly speaking, a distinct language – a "metalanguage" – isn't required. That's just the traditional way of doing it. For example, it's possible to have one language in which the interpretation of a part of that language take place in another part, and where the two parts are syntactically isolated from one another. I should add that in classical settings the background interpreted metalanguage is usually (a version of) set theory – that is, a mathematical subject matter that's ordinary informal rigorous mathematics (in a natural language). See what follows.

been supplemented with specialized vocabulary – in standard cases, with set-theoretic vocabulary.[81] If the metalanguage – in which this mathematical specification of the syntax and semantics of the algorithmic system takes place – is, in turn, formalized then the same process (of interpretation) can be repeated.

In a purely informal setting, the generality problem coalesces onto the reading-in and reading-off procedures; and this version of the problem has troubled mathematicians (with respect to diagrams) right from ancient times until the present. The Euclidean version of the problem is this: how is a diagram to be understood – to what do the elements of the diagram refer? Consider a drawing of a triangle, for example. One (natural) interpretation of it is that it represents a class of triangles that (roughly) match the *drawing's* angular properties: the acute triangles are referred to by drawings of acute triangles; oblique triangles are referred to by drawings of oblique triangles; and certain properties of other drawn figures – *and not others* – play similar scope-indicating roles. Call these *resemblance interpretations* of the diagrams in a diagrammatic practice.[82] Euclid's proofs don't seem to respect any obvious resemblance interpretation systematically: sometimes certain properties of a figure seem involved; sometimes other ones do. The generality problem (in the Euclidean setting) is made complicated by the fact that what determines the scope of

[81]Model-theoretic approaches to interpretation (and Davidsonian approaches to interpretation, therefore) cannot, contrary to Davidsonian claims (Davidson 1986), be taken as providing the theoretical framework for explanations of how we understand languages and of how the meanings and references of these languages are facilitated – that is, what the machinery is by which the terms of a language acquire the referential scopes that they have (e.g., that "everything" refers to everything; that "gold" has the extension it has). Call the latter language-world questions; call the former language-mind questions. The reason Davidsonian approaches don't answer language-world and language-mind questions is that, as I've just mentioned, the mechanism by which Tarskian-inspired model theories interpret languages is by providing compositional-element-to-element *correlations* between target-language elements and metalanguage elements that provide the interpretations for targeted elements by simply giving them the referential and meaning properties of the correlated metalanguage elements. Doing this can't answer language- world and language-mind questions unless we *already* have answers to those questions with respect to the metalanguage elements. That is, it *defers* answers to these questions for a targeted language to whatever answers we have for the metalanguage – none as far as the Davidsonian approach is concerned since that approach bizarrely takes the targeted language questions as *answered* by these correlations. Notice the objection *isn't* the truistic complaint that, if a theory of how language elements refer to the world is given, such a theory needs to be given *in* a language which embodies (or has) language-world connections and is one that we understand. The point, rather, is that no illumination of language-world and language-mind questions is given by "explaining" that how "pomme" manages to refer to all and only the pommes is that it happens in just the same way that "apple" manages to refer to all and only the apples. An analogous point holds of the question of how Capucine understands "pomme"; it doesn't help to say that she understands it in just the way that I understand "apple." See Azzouni (2017b) for an attempt to spell out what's required for a genuine attempt to answer language-world and language-mind questions. I'll also note that to complain this way about truth-conditional semantic theories isn't to complain about their ability to capture the compositionality of languages: they *successfully* capture compositionality phenomena.

[82]Philosophically refined versions of resemblance interpretations are still taken seriously – by for example, Shin and Giaquinto. I discuss them in Sect. 12.

a diagram are the reading-in and reading-out procedures; but they're *implicit*.[83] The result is centuries-long controversies over whether Euclid provides sufficient diagrams to cover all the relevant cases that seem to fall within the scope of his established results – whether, in fact additional diagrams are needed for particular diagrammatic proofs to successfully prove results that he seems to understand as having a certain generality (e.g., as about all triangles, as opposed to some obeying such and such specific conditions – for example, acuteness)[84].

The generality problem for informal diagrammatic practices seems to have a different flavor than the one faced by language-based systems. This is because there are additional properties that we're visually sensitive to above and beyond those visually available in one-dimensional concatenation systems. In addition to adjacency, for example, there are topological properties (containedness) that it seems that reading-in and reading-off procedures in some diagrammatic traditions can (and do) exploit. In those diagrammatic practices, additionally, mathematicians "just see" visually available relations that are often interpretationally correlated with properties of the mathematical items the diagrams are about.[85] This "just seeing" is (largely) why the reading-in and -off procedures exploiting what's "just seen" are tacit. Nevertheless, the generality problem is the same one that's faced by language-based systems; this is because nothing requires the visual properties of a diagrammatic system to be exploited by the reading-in and reading-off procedures: it's a convention to so-interpret syntactic properties – diagrammatic or otherwise – *regardless* of whether the procedures, that exhibit these conventions and that provide the interpretations, exploit resemblances or not.

When an informal diagrammatic practice is formalized, one explicitly "solves" the specific version of the generality problem that diagrammatic practice faces – for example, the Euclidean diagrammatic practice – via *two* moves, versions of both of which are used when formalizing *any* informal inferential practice. The first move is to mathematize the (physical) diagrams themselves by identifying them with one or another kind of mathematical object. Shin (1994), for example – recall Sect. 8 – mathematizes Venn-diagram drawings by characterizing them as closed curves

[83]Mumma (2010, 256–257) states the generality problem for the informal rigorous Euclidean practice this way: "The generality problem arises with Euclid's proofs because the diagram used for a proof is always a *particular* diagram. Euclid clearly did not intend his propositions to concern just the figure on display beside the proposition. They are applied in subsequent proofs to other figures, which are not exact duplicates of the original. And so, for Euclid, consultation of the original diagram, with all its particular features, is somehow supposed to license a generalization. But Euclid leaves the process by which this is done obscure."

[84]See Heath 1956, 245–246.

[85]These have come to be called "free rides" – a phrase introduced by Barwise and Shimojima (1995). I'll eventually characterize these in terms of what I'll call "embodied algorithms." See Sect. 13 below. Also see Azzouni (2013a), where I discuss the free-ride phenomenon, although without using that nomenclature.

within rectangles (that can be connected by lines) with certain mathematical properties.[86] This corresponds to our making metamathematically explicit the syntax of a formal language – as when the sentences of a language we speak are identified with certain abstract objects. As I described it (in Sect. 8), well-formed syntactic items are characterized, the syntactic-transition rules are given, and so on. The second move is to provide a model theory (a semantics) for the resulting language-based or diagrammatic formal system. Although the diagrams are recognizably identified with well-formed syntactic items, the reading-in and reading-out procedures are (relatively invisibly) encapsulated into the interpretations given by the correlations of the mathematical objects standing in for the actual diagrammatic devices (drawn circles, etc.) to model-theoretic items.

I now turn to a closer discussion of the formalization of the Euclidean diagrammatic practice.

11 An Algorithmic Device in Natural-Language Mathematics: Euclidean Diagrams

Everyone admits that Euclidean geometry, the *Elements*, is the most influential reasoning practice in human history.[87] Consider Book I of Euclid's the *Elements*. A post-Fregean temptation – one that's still alive among contemporaries – is to think of Euclid's approach as *the* earliest axiom system: a pioneer version of the formal language-based systems that emerged with Frege, but occurring in natural language, and in which diagrams play a purely heuristic role.[88] Views about exactly *how* the

[86]This is often implicit, but important: The abstracta that in the formalization replace the physical items we actually use in the informal practice – for example, the actual drawings – are chosen to preserve (at least in principle) the intuitive-effectiveness of the recognition procedures of the informal rigorous mathematical practice. Preservation of certain properties of the phenomenon being mathematicized is a typical precondition on the application of branches of mathematics; in general relativity, for example, we choose a mathematical object (a manifold) that replicates – at least up to current observational thresholds – the properties of spacetime.

[87]Mumma (2008b, 256, italics his) puts it nicely: "[The *Elements*] represented the limit of mathematical explicitness. It served as *the* paradigm for careful and exact reasoning." This is seen by Manders (1995), Mumma, and others studying the practice, to pose an historical puzzle: why the relatively widespread repudiation as being *obviously* inadequate of the Euclidean proof-practice by later nineteenth-century mathematicians? I provide my answer to this question in what follows.

[88]Note the suggestion: diagrams play a purely heuristic role *in the informal rigorous Euclidean practice.* That the practice can be formalized one way or another in a pure language-based system (e.g., in the formal system of Avigad et al. (2009)) is irrelevant because it follows from Hilbert's thesis that this can always be done.

reasoning with this system works – in particular, what role the diagrams have – has shifted over time. Plato's early characterization treats the diagrammatic elements as crucial to reminding us what the proof elements (words and diagrams) refer to, and therefore why the results diagrammatically shown are true.[89] Later views of reasoning treat a perfect item of reasoning – a proof – as a completely explicit series of inferences without gaps (no "missing steps"); this view is present in Descartes[90] but remained programmatic until Frege. Frege, however, sustained the picture by assuming, naturally enough that the (artificial) language that proofs occur in is one with a fixed semantic interpretation, and where each step follows immediately (by rules) from earlier ones. Once the uniqueness of the possible interpretations of artificial languages (or of the introduced terminology in natural languages) is stripped from the picture, what remains (indicated by the phrase "by rules") are intuitively effective recognition procedures for proofs. The internal syntactic structure of the language and the interpretations of the logical operators across models that it embodies are all that remain to fix the interpretations of its sentences and that of the other language elements.[91]

Until it was recognized that diagrammatic proofs – specifically, the transitions between diagrams in a diagrammatic proof – utilize intuitively effective recognition procedures just as language-based proofs do (and thus are equally open to formalization), the temptation remained to treat our recognition of the inferential properties of proofs as matters of "intuition" to be eliminated. So, I'm hypothesizing that a certain picture of proof (gaplessness) and the impression that gap-free proofs are

[89]My interpretation of Plato's view of reasoning is that it's akin to perception: "seeing" in the sense of understanding and "seeing" in the sense of visually perceiving aren't ambiguously different meanings of "see" as they appear to be. (This is how I'm stating Plato's position in English; I'm certainly not making any sort of claim about the corresponding Greek words.) This shortly mutated into a view where reasoning was seen as a matter of deducing particulars from universals, although, I think, this deducing continued to be regarded as a kind of "seeing" – the *universals*, in particular.

[90]Descartes (1931, 19) writes of deductions that they must be "scrutinized by a movement of thought which is continuous and nowhere interrupted. . .." I'm tempted to credit Descartes with originating this view of proof, but this is a matter for historians to determine, not me: I don't know whether there were earlier expressions of the claim or (as important) whether Descartes knew of and was influenced by them. The idea, of course, may originate in the impression that inferring is like seeing.

[91]Thus: the emergence of unintended interpretations.

only possible in language-based media were decisive in turning mathematicians against the use of diagrams.[92]

There are several contemporary formalizations of Euclidean geometry. In this section, I'll focus on two: Miller's FG and Mumma's Eu.[93] I'll first give a short overview of how I regard the original Euclidean practice – this involves a bit of speculation, of course.[94] Then I'll turn to sketching how Miller and Mumma formalize the Euclidean practice; this naturally raises issues about which properties

[92]Mumma (2010, 257–259) suggests that what instead turned mathematicians against diagrams, and, specifically, Euclidean diagrams, was the generality problem.

A different challenge to my historical hypothesis is posed by something Frege (1879, 5) writes of his own version of mathematical proof: "To prevent anything intuitive [Anschauliches] from penetrating here unnoticed, I had to bend every effort to keep the chain free of gaps." This makes it sound like the gapless ideal for proof was introduced by Frege to avoid "intuition," and not that the programmatic gapless model of proof was appealing (and motivating him) in its own right, and thus was what was undermining the acceptability of "intuition." My interpretation is saved, however, if Frege's use of "anschauliches," is read – as I think it should be – not as only a label for pictures but as standing for *anything* unarticulated that enables a mathematician to "see" his way from p to q without using the intermediate steps that are presumed present in a "fully-explicit" canonical proof. "Intuition," when used to describe the mathematical insights that diagrams enable involves *several* elements that weren't clearly distinguished. One is the historically unrecognized role of intuitively effective recognition procedures directly involved in informal diagrammatic proof; but a second element (that I discuss in further detail later) is the implicit interpretations of diagrams via the reading-in and reading-off procedures.

Still another apparent challenge to my historical interpretation of Frege being primarily focused on gapless proof is that he also seems to explicitly commit himself to purity views of mathematical proof, as Detlefsen (2008, 187) illustrates with a quotation. Frege's purity condition, however, is specifically focused on the exclusion of "geometrical elements" from arithmetic. And, further, it also seems that Frege is thinking that the "geometrical elements" are ones that aren't *logical* – he writes, in the quotation that Detlefsen gives, "the task of deriving what was arithmetical by purely arithmetical means, i.e. purely logically, could not be put off." This quotation, therefore, is compatible with the gapless logical ideal of proof still being Frege's central motivation, since he doesn't commit himself to a more general form of purity of *mathematical* subject-matter. See footnote 46 for examples of philosophers and mathematicians who extoll purity goals in mathematical proofs, where those goals are driven by subject-area considerations and not logic.

[93]See Miller (2007, 2012), Mumma (2008a, b, 2010, 2019). There is ongoing controversy about Eu, and so this system is, as a result, still somewhat in flux. Miller (2012) shows that the earlier version of Eu (Mumma (2010) – and elsewhere) is inconsistent, unsound, and has several other infelicities as well. Mumma (2019) addresses the issues Miller raises by substantially modifying the system. (Although Mumma has not done so, the two systems should really be distinguished by different names.)

[94]This discussion further supplements the picture I gave of the Euclidean practice in Azzouni (2004). I wrote that paper in 1998, for the *New Trends in the History and Philosophy of Mathematics Conference* held at the University of Roskilde, Denmark, August 6–8, 1998; the conference papers, however, weren't published until 2004 – thus my neutrality vis-à-vis mathematical ontology in the paper (which is the same version I gave at the conference) instead of my by-2004 adopted nominalism. I should add that both in this chapter, and back in 1998, I'm not and wasn't attempting a suitably careful historical analysis of the Euclidean practice. See, instead, for this, Manders (1995) and Manders (2008). I'm avoiding, for example, the complex question of diagrammatic proofs-by-contradiction that he (1995) discusses with such care.

of informal rigorous proofs can be successfully transferred to their formalized cousins, and which can't – in particular if and when such formalizations replicate the phenomenological properties of the original proof practice.

There is an implicit (and sometimes explicit) assumption by those who formalize informal rigorous diagrammatic practices (e.g., Miller, Mumma, Shin, and others) that the informal reasoning practice is *captured* by these formalizations – that the formalizations reveal the reasoning implicit in the informal practice. Mumma (2008b, 256, footnote 1) writes, for example: "One should keep in mind that my criticisms [of Miller (2008)] are closely connected to my views on how my work and Miller's compare with respect to capturing Euclid's reasoning." At least insofar as the implicit reading-in and reading-off procedures are concerned, this is wrong: these informal procedures are invariably indeterminate in various respects that *cannot* be captured by any formalization – simply because formalizations decide interpretational issues that are indeterminate as far as the informal rigorous practice is concerned. Apart from this, both Millers' and Mumma's formalizations fail to replicate the informal practice as I'll indicate in what follows: specifically, these formalizations don't capture the case-structure of the original Euclidean geometry because they substitute different diagrammatic cases for Euclid's; more dramatically, they substitute a *mathematical basis* that diagrams are constructed from that's phenomenologically alien to our experience of the physical diagrams themselves. I'm not making a point about the interpretations of the Euclidean diagrams and those that Mumma and Miller give; I'm making a point about their metamathematics: how they characterize the *syntax* of the diagrams.[95] I now illustrate this.

Consider a preliminary observation about Mumma's approach. Mumma (2010) adopts Manders' (1995) distinction between exact and co-exact properties of diagrams. This (roughly) is a distinction between the metrical properties – the "exact" properties – of the figures in a diagram (the lengths of lines, the areas of triangles, the relative sizes of corresponding figures, etc.) and their topological properties, the "co-exact" properties (what regions are defined by figures, what elements are within and without figures, etc.).[96] Mumma claims – following Manders (1995) – that the original practice involved two proof systems, a diagrammatic one and a language-based one; both philosophers claim that only the co-exact properties of diagrams are used in the (strictly) diagrammatic Euclidean proof-system; the exact properties are either stipulated of the figures or proven in language-based proofs. (Mumma (2008a,

[95]Shin's approach, described in Sect. 8, is much closer to the original informal Venn-diagram practice, and retains much of the phenomenological qualities of the original informal diagrams – despite the fact that she introduces closed curves for circles (not *all* of her diagrams retain the relevant phenomenological qualities, but *some* do; I discuss this further in Sect. 12).

[96]See Manders (2008, 69) for a nice description of his exact/co-exact distinction. He adopts the term "appearance" for the set of co-exact conditions on a diagram. I'll suggest later in this section, at least as far as the experience of these diagrams is concerned, that this is misleading terminology. Even if the proof-machinery operates solely via the co-exact conditions of a Euclidean diagram, our *appreciation* of what it shows – including how much its results hold of diagrams different from the one being seen, turns on our perception of how it appears: its *geometry*.

italics his) writes: "The key observation is that Euclid's diagrams contribute to proofs *only* through their co-exact properties.") I've not determined whether this claim is true of the original proofs in Euclid – it certainly looks like it might be – but, in any case, the informal rigorous Euclidean practice isn't obviously divisible into two proof procedures in this way. Manders' observation about co-exactness, if right, is a substantial *discovery* about Euclidean proof-practice.[97]

Mumma (2010) also takes Eu to "solve" the generality problem (the question of what the diagrammatic elements in Euclidean proofs refer to), and criticizes Miller's earlier approach on the grounds that *its* solution to the generality problem increases the number of diagrams that any diagrammatic proof requires; he denies that the original practice could have operated in this way since Euclid never considers so many cases – and more importantly, couldn't do so (Mumma (2010), 263–264, footnote 4) because of their "staggering" number and because most of them "are not physically realizable."

The first point to make is to object to a mutually held assumption of Mumma and Miller. Formalizations of any informal rigorous mathematical practice always involve well-defined interpretations (models are given), and so they always "solve" the generality problem one way or another. But any such "solution" invariably deviates from the original practice because there is no solution (in the informal rigorous practice itself) to the generality problem *that original practice* faces: the scope of a diagram – the particular theorem it establishes – and, relatedly, the references of its elements are given by the reading-in and reading-out procedures, and (since the interpretations these give occur only tacitly in the practice, and even tacitly in the natural-language sentences that supply the interpretations) the informal practice is necessarily indeterminate in referential scope. I'll discuss this further in Sect. 13. I'll add now, however, that a similar generality problem occurs with respect to language-based informal rigorous mathematical proofs – when specialized terminology is involved. This is because specialized mathematical terminology can (and usually does) referentially *mutate* over time: consider the notorious case of the notion of a "function," during the course of several centuries.

The original Euclidean practice, of course, doesn't explicitly exhibit the neat distinctions *I* drew in the last section *either* – between diagrammatic transitions, on the one hand, and the reading-in and reading-off recognition procedures, on the other. This is hardly surprising since, in my description above, the reading-in and reading-off

[97]Although the insight is based on an observation commonly made through the centuries: Euclidean proofs avoid exact measurements (marked rulers) of the figures that are diagrammatically manipulated. One supporting consideration in favor of Mander's two-proof-procedure suggestion – diagrammatic and language-based – is that slash-marks (which are diagrammatic) seem to be a nineteenth-century innovation (Manders 1995, 97, footnote 14). On the other hand, another interpretational possibility is the conventionalist construal of the diagrams (see the definition of the "conventional option" shortly below) coupled with a meta-diagrammatic language in which *all* the proofs take place. According to this interpretation, there are no "diagrammatic proofs": rather, in the meta-diagrammatic language, one has the resources to "point to" aspects of diagrams – both exact and co-exact features. (Diagrams are, as it were, "quoted" in the metalanguage.) I entertain this interpretational hypothesis in Azzouni (2004); I claim that it wasn't available to ancient Greeks as a possible interpretation of their Euclidean practice – even if it was *true* of that practice – because of their implicit philosophical views about (correspondence) truth.)

procedures (which supply interpretations for the diagrams and their elements) are sharply distinguished from the syntactic obtainability relations among diagrams; by contrast, talk of diagrammatic elements and talk of the interpretations of those elements are, generally, not distinguished in Euclid's *Elements* – less charitably put, they're systematically *confused*. Consider the following definitions:

1. A **point** is that which has no part.
2. A **line** is breadthless length.
3. The extremities of a line are points.
4. A **straight line** is a line which lies evenly with the points on itself.
5. A **surface** is that which has length and breadth only.[98]

These (with the exception of (3)) purportedly describe the *mathematical* objects of study. Items which have no parts, or are breadthless, or have length and breadth only, can't be the actual diagrammatic items we draw and so they're *abstracta*. Call this *the Platonic option.* This option, that is, treats diagrammatic elements as referring to abstracta, and it treats the definitions as attempting to determinately *fix* the referents of these pictorial elements, drawn points, lines, etc. that appear in diagrams. For those who take diagrams to refer to Platonic entities, these definitions must fail as a result (worse, they're pointless): one cannot in this way provide interpretations; one can, at best, restrict the interpretations of primitive terms via axioms, which interlock those interpretations to one another in various ways.

This problem is quite general. The primitive terms – and now I use the phrase "primitive term" broadly to cover both the words in language-based sentences and the pictorial elements in diagrams – cannot be defined in this way, as we now know. Where referents are physically available, they can be indicated by language-exit rules (gestures and the like); when they aren't, these referents can only be fixed by axioms and inference rules (diagrammatic or otherwise) that constrain – but generally can't determine uniquely – possible interpretations. And this exhausts what can be done *within* a language. Within the confines of another language (a "metalanguage") a model can be given – this includes explicit interpretations of the primitive terms, which are given with the model. The *generality problem*, in the context of an informal rigorous mathematical practice, is the problem of how the primitive terms of that practice are given interpretations.

A second option for characterizing the role of these definitions takes them to be meant to describe diagrammatic items in a way that indicates *some* of the conventions governing the drawing of diagrams; and how, as a result, we're to understand such items. In this case the subsequent proofs involve claims – in natural languages – about the conventionalized diagrams themselves. I'll call this *the conventional option*.[99]

[98]Heath (1956, 153); his numbering, his boldface.

[99]Leibniz writes: "[Geometrical] figures must also be regarded as characters, for the circle described on paper is not a true circle and need not be; it is enough that we take it for a circle" (quoted by Manders (1995, 80). See Azzouni (2004) for further discussion of these two options and the evidence for why the Platonic option was eventually universally adopted despite the *Elements* retaining aspects of a conventional diagrammatic-practice, for example, in the statements of some postulates, as I indicate shortly.

On this view, diagrammatic elements are (exactly) like chess pieces; it's *understood*, that when a chess piece is moved, it's subsequently located in one and only one square even if it's been placed sloppily on the board (or even if the board is designed so badly that it can be hard to tell where a piece is). This involves understanding *physical* chess pieces conventionally – by imposing laws of movement on them via stipulations: these are laws of movement they'll otherwise violate. It *isn't* – notice – a matter of treating chess pieces as standing in for (or referring to) chess-piece abstracta that actually have the properties that chess pieces are conventionally treated as having (that's a version of the Platonic option – again).

In any case, the *Elements* both describes diagrammatic syntactic-transitions of diagrams in terms of what can be done to a diagram with respect to the above visual points, lines, etc. but runs this together with assumptions or claims about the interpretations of those visual items when they appear in diagrams, as in the postulates:

1. To draw a straight line from any point to any point
2. To produce a finite straight line continuously in a straight line
3. To describe a circle with any center and distance.[100]

Although naked infinitives are hard to interpret (and although I'm relying on Heath's *translation* when I say this and interpret the words as I do in the next few lines – assuming, that is, that what I say is true of the ancient Greek), the postulates (1) and (2) seem to describe permissions for possible actions that can be taken on diagrams; they don't seem to be characterizations of what the diagrammatic items, points and lines, refer to (i.e., to the mathematical objects: points and lines); they aren't, to put it another way, existence claims about what the elements of the diagrams depict. This "action-interpretation" of these postulates follows from the use of the phrases "to draw" and "to produce." On the other hand, (3), because of the word, "describe," seems, in addition to apparently describing an admissible action that may be taken to construct a diagram, to be offering an interpretation of what that diagram (of a drawn circle with a particular center and distance) is to stand for. According to the Platonic option, these definitions together with the postulates exhibit various use/mention confusions; according to the conventional option, there aren't such confusions (except insofar as interpretational issues are intruding in what otherwise would be a pure description of the syntactic conventions of a diagrammatic practice, and the nature of the syntactic idealizations it involves).

Recalibrating the informal Euclidean practice so that it accords with the device view (as it was described in Sect. 9) entails very little by way of changes to the look of the actual practice. One needs to, first, distinguish the diagrammatic/notational elements from the interpretations of those elements, second, to describe (in an

[100]Heath (1956, 154); his numbering, his spelling.

interpretation-free way) the syntactic-transitions embodied in that practice, and third, to indicate the interpretations of the diagrammatic/notational elements. That's not changing much.

I claim this is generally the case with the device view – in contrast to current formalizations of informal mathematical proofs, especially those of the Euclidean practice. I feel safe, thus, in regarding the device view as providing a theoretical *schematic* that enables *descriptions* of ordinary informal mathematical practices – diagrammatic and otherwise – despite its drawing a sharp distinction between actions on elements (of diagrams or languages) and how those elements are interpreted, a distinction which isn't exhibited directly in those practices themselves (as the discussion of the Euclidean case indicates). Reformulating an informal mathematical practice according to the device view should leave all the proof-theoretic flaws (if any) in the practice intact. For example, if (as many have illustrated) Euclidean diagrams can be ambiguous or misleading, the presence of these ambiguous or misleading diagrams should survive the practice being recast according to the device view. Second, it should also leave intact interpretational flaws – for example, failures to (fully) solve the generality problem. In this sense, if only because formalizations are consistent and determinate, they impose normative constraints on the informal practice that the practice itself needn't exhibit.[101]

The upshot: Attempts to formalize informal rigorous mathematical proof practices pose challenges that go quite beyond what's required to frame that practice correctly and according to the device view. In particular, with respect to diagrammatic reasoning, since (almost invariably) there is relevant reasoning occurring in the natural language apart from the syntactic transitions from diagram to diagram, that reasoning must be formalized as well. In addition, the reading-in and reading-out procedures must be treated both as supplying interpretations – so they are implicit guides (for example) of the model theory that is to be used to interpret the formal system – and as providing crucial inferential structure between the mathematical content expressed by ordinary-language sentences and that expressed by the diagrams licensed by the algorithmic devices.

[101] I'm not saying, of course, that an informal mathematical practice need be flawed in various ways; but whether it is or not is usually clear to practitioners at the time that the practice is living, and not because they're aware of one or another formalization that they're comparing the informal practice with. This is true, for example, of the ancient debates over how many diagrams should appear in a diagrammatic proof, and whether some diagrams are "ambiguous." This is similarly true of the debates over the acceptable manipulations of the notation for infinite series in the eighteenth and nineteenth centuries. It's important to realize that these debates are (often) resolved in the informal practice itself by notational reforms of various sorts along with changes in the rules for manipulating the syntax of an algorithmic device: these changes can be characterized in ways that don't require discussions of formalizations. (There is an exception, of course, once formalizations themselves become part of the mathematical toolkit among ordinary mathematicians; then a formalization may itself replace the previous informal rigorous mathematical practice – at least in some respects.)

Miller and Mumma formalize Euclid's *diagrammatic* practice in (quite distinct) formal diagrammatic systems. That means, to begin with (as I indicated earlier), that in both cases the physical diagrams themselves are identified with certain kinds of mathematical objects – certain kinds of two-dimensional abstracta – that can be (intuitive-effectively) recognized as having certain properties and not others. Right at this point both formalizations deviate in a significant way from the Euclidean (book I) practice; this – all by itself – faults claims that either resulting formal system "captures" the reasoning embodied in the original practice.

First, recall that the figures in the original Euclidean practice are constructed *only* by using straightedge and compass.[102] Actual physical drawings – I stress again – can be identified (preliminarily to representing an informal practice formally) with mathematical objects of any sort; the mathematical objects chosen will vary, of course, in how adequately they capture the original practice. But to identify physical drawings with any particular set of abstracta involves decisions of certain sorts that bear directly both on the question of how the figures in the drawings are being interpreted, and specifically, on how those figures are being interpreted to pick out certain items in the formal domain *and not others.* The geometrical properties of the actually drawn figures don't all by themselves dictate an answer to what abstracta they should be identified with. For example, we may choose to identify the physically drawn lines with various nonlinear curves of all sorts – not just straight lines – on the grounds that such physically drawn lines (especially when drawn badly, as they can be) *really do* approximate nonlinear curves of various sorts more closely than straight lines.[103] The same point can be made about the curves generated using a compass – they needn't be literally circular but only approximately circular, and we may take them to better approximate something noncircular. Miller's FA and Mumma Eu are formal systems based on an interpretation of Euclid's figures that identifies them syntactically with what at first glance appear to be quite broad classes of mathematical objects.

Miller, for example, defines the notion of a "nicely well-formed diagram" in terms of four primitive symbols (compare this to Shin (1994) – the strategy is the same one): frames, dots, unbroken lines, dash-lines, and slash-marks.[104] Any diagram

[102]In addition, points can be placed into the diagram – pretty much anywhere you want to drop them (subject, of course, to resolution considerations that prevent points from being too close to one another). This doesn't falsify the claim I just made about *figures.* In the Euclidean context, you *can't* drop a bunch of points in succession and use *them* to design a nonlinear/noncircular curve (that goes through all of them). The automatic existence of various (infinitely many) one-dimensional curves going through a set of points goes quite beyond the Euclidean system. Any one-dimensional curve that connects *any* two points *must result* from the operation of straightedge or compass.

[103]Miller (2007, 3) stresses right at the beginning of his study, that the "different kinds of line segments" that appear in Euclidean diagrams "do not have to really be straight."

[104]"Dash lines," are broken lines, for example, -----, as opposed to unbroken lines, for example, ——. I'm taking a few expository shortcut liberties in my description of Miller's approach, for example, "marked diagrams" are defined, not by the introduction of slash-marks as part of the primitives for diagrams, but as an extension of diagram equivalence to "marked diagrams" (see Miller 2007, 31).

occurs within a frame and it's composed of a finite number of dots, unbroken lines, and dash-lines – the unbroken lines represent Euclidean lines (although they needn't be straight) and the dash-lines represent arcs of circles (although they needn't be circular arcs). The definition of nicely well-formed diagrams includes a list of conditions that force unbroken lines and dotted lines to behave roughly (that is, topologically) like Euclidean lines and circles. (For example, one condition is that two "circles" intersect no more than twice.) To replicate Euclidean reasoning, these diagrams need these and additional characterizations. The result is that, again roughly, Miller's "nicely well-formed" diagrams can be associated with the original Euclidean diagrams. Miller then designs the actual proof-system in terms of topologically equivalent diagrams.[105]

Mumma's Eu, on the other hand, proceeds in a strikingly different way.[106] Instead of correlating Euclid's physical diagrams with a domain of rectangles containing arbitrarily nonlinear curves (except for obeying certain conditions, as mentioned above) and dashed curves (also, generally, noncircular, except for obeying certain conditions), etc., Mumma's domains are finite rectangles defined by square arrays of evenly spaced hollow ("○") and solid ("●") dots. The dots can be connected by lines, and some of those lines represent Euclidean lines; the finite lines, however, that are part of various convex polygons (together) represent circles. Like Miller, Mumma starts with an initial characterization of diagrams (call them "pre-diagrams") but then, like Miller does with *his* pre-diagrams, Mumma places an equivalence relation on them. *A* completion (nonunique) of a diagram D is one, D*, that's like D except that it has additional evenly spaced hollow and solid dots – enough so that every intersection point between the drawn lines and rays occurs as a dot. A definition of equivalent diagrams in terms of completions of them is then given by Mumma.

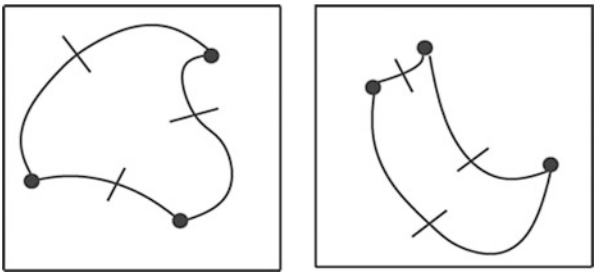
The result still deviates greatly from the informal rigorous diagrammatic practice – the experience of working in Mumma's system, specifically, deviates phenomenologically from Euclid's original diagrammatic practice. Why? For two reasons. The first is relatively insignificant: the diagrams we work with in Mumma's system involve visually recognized lines and polygons – not circles. Circles are conventionally represented by polygons. But the important difference should be visible, even given my rather sketchy description of the approach: the visibility of the array of hollow (and solid) dots that diagrams occur on. This transforms proofs in the Euclidean context – where diagrams are built upon one another by dropping points arbitrarily into what appears to be a manifold, and by drawing lines between points,

[105]This equivalence relation is technically involved – using a mapping between nicely well-formed diagrams and planar graphs. In terms of this mapping, two diagrams are defined as equivalent if they have the same corresponding graph structure. The different cases that must be considered in one of Miller's proofs then correspond to how many diagrams with differing graph structures become involved. It's worth pointing out, when comparing the reasoning in Miller's system with that of the original Euclid that the computer (which carries out the reasoning in Miller's system) works not with diagrams but instead with planar graphs. I make something of this shortly.

[106]I'm here following Mumma's (2019), where he lays out the modified system nicely.

and otherwise, by drawing lines arbitrarily and by drawing circles arbitrarily as well – into something experientially very different. The array-structure of the Euclidean context – in ordinary Euclidean proofs – as I said, isn't directly visible; it's required only by virtue of the incapacity of the practitioners to resolve arbitrarily small differences between drawn figures.

This suggests that Miller's identification of Euclidean figures with curves results in something phenomenologically much closer to the informal Euclidean approach than Mumma's is: it's one, recall, where figures are (apart from certain conditions) are arbitrarily nonlinear and noncircular – despite being "lines" and "circles." The manifold-flavor, that is, of the original diagrammatic proofs seems preserved. Nevertheless, Miller's approach isn't phenomenologically closer to Euclid's original practice than Mumma's reincarnation of it is. One reason (there are several) is because of something about the original Euclidean practice that's right on the surface. As Mumma (2008b, 259) points out in his review of Miller (2007), rather strange – from the Euclidean perspective – diagrams can appear in Millers' system. Mumma's example (his Fig. 3) – of "two ways to represent an equilateral triangle in **FG**" – follows:



Mumma (2008b, 262), further criticizing Millers' approach, writes (italics and boldface his):

> . . . when a case-heavy **FG** formalization is laid beside Euclid's original version, the original does not appear deficient. Rather, the multitude of cases generated by the rules of FG appear excessive. The geometric differences recorded by a case-branching often do not seem material to the issue the proof decides.

This criticism, however, largely misses the point. It primarily focuses on the sheer number of cases; but a formalization captures the phenomenology of an informal rigorous mathematical practice not by (even somewhat closely) matching the *number* of cases that appear informally; what's important is what *kind* of cases are involved: do the cases that are required by a formalization of Euclid's approach track the spirit of why the particular diagrams in the original practice come up? More important is this consideration: does the phenomenology of the original diagrammatic practice match (at least to some extent) the phenomenology of the formalized practice?

Mumma's criticism focuses on the fact that Millers' approach multiplies the number of cases that a Euclidean proof requires in a way that goes beyond the cases that the Euclidean approach seems to consider – even when that approach is supplemented with additional diagrams, as occurred later in the geometrical tradition. But the way that Millers' approach deviates from the Euclidean approach, although indicated by Mumma's Fig. 3, isn't stressed by him. This is that it treats the geometric information a diagram supplies as irrelevant to the proofs. It may be true that the geometric information a diagram supplies is irrelevant to the proof procedures that Euclidean geometry licenses but it's surely not irrelevant to how we come to *understand* these proofs because of how the diagrams *look.* Miller's approach is designed to facilitate a certain computer implementation, CDEG.[107] But the computer doesn't manipulate Miller's *diagrams*; it manipulates the *graphs* that the diagrams determine nonuniquely. Thus, the proof-practice Miller's formalization licenses amounts to this. A Euclidean diagram D is represented by a Miller diagram, M – more accurately, D is represented by a finite set of Miller diagrams. M, in turn, isn't itself manipulated according to a proof procedure; rather, M is used to generate a graph G, and it's G that's manipulated proof-theoretically. In turn, then, G is either transformed into programming code (which can be printed out), or into a canonical Miller diagram M*. This, it should be clear, is very far from the original Euclidean practice. In particular, Miller's approach cannot be used to explain what it is about Euclidean diagrams that makes the results they license so "intuitively" *comprehensible*.

In fact, neither Miller's nor Mumma's approach has even a hope of managing the replication of the understanding/insight that the Euclidean practice provides to its practitioners; this is because of the initial way both approaches mathematicize Euclidean diagrams. Return to the original practice for a moment. Three and only three sorts of primitive diagrammatic elements show up: points, lines, and arcs of circles. *That's it.* Diagrammatically speaking, there are no other entities that appear *in* diagrams. Of course it's true that what's drawn (physically) can unpleasantly deviate from what we (conventionally) take points, lines, and circles to *resemble.* But the expected (and allowable) response, if the intention is to formalize the practice in a way that captures the original reasoning, isn't to formalize the original proof-processes where badly drawn figures that deviate from what looks like circles and lines *become crucial to the cases that a proof must accommodate.* Rather, the response is: "that's drawn badly; I can't see what's going on; can you make a better one?"[108]

This means that, in a formalization of the *syntax* of a formal Euclidean diagrammatic system, the appropriate domain (the appropriate *alphabet*, as it were) should

[107] I'm here relying on Miller (2007, Sect. 3.5).

[108] See Manders (2008, 71) on how the original Euclidean practice tried to avoid "sensitive situations." This dovetails with what I've earlier called exclusion idealizations (defined in Sect. 2).

be one in which *only* circles, lines, rays, and points appear, and where these items are restricted in their sizes (and how they interact with one another) so that they are (by eye) surveyable.[109] The formalization approach I'm sketching treats deviations from circularity and linearity not as diagrammatic phenomena to be captured or replicated in the syntax of the resulting formalization but instead, as it was in the original practice, as items to be *excluded*.[110] The cost of not doing this – as I've indicated – is to "replicate" the informal practice by a formalization that doesn't respect the phenomenological qualities of the original practice – this matters because those phenomenological qualities are what underlie our experiences of understanding proofs, specifically the "aha"-epiphany. I now turn to an explicit discussion of this and its relation to the generality problem.

12 Phenomenologically Faithful Embeddings of Algorithmic Devices in Formal Algorithmic Systems

The phenomenological flavor of a proof is a somewhat elusive matter (and so it's dangerous to venture saying anything about it). Nevertheless, it's, importantly, what I think philosophers are tracking when they describe certain proofs as explanatory and others as unexplanatory; the same phenomena – the phenomenology of a proof (how the proof is experienced) – is also being tracked by mathematicians when they describe certain proofs (or, as commonly, certain subject areas – with their typical proofs) as beautiful or ugly. I'm not going to dwell on issues about explanation in mathematical proof – this is too tangled and complex to take up even in a chapter this big. But I do want to describe the phenomenological aspects of informal proofs enough to give a rough characterization of how – and to what extent – formalizations capture these qualities of informal proof practices.

[109]This characterization of the syntactic domain is, of course, subject to the persistence and exclusion idealizations given in Sects. 2 and 4, and later. Despite appearances (i.e., the phrase "by eye"), I'm describing a purely mathematical exclusion condition on circles, lines, rays, and points: that is, we translate an empirical fact about average-resolution capacities into numerical lower-limit conditions on admissible circles, lines, and rays.

[110]I don't know of, at the moment, any formalization of the original Euclidean practice that approaches it the way I'm suggesting here. I don't see any reason, however (offhand), to rule it out. I'm gambling in saying this, however, because an approach to formalization can always be ruled out by unexpected technical obstacles. Illustration: The original Venn diagrammatic practice used overlapping circles. In order to generalize the approach to finite collections of sets (recall Sect. 8, specifically footnote 61), Shin – relying on a result due to Polythress and Sun (1972) – replaces the circles of the original practice with closed curves. I should add that I don't claim that the resulting formal system I'm sketching an approach to won't be heterogeneous, rather than purely diagrammatic. It might be, and it might respect some descendant or other of Manders' exact/co-exact distinction. But the informal practice underdetermines exactly what belongs to the language-based part of the formal system and what belongs to the diagrammatic part – for example, exact-numerical identifications between figures and their parts might be indicated diagrammatically by slash-mark notation or by language-based characterizations accompanying the diagrams.

Recall the initial discussion of the "aha"-epiphany described by Feferman (2012) in Sect. 3. Recall, for that matter, the constraint on derivational accounts, *Phenomenology*, that such accounts must explain why formal transcriptions of informal rigorous mathematical proofs don't replicate that experience. The first point is that, although formalizations are often described as lacking the epistemic "aha, now I see why this is true" epiphany that's sometimes experienced with an informal proof, this simply isn't true of formalizations, *in general*: they needn't be so lacking. Other philosophers who contrast informal rigorous mathematical proof with formal derivation disagree with me.

Giaquinto (2008a, 27) writes, for example, "...there is a reason to avoid going formal: in a formalized version of a proof, the original intuitive line of thought is liable to be obscured by a multitude of minute steps." It should be clear from the foregoing that, even though it's a requirement on a formal system that its syntax be completely given, it's not a requirement that the syntactic transitions licensed by the formal system involve minutia.[111]

Rav (2007, 315, and elsewhere) suggests that formalizations *must* fall short in relation to their informal cousins because built into the appreciation of informal rigorous proofs and not their formalized cousins are the meanings of the terms used in the sentences of that sort of proof. He writes: "I hold that mathematicians' manner of reasoning and inferences are based on *meanings* and an informal notion of truth that a formal deduction calculus cannot capture" (italics his).[112] Rav (1999, 12) some years earlier puts his claim about the experiential distance between informal proofs and formalizations of them far more melodramatically (italics and spelling his):

> Once we have crossed the *Hilbert Bridge* into the land of meaningless symbols, we find ourselves on the shuffleboard of symbol manipulations, and as these symbols do not encode meanings, we cannot return *via* the Hilbert Bridge and restore meanings on the basis of a sequence of symbols representing formal derivations. After all, it is the very purpose of formalisation to squeeze out the sap of meanings in order not to blur focusing only on the

[111]This is an impression many have from a familiarity with formal language-based systems that involve, say, a lot of parentheses, or where the transitivity and symmetry of "&," and other connectives aren't built into the syntactic recognition procedures. All that's required of a formal system, however, is that its syntactic transitions be effectively recognizable. Thus, a formal system can be substantially modified by "shortcuts" and abbreviations," that make it far more user-friendly – as long as these are open to intuitively effective recognition procedures. I should add that in past work I've also contrasted formal and informal proof in just this way (mea culpa).

[112]A position in the same neighborhood is expressed by Larvor (2012, 723) when he writes: "The benefit of viewing inference as action is that we can see how the *subject-matter* of informal arguments shapes and contributes to inferences" (italics mine), and by De Toffoli and Giardino (2015, 332–333) who explicitly follow Larvor in this, writing: "In Rolfsen's proof, we saw that among the permissible actions on the pictures are continuous transformations. These are part of the background material in the sense that any topologist knows immediately that these transformations *can be interpreted* in terms of homeomorphisms. The validity is thus based on the 'practice' ..." (again, italics mine). Notice that De Toffoli and Giardino describe "continuous transformations" as permissible actions on *pictures*. This is a confusion.

> logico-structural properties of proofs. Meanings are now shifted to the metalanguage, as is well known.

This misleads how much informal phenomenology – specifically the experience of *meanings* – can occur in a formal setting. First point: meanings aren't, in any case, shifted to the metalanguage, as Rav writes – rather the meanings of the object language expressions are *given in terms of* the metalanguage (recall the discussion of this in Sect. 10). Second: In any case, our ability to psychologically invest formal terms with meanings should already be obvious from the centuries-long practice mathematicians have had with the routine introduction of new terminology into mathematical settings. Indeed, the point should be clear from the ubiquitous practice already in place with ordinary words – we (collectively) both modify the meanings of words and phrases already in public possession and routinely introduce new terms and phrases by indicating their meanings. What's striking, in addition, is that we can have the experience that a meaningful expression has been introduced (and that we grasp it) without being given a definition but just an illustration or two – typically all that's presented in dictionaries. Many of us continue to learn what we experience as new meaningful expressions all our lives.[113] Nothing prevents us doing the same thing to new terminology that's been introduced in a formal setting. (Indeed, we *regularly* do this; Rav's remark, quoted above about Hilbert's Bridge is especially surprising in light of the fact that, even when focusing on syntax, it's rather hard not to interpret certain logical expressions – notably "&" and "$\exists x$," among others – as having *fixed* meanings derived from natural language.)

At this juncture, it's natural to attempt a preliminary characterization of the phenomenological closeness of a formal system to an informal practice that it's taken to formalize. Consider an algorithmic device **A** (diagrammatic or language-based) that's employed in an informal rigorous mathematical practice. Describe that device as *embedded* in a formalization **F** if

(i) There is one-to-one mapping *M* of the elements of **A** to the syntactic elements of **F**. (*M* doesn't have to be "onto" – **F** can, and usually does, have additional elements.)

[113] I discuss our experience of meaning, in natural languages in Azzouni (2013b). Especially pertinent is a common experience that we have – with respect to certain expressions – of their being meaningful even though we don't know what their meanings are (Azzouni (2013b), 93). It's true that there are cases where we cannot experientially dislodge a meaning that we experience a word to have and replace it with another (e.g., "cold" for "hot") as I there discuss (Azzouni (2013b, Sect. 1.4). Nevertheless, we're quite good at introducing new words and, in specific contexts, like mathematical ones, of even setting aside the meanings that words apparently have – for example, stripping away the impression that "and" has a temporal dimension (e.g., "John brushed his teeth and got out of bed"), as we routinely do in mathematics.

(ii) Given any two elements D_1 and D_2, of **A**, given an intuitively effective-recognizable obtainability relation $\vdash_{\mathbf{A}}$, for that practice, and given that syntactic transitions $\vdash_{\mathbf{F}}$ for **F** are defined, then if $D_1 \vdash_{\mathbf{A}} D_2$, we have $M(D_1) \vdash_{\mathbf{F}} M(D_2)$.

So, given a formalization **F** and an algorithmic device **A**, call the mapping M that obeys (i) and (ii) an *embedding* of **A** into **F**. We say, further, that M is *phenomenologically faithful* to **A** if the experience of the inference, accompanying a syntactic transition $D_1 \vdash_{\mathbf{A}} D_2$, is relatively similar to the experience of the inference accompanying the syntactic transition $M(D_1) \vdash_{\mathbf{F}} M(D_2)$.

Why have I introduced the qualification "relatively similar" into the definition of "phenomenologically faithful"? Because (I take it) if we change the notation an inference is couched in – even minimally – we, as a result, change the experience at least somewhat: A = B, therefore, B = A is an experience of an inference that feels (slightly) different from $x = y$, therefore, $y = x$. There is, however, a bit more to say about the experience of inference – and the psychological mechanisms – that will give more content to the above characterization of "phenomenologically faithful." I'll turn to that in the next section.

I do need, at the outset, to stress two important aspects of phenomenological-faithful embeddings of algorithmic devices into formalizations. One is that the process of so embedding these devices invariably involves the inclusion of additional proof procedures (in the formalization) that don't possess the phenomenology of the original practice. This is the case no matter how carefully we choose the diagrammatic abstracta to match the original physical diagrams; and *this* is because the phenomenology itself is often fragmentary in its reach (our "aha"-epiphany, e.g., occurs only with fragmentary aspects of any informal proof-practice – let alone the extension of such a practice that results from formalization). A second point is that because we sometimes have free-ride experiences with respect to an informal rigorous proof, the actual algorithmic device involved in such a proof isn't itself – even informally – characterized. The algorithmic devices involved in such visual proofs remain tacit even in the informal mathematical practice. I'll round out this section by giving examples of both of these cases.

Start by recalling the original Venn diagrams, and comparing them to Shin's (1994) formalizations. Our "aha"-epiphany with the original diagrams – immediately seeing ("free riding") certain implications only occurs when a small number of circles are involved (about three). Furthermore, the experience is sensitive to circularity: change the figures involved into different (weirdly shaped) closed curves and the experience vanishes (one has to work out the implication visually – take a few moments to "see it"). That is, the immediate-recognition property doesn't work with other sorts of figures, as the reader can easily determine. As I'll discuss in the next section, this is because the particular "inference packages" we employ to recognize

the implications of Venn diagrams are (perceptually) content-sensitive: they work only with certain sorts of figures, and visual patterns, and not others. Thus, any formalization – especially an ambitious formalization (e.g., one, like Shin's, which is designed to capture, say, full monadic reasoning) – and even one that's otherwise diagrammatic, will replicate the phenomenological experience we have with the original diagrams only with a few of the formalized diagrams.[114]

I'll now illustrate the second kind of case with the diagrammatic proof of the "mutilated chessboard." Here's a description of it due to Black (1946, 157) that I've borrowed from Tanswell (2015, 305):

> An ordinary chess board has had two squares – one at each end of a diagonal – removed. There is on hand a supply of 31 dominos, each of which is large enough to cover exactly two adjacent squares of the board. Is it possible to lay the dominos on the mutilated chess board in such a manner as to cover it completely?

And here's the solution, quoted from Gardner (1988) – but I'm again taking the quote from Tanswell (2015, 305):

> It is impossible . . . and the proof is easy. The two diagonally opposite corners are the same color. Therefore their removal leaves a board with two more squares of one color than of the other. Each domino covers two squares of opposite color, since only opposite colors are adjacent. After you have covered 60 squares with 30 dominos, you are left with two uncovered squares of the same color. These two cannot be adjacent, therefore they cannot be covered by the last domino.

This proof and many other diagrammatic proofs[115] do *not* occur against an informal proof-theoretic background the way, for example, that the ancient Euclidean diagrammatic practice (and the Aristotelian syllogistic tradition) do. But it's not difficult to see what such an informal proof procedure would look like – it's not difficult to *create* one. An informal rigorous mathematical two-color-domino practice (on an ordinary chess board) would involve the placing of domino pieces on the board. The results – some immediately seen and others shown – would be various generalizations about what sorts of patterns of domino placements on the chess board are possible, and which aren't. Another family of results – some immediately seen and some not – is about which initial placements (of a few dominos) can be "completed," into a full covering of the board with dominos (with certain color patterns) and which can't. Lastly, one can consider results of domino-tiling various mutilated chess boards, as in Black's posed

[114]The problem is already visible in informal practices. That certain proof procedures can be characterized quite broadly using persistence idealizations runs well beyond when such proofs are convincing and understandable. (So my use of "intuitive," in Sect. 4 and elsewhere throughout this chapter, in, for example, "intuitively effective function" has to be understood as a somewhat specialized usage of the word – introduced because of Turing's own use of the word (see footnote 28).) Part of the phenomena here is described by Manders (1995, 107, and elsewhere) as "appearance control."

[115]for example, the proof in footnote 118

problem. In turn, these just-described informal practices can be embedded in one or another formal diagrammatic system that's phenomenologically faithful to these posited informal-proof practices. These can – Hilbert's thesis tells us this – be otherwise formalized in various language-based formalizations.[116]

13 Inference Packages (Embodied Algorithms) and Phenomenological Faithfulness

It's undeniable that the use of certain diagrams enormously facilitates our abilities to reason to and from various mathematical results these diagrams are taken to depict. Related to this is that diagrams also seem to enable us to understand the reasoning involved, and often to provide an understanding of the content of the results and assumptions (that the results follow from) that language-based formal transcriptions of that reasoning fail to provide. One approach to explaining this focuses on the apparent similarity between the elements of certain diagrams and what they're diagrams of – what I earlier called a "resemblance interpretation." If *A* pictures *B*, then we can use *A* to understand aspects of *B*. A photograph, for example, or a drawing, replicates certain aspects of the thing photographed or drawn, and by directly considering the photograph and the drawing, we can understand (or realize) something about the things themselves.

Despite the temptation to centralize visual similarity – resemblance – in an explanation of the just-described value of diagrammatic proof, pressing a resemblance interpretation looks bizarre almost on the surface; and it has led to serious mistakes among professional mathematicians when evaluating the value of diagrammatic proofs; these mistakes continue to affect contemporary philosophical discussions of diagrams. To start with, consider the case of Euclidean figures: points and lines. Given what these are supposed to be, it isn't even *sensible* to describe them as "resembling" physically drawn points and lines. Apart from the fact that no physically drawn figure lacks the dimensions that the mathematical objects, points and lines, officially lack, there is the related problem that the physical items have –

[116]Tanswell (2015) and Tanswell (forthcoming) press against derivation accounts of informal rigorous mathematical proof (Sect. 1) his "underdetermination" problem – that such accounts have the problem that attempts to capture the epistemic properties of informal proof via formalizations face the fact that there are equally good (equally close) formalizations that nevertheless involve drastically different mathematical ideology. Although derivational accounts (Sects. 1 and 3) have been rejected here, Tanswell (forthcoming) frames the underdetermination problem in a way that threatens a different claim that I've made in this chapter – that in general, phenomenologically faithful formalizations for informal rigorous mathematical practices exist. He writes of the mutilated chess board proof, in particular, that it "is not obviously algorithmically checkable, so if it is claimed to be then we would like to see the algorithm that does so given explicitly . . .." His suggestion is that if it isn't, then any embedding of the proof in an algorithmic system will face underdetermination. The remark that a system of recognizing patterns of two-color dominos on what amounts to a finite array isn't "obviously algorithmic" is puzzling: it looks exactly like other cases of intuitively effective procedures that – via Church's thesis – are Turing computable.

geometrically speaking – *the wrong* "*shapes*." Notice the point. This isn't a criticism of one or another theory of "abstraction" as a theory of understanding – that we *understand* what a line is, say, by abstracting a certain approximate aspect of drawn lines: pure "straight-line directionality," or whatever. It isn't even to criticize a view of understanding that claims we understand mathematical straight lines via "approximations" of them by visually thin lines. Some theory or other like this about how we understand points and lines might be true. The point, rather, is the resulting objects – *abstracta* – even if we can *understand* what they are supposed to be, aren't *seeable.* Despite whatever value a theory of abstraction has as a theory of understanding, it has none as an explanation of the value of diagrams of lines and points taken as "visually resembling" actual points and lines.

Similar complaints can be made about the diagrams that appear in other diagrammatic practices. Shin's diagrams don't visually resemble (in any sense) classes or their relationships to one another: two circles that overlap don't *visually resemble* the relationships two sets have when they have elements in common – this isn't even true if the overlapping region is shaded. Finally, recall (footnote 112, Sect. 12) that De Toffoli and Giardino (2015, 332–333) treat pictures and what's pictured as so similar that they feel they can describe diagrammatic actions on pictures as continuous transformations.

Mistaken resemblance interpretations are very old ones, and their implicit operation is one of the central factors behind the late nineteenth-century repudiation of visual methods of proof. Unaware of the diagrammatic constraints on Euclidean diagrams that were necessary to making Euclidean diagrammatic proof coherent, pictures of functions – printed drawings of curves in books and articles (let's be accurate about what the diagrams in question *were*) were treated as depicting functions, *of any sort*, by sheer visual resemblance. More accurately, drawings of functions – ink on paper – were treated as yielding "intuitions." Intuitions, so called, can only be understood in this case as *visual imaginings* of the curves in question – the scope of those visual imaginings supposedly telling us what sorts of curves are and aren't possible. The implicit idea was this: diagrams elicit our visual faculties. But when we so-visualize functions, we can get it very wrong. This, however, is the wrong picture of diagrams of functions (or the diagrams of any mathematical object, really). We cannot "visualize" functions any more than we can "visualize" lines – and for the same reason. Functions – if characterized geometrically – are one-dimensional[117]: that means we *can't* and *don't* visualize *them*.

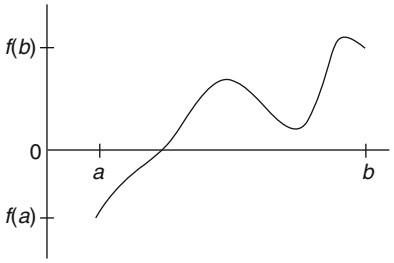
Giaquinto (2008a, 35) channels this nineteenth-century mistake about the role of visualization in mathematics. He writes:

> When it comes to analysis mathematicians of the nineteenth and twentieth centuries were right to hold that visual thinking rarely delivers knowledge Visualizing cannot reveal what happens in the tail of an infinite process. So visual thinking is unreliable for situations in which limits are involved, and so it is not a means of discovery in those situations, let alone a means of proof.

[117]Even "space-filling" curves are, nevertheless, one-dimensional!

The letter of this remark is correct: We cannot design a diagrammatic proof procedure that will handle the tails of infinite processes.[118]

But this remark occurs nested (as was also true of nineteenth- and twentieth-century objections to diagrammatic proofs by mathematicians) among misapprehensions about (informal) diagrammatic proof. Consider this well-known informal diagrammatic proof of the intermediate zero value theorem:



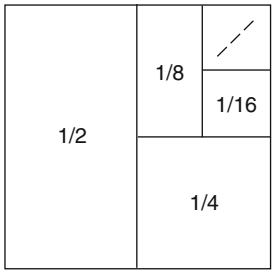
Giaquinto (2008a, 35) criticizes Brown (1999) for suggesting that "reflection on the diagram [above] suffices to prove the Intermediate Zero Theorem." Giaquinto (2008a, 36) notes there are many functions visually indistinguishable from a continuous smooth function defined on the reals, as above, of which this theorem is false.

But speaking this way of "visual thinking" (it should be clear) overlooks that an informal rigorous diagrammatic practice that treats diagrams of functions, as above, as referring to (and only referring to) smooth continuous curves, *does show* the intermediate zero theorem for that class of curves.[119] Diagrammatic practices must be curtailed sharply in what mathematical items are to be treated as the referents of their elements, and thus, what generalizations they can be taken to have shown. This

[118]Actually, no. Giaquinto's remark, about the inability of diagrammatic reasoning to capture "the tails of infinite processes," is *false*, as the following proof that ½ + ¼ + . . . = 1, indicates:

Proof:

Proof:



What's true is that no diagrammatic proof-procedure can be designed that adequately handles all the tails of infinite processes – more accurately, that handles all possible functions – as "function" is understood in the contemporary mathematical setting.

[119]The informal proof, of course, can be successfully extended to smooth curves with a finite number of discontinuities, and other classes of functions. I omit further discussion of this.

can't be done on the basis of vague impressions of "resemblances" between diagrams and mathematical abstracta.

The same point can be made against Giaquinto (2008a, 31) when he writes:

> Missing an untypical case is a common hazard in attempts at visual proving. A well-known example is the proof of Euler's formula V – E + F = 2 for polyhedra by 'removing triangles' of a triangulated planar projection of a polyhedron. One is easily convinced by the thinking, but only because the polyhedra we normally think of are convex, while the exceptions are not convex. But it is also easy to miss to miss a case which is not untypical or extreme when thinking visually. An example is Cauchy's attempted proof (Cauchy 1813) of the claim that if a convex polygon is transformed into another polygon keeping all but one of the sides constant, then if some or all of the internal angles at the vertices increase, the remaining side increases. . .. The frequency of such mistakes indicates that visual arguments often lack the transparency required for proof; even when a visual argument is in fact sound, its soundness may not be clear, in which case the argument is better thought of as a way of discovering rather than proving the truth of the conclusion.

This, as earlier, is to use the generality problem – which, recall, is a problem *all* proof-procedures face, diagrammatic *and* language based – against a diagrammatic proof procedure which, otherwise, can be syntactically characterized coherently. There is nothing wrong with taking the above diagrammatic proof-procedure to show Euler's result for *convex* polygons. What follows from the frequency of such mistakes isn't that "visual arguments often lack the transparency required for proof" – in particular, that it isn't obvious that they're sound. Soundness turns crucially on interpretation – and what this shows is that interpretations must be chosen with care; this is especially the case when an informal practice is being embedded in a formal practice. One thing these failures *do* show is that diagrammatic proofs often have restricted domains of soundness that are narrower than the range of abstracta that mathematicians are concerned to show results about.[120] But there is nothing obvious, about diagrammatic proofs, that shows this will always be a problem, when comparing such proofs to language-based proof procedures.

My point is that Giaquinto's analysis presupposes (something nineteenth-century mathematicians presupposed as well) resemblance interpretations at work: visual proofs represent functions by drawings that resemble these functions. But this is wrong, and as a result the wrong interpretations are imposed on diagrammatic practices – sometimes (as with the case of functions), the drawings of curves on a page are being confused with the functions they're being taken to depict, with the result that visualization-proof methods are saddled with the expectation that they're responsible for depicting functions for which no syntactic diagrammatic system has ever been characterized, even informally. At root, as I've mentioned, are confusions between the diagrams themselves (in this case, drawings on paper) and functions that can't be seen. The use of the word "intuition," as used in "it's intuitive that a function can't be everywhere continuous but not differentiable anywhere" enables a

[120]This is especially the case with the notion of a function, which from the eighteenth century to the nineteenth century, drastically changed in what it was (implicitly and explicitly) taken to refer to.

confusion between pictorial methods of proof and the items being studied. Lesson: Vague intimations of visual resemblance don't show that a cogent diagrammatic practice has been established; worse, such vague intimations don't sensibly provide interpretations when a diagrammatic practice is cogent.

I've complained about one error that the visual-resemblance views make: confusing a method of *understanding* abstracta with a method of *visualizing* abstracta. This is a failure to realize that a visual process can be used to *understand* something without it supplying a *visualization* of that something.[121] But there is a second way that focusing on visual resemblances – as the machinery that governs the implicit interpretations for diagrammatic elements – goes wrong. This is that there is an implicit *suggestion falsi* that a diagram works its magic by capturing structural resemblances between pictorial elements and the abstracta they depict.[122]

This second important mistake goes far beyond diagrammatic proofs; it infects views of (scientific) modeling generally. Although there is a narrow class of models that can be described as ones that capture aspects of what they model purely by virtue of the models embodying structural resemblances to the items modeled, this is generally not the case.

Consider a computer simulation of a certain dynamical process – the flow of water through a pipe, for example. It would be a mistake to think that we can rely on the simulation to predict certain aspects of that process – when we can – because what happens "in" the computer "resembles" the flow of water through a pipe. That's, frankly, pretty absurd – although this absurd suggestion is made natural by the misleading label: simulation. What happens with a successful computer simulation is quite different: the computer simulation has been designed with certain aspects of water flow in mind – more specifically, it has been designed by taking into consideration certain events that occur in (or during) the flow of water through a pipe, and by ignoring many other ones. Water flow, in particular, is an extremely complex (and badly understood) process where a great deal is going on. It would be a naïve analysis to divide – as it were – water flow into levels: the quantum level, a higher level (where the water flow is approximated by continuum-fluid idealizations), etc. What's actually going on is that certain effects in and to the water are being taken account of and other ones are being ignored, where these effects cross

[121] See Azzouni (2020) for further discussion of this distinction between imagining and conceiving.

[122] See Giaquinto (2008b). It's perhaps no surprise that Giaquinto takes the cognition of abstracta-structure seriously as an explanation of the value of diagrammatic proof: it's a natural move for someone who, to begin with, thinks that resemblance to abstracta is how diagrammatic elements refer to those abstracta. See Resnik (1997), for an earlier book-length argument for this kind of epistemic position vis-à-vis abstracta. Notice that a nominalist must reject this picture of the understanding of proof in any case: I'm not presupposing my nominalism, however, in raising any of the objections of this paper.

"levels" in intricate and subtle ways.[123] The hope, sometimes dashed and sometimes fulfilled, is that the aspects of a phenomenon (water flow) that are being taken account of – by approximations, usually – are ones that will enable the model to capture certain causal effects of that phenomenon (e.g., in the case of water flow the average pressure on the inner pipe surface) while ignoring other ones (e.g., in the case of water flow, changes in temperature of the inner pipe surface). As I said, it would be naïve to impose a structure-picture on such models and what they model – although this is, imaginatively, extremely natural to do. Unfortunately for what's psychologically natural here, the actual interaction (causal and otherwise) between what's being ignored by a model and what's being taken account of is too complicated for that. The process can be *imagined* – misleadingly, to repeat – as one in which the water, in the case of water flow is, at a certain "level" being structurally modeled by the computer simulation. But this, it must be stressed again, isn't accurate to what's being retained and what's being ignored by the model – for example, what's being ignored aren't simply the quantum-mechanical, discrete, elements of the water-flow phenomenon.

Instead, and this alternative characterization of the computer simulation directly applies to diagrammatic proof as well, there is a body of *statements* – "predictions," in the case of water flowing through a pipe. And the model is a piece of computer machinery (that yields statements of the same form as the predictions) that we hope will replicate those predictions that are *true*.[124]

Summary: presumed visual resemblances between diagrammatic elements and the abstracta they supposedly resemble fool mathematicians and philosophers into thinking, in the case of drawing curves, that these resemblances are the proof-theoretic and interpretational machinery of diagrammatic proof – that is, that visual resemblances supply both intuitively effective recognition procedures and visually determined (by resemblance) interpretations for diagrammatic elements. These are mistakes.

14 Inference Packages and Shin on Perceptual Inference

Sun-Joo Shin (1994, Chap. 6) offers a more sophisticated theory of diagrammatic reasoning than resemblance interpretations do. Central to her view are the roles of *perceptual inference* and *convention* which she uses to explain in what ways, and to what extent, any specific formal system is diagrammatic and in what ways and to what extent it isn't. The difference between the use of perceptual inference and the use of convention (when looking at something), on her view, is that conventions

[123]Consider the fact that gravity is relatively weak if you're small enough. Your biological mechanisms for handling your recognition of "up" and "down" can't turn on gravity as it can for bigger things. Similarly, in engineering design, certain effects, wind, torque, etc. can be ignored when the items (bridges, shoulders) are certain sizes, and not otherwise. How, and to what degree, causal effects can be ignored or minimized by a model is badly captured by thinking in terms of "levels."

[124]Exactly how inferential practices capture the supposed properties of mathematical entities will be described in terms of our capacity to "simulate algorithms" – where I'm using "simulate" in the same misleading way it's used above. See Sect. 14.

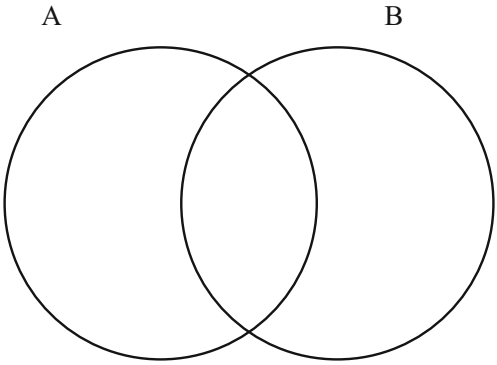
need to be learnt; on the other hand, when we use perceptual inference, we exploit aspects of a diagram that we don't have to learn how to use. Importantly, she thinks, the respective amounts (as it were) of conventionality and perceptual inference involved in our ability to navigate linguistic texts, diagrams, and pictures comes in degrees. A photograph has no conventional elements, nearly enough: we use and only use perceptual inference to recognize what visual elements in a picture refer to (and, therefore, how a photograph depicts things to be). A pure language-based piece of text, using symbols, is entirely conventional. Diagrams are in-between – usually involving both conventional elements and perceptual inferences.

The examples Shin explicitly gives, and others that we can easily apply her distinction to, make that distinction tolerably clear. A depiction of the seating arrangements of Tom, Susan, and Mary like so:

Tom Susan Mary,

involves convention insofar as "Tom" refers to Tom, "Susan" to Susan, and "Mary" to Mary; it involves perceptual inference insofar as the side-by-side seating arrangement of Tom, Susan, and Mary is recognized to be as depicted above.

Similarly, in Venn-I, it's a convention that the closed curves and rectangles represent sets, and – specifically – that their interiors represent the interiors of those sets.[125] It's equally conventional, in a language-based setting, to introduce capital letters, A, B, . . . for names of sets, lower-case letters, a, b, . . ., for names of elements in sets, and to introduce a symbol, $\in$, for membership. Shin takes the distinctive roles for perceptual inference and for convention in Venn-I, as opposed to a language-based class system to contrastively emerge when we consider relations between sets. In the language-based case, we need to introduce a *new* syntactic device to conventionally represent intersection: $\cap$, so that "A $\cap$ B" thus can represent the intersection of A and B. In the case of Venn diagrams, we don't need to do this. Consider, for example, the following figure:



Shin claims that, given the previous conventions, the interpretation of the common spatial area of the circle associated with A and the one associated with B *must be* the

[125] Shin (1994, 169) writes: "In Venn-I we adopt a convention that assigns a set to a basic region."

intersection of the sets A and B. This isn't, therefore, the introduction of a new syntactic convention; instead, we use perceptual inference, along with the earlier-mentioned conventions, to see what spatial area in the diagram represents the intersection of the sets.

Shin (1994, 161–162) similarly argues that if we already have in place a convention that (two-dimensional) boxes represent sets and dots represent individuals, then to represent the set-theoretic membership relation, one need only place a dot in a box. She adds, "Putting down an object *in* another object does not involve any new syntactic device. A spatial arrangement between a dot and a box represents a nonspatial relation, 'being a member of'" (italics hers).[126]

There's an important subtlety that Shin's remarks – as quoted – overlook. If we interpret dots and rectangles (and closed curves) – the lines of the figures, that is – as Shin suggests, then we need an additional convention that dictates that the *interiors* of squares and circles represent where the members of the corresponding sets are located. Even if we represent *area-filling* rectangles (as opposed to the borders alone) as sets, it's still open to us to conventionally dictate an item as a member of a set only if it appears *outside* the interior of the figure rather than inside.[127] Putting a figural element inside another figural element *is* a piece of (two-dimensional) syntax that needs to be interpreted, and the interpretation of which goes beyond the sheer convention that a two-dimensional figure (area-filling or otherwise) represents a set. We can see the point I'm making if we consider the typical language-based notation, Pa, in which a piece of syntax (concatenation) is interpreted as predication. The situation is exactly the same one.

Nevertheless, I think Shin's approach to diagrammatic reasoning is largely correct, insofar as she recognizes the role of what she calls perceptual inference. I now introduce some alternative terminology and make a few other changes to her approach. Perceptual inference involves a number of *cognitively embodied algorithms,* what I call *inference packages*.[128] Inference packages are modularized and content-specific.[129]

---

[126]She continues:

> An isomorphism between this spatial arrangement and the relation "being a member of" is not as perceptually obvious as an isomorphism between a spatial arrangement in a diagram [as in the Tom, Sally, Mary example above] and the relation "being to the right of." However, this isomorphism is more perceptually obvious than any linguistic symbol that a linguistic representation adopts, since no extra convention involving syntactic devices is required.

In adapting elements of her position, I'll remove talk of isomorphisms.

[127]For manageability, the shadings and dots, etc. to be placed outside squares could be conventionally quite close to the outsides of the figures.

[128]I borrow, in part, this discussion of "inference packages," and other aspects of visualization, from Azzouni (2005).

[129]Exactly how inference packages are modularized is a subtle empirical matter that I have to avoid saying much more about. There is more than one visual mechanism at work in visual perception – the evidence for this is that we naturally recognize some visual patterns and not others, and that these recognitional abilities differ greatly between individuals. Exactly what neurophysiological resources are at work, and how they operate in tandem is undergoing (currently) intense study. I *don't* assume one-to-one relationships between inference packages and visual-perception capacities.

A nice illustration of one, however, is our capacity to imagine triangles on a plane or a sphere. We recognize that if we move the triangles rigidly about on a plane that doesn't change their areas or change the magnitudes of their interior angles. If we imagine an equiangular triangle growing in area in a way that preserves its equiangularity, the sum of its angles won't change. This isn't true, we immediately recognize, if we instead imagine a triangle on a sphere. In this case, moving the triangle about rigidly won't change the magnitude of its interior angles, or the areas of those triangles. But if we grow an equiangular triangle in a way that (again) respects its equiangularity, the magnitudes of those angles change: It gets "more curved" and its angles gain magnitude. One can also imagine blowing up the sphere – like a balloon – uniformly, although keeping the triangle the same in its area; in this case its angles flatten and lose magnitude. Triangles moving around on an ellipsoid act differently still: if we imagine moving a triangle from the flattest part of the ellipsoid to one of its ends, we can see how the magnitudes of the interior angles of the triangle will increase and decrease.

Involved here are various "perceptual inferences": we can see some facts about the angles, lines and areas of the triangles immediately (they're "free rides"); others we see quickly, or we can work them out with a step or two. I call these inference *packages* because, from an axiomatic point of view, a number of different relations between the properties of these figures (that can be distinguished axiomatically) are bundled together. I stress again that these packages are content-specific: the inferences govern exactly what we imaginatively experience them as governing: certain sorts of visual phenomena. I hypothesize that there is more than one inference package that we can apply to two-dimensional visualizations; this is a matter to be determined empirically. Included among them, however, are the part/whole inferences about spatial regions that we see at a glance: for example, when a spatial area is part of another area, and when they're disjoint. It's important to realize that we have inference packages with respect to one-dimensional figures as well as with respect to three-dimensional figures, and that these aren't the same. (Some of them, at best, overlap.) We effortlessly recognize a number of relations alphabetic items have when in concatenated strings. Certain patterns "leap out" at us; others don't. The same is true of the inference packages with respect to three-dimensional objects located in space. These differ from two-dimensional ones simply because we can imagine two-dimensional objects as *on* surfaces, and as inheriting their properties from those surfaces. Three-dimensional objects are "in" space, and not experienced as "on" anything. This affects what kinds of inference packages are available with such space-filling figures.

Diagrammatic conventions can be chosen in ways that run in parallel with our inference packages or in ways that work against them – even though the diagrammatic conventions in both cases can be equally coherent. Imagine, for example, a systematic diagrammatic Venn system, involving rectangles, closed curves, diagrammatic elements, ⊗, —, and shadings, such as Shin's, but where the

representation conventions for regions are inverted: for example, to indicate that a region R has no members, we must shade all the regions *outside* R.[130] This, coupled with the appropriate conventions for the other elements, yields a perfectly consistent system; it's – logically speaking – impeccable. It will, however, be a very *user-unfriendly* system because it works against our inference packages which operate naturally via spatial wholes and *their* spatial parts. This isn't to say we couldn't get used to such an alternative diagrammatic practice – and that some of us would even find ourselves as able to work with it with some comfort; it's to say there would be a learning curve.[131]

In describing this imagined alternative to Shin's Venn-I as user-unfriendly, I'm making a phenomenological point: to use such a diagrammatic system for proofs feels differently from so-using Venn-I (at least with respect to those diagrams in Venn-I that phenomenologically resemble the diagrams in the original Venn practice). When we engage in a proof-procedure that, relatively directly, uses our cognitively embodied inference packages *we feel we understand what's going on*: we *get* it. That's true with all cognitively embodied inference packages: the inferentially packaged reasoning we engage in is one we always feel we understand: we feel we recognize why it must be right.

A simple phenomenological rule for proof procedures – formal and otherwise: The more closely we can use our cognitive-embodied inference patterns to simulate the processes involved in carrying out a proof, the more we experience that proof as one we understand or "get." To illustrate, consider sets. Sets, recall, are supposed to be abstract objects that have members. We can imagine a set as a kind of box in which its members are contained – but that's a spatial metaphor that only goes so far. Sets aren't in space and, in particular, they aren't located where their members are. The set containing the six umbrellas, the one that I have in my possession now, and the five that I lost last week, isn't located at (or where) the umbrellas it contains are. There is a sense in which "sets," therefore, make no sense. What sorts of things can these be? But the reasoning about sets can be imitated – up to a point – by reasoning instead about objects in boxes. More pertinently to Venn diagrams, reasoning with sets can be imitated – up to a point – by reasoning about regions and their interiors. And so, reasoning about sets can be executed by a notational device that exploits our ease with reasoning about regions and their interiors.

To stress again: inference packages (cognitively embodied algorithms) always come with content; they are always interpreted – and indeed, the interpretations are

[130]Again, with a convention, as described in footnote 127, to make markings outside squares manageable.

[131]Consider Polish notation. Ordinary alphabetic formal systems, using parentheses and the like, operate in parallel with our one-dimensional containment inference packages. The result is that we can read that notation easily, and learn it quickly. Polish notation flouts these inference packages – and so is "intuitively unappealing."

always *sensory*.[132] But when mathematicians use these inference packages they invariably *reinterpret* them. I've just illustrated one way that this is done: by using them to manipulate diagrammatic notation that our cognitively embodied algorithms are at ease with, although those diagrammatic elements (officially) refer to something else.

Let me return briefly to the question, raised in Sect. 8, about the distinction between when notation is diagrammatic and when it's not. The foregoing implies, I think, the following result. There are distinctive visual capacities that enable distinctive inference packages with respect to one-, two-, and three-dimensional visual experience. When a two-dimensional notation doesn't take advantage of the distinctive inference packages available with two-dimensional notation (but not one-dimensional notation), but only relies on, say, adjacency, that notation isn't diagrammatic. Thus, I suggest, matrices and integral notation aren't diagrammatic notation. When notations rely on distinctively two-dimensional inference packages, as Euclidean and Venn notation do, they are diagrammatic. This distinction requires an empirical underpinning, which I can hope will be supplied in the future; it doesn't turn – notice – on semantic considerations, that is, it doesn't turn on interpretation. (I think this is an advantage of it.)

15 Ideology and Formal Systems

Before (finally) concluding this chapter, I'd like to revisit the interrelationships between Church's thesis, Hilbert's thesis, formal systems, and informal rigorous mathematics, while at the same time discussing some recent work by Avigad and Hamami that defends a particular version of the derivational account.

Twentieth- and twenty-first-century mathematics is extremely rich – and in large part a lot of that richness is a result of mathematical developments subsequent (and in contrast) to the logic that emerged with Frege and was joined with set theory by Russell and Whitehead, and others. In particular, major parts of contemporary mathematics are the alternative axiom systems that have emerged *in contrast to* Zermelo-Frankel set theory with the axiom of choice (ZFC) that's couched in the language of classical first-order predicate logic. Intuitionism is well-known: it has generated a great deal of *informal rigorous* mathematics – in (intuitionistic) analysis, in particular. But, of course, there are also numerous "alternative logics" and some of these alternatives – paraconsistent approaches, among others – are actively pursued not just as logical disciplines but in terms of the mathematics they also enable. There are also explicit alternatives to ZFC, including ZF + the axiom of indeterminacy. Again, these have led to additional pursuits in bread-and-butter mathematics, for example, alternatives to standard measure theory.

[132] Although: they're not always *visual*.

There is no choice, I would have thought, but to be a *pluralist* as far as contemporary pure mathematics is concerned. It's simply a fact of the contemporary mathematics that these numerous alternatives – alternative to classical logical frameworks, alternatives to standard Zermelo-Frankel set theory with the axiom of choice – exist. Call the formalized pursuit of these alternatives *axiomatic pluralism*.[133]

Much – if not most – of this mathematics *isn't* restricted to the deduction of theorems within formal systems, as I've already indicated; rather, it's bread-and-butter informal rigorous mathematics. That's the context, actually, in which such axiomatic systems are studied. More obviously, it's in the context of informal rigorous mathematics that the knock-off studies I described above, in one or another nonstandard framework, a particular logic and/or set-theoretic framework, or something else (e.g., category theory) occur. Understanding informal rigorous mathematical proof as a matter of mechanical recognizability – either according to the algorithmic-device view or some other – enables an accommodation of this pluralism, which I'll call *informal mathematical pluralism.* This also accommodates the datum that mathematicians can recognize good proofs across mathematical traditions.

Informal mathematical pluralism is why, however, that the derivational accounts I've been concerned with in this chapter, and in earlier work, have been *ideology-neutral* accounts. The formalizations in question that are supposed to explain the epistemic properties of informal rigorous mathematics can't be restricted to frameworks governed by standard classical logic and ZFC. Indeed, foundational projects for mathematics – ones dedicated to transcribing all mathematics into one or another *specified* formal system (e.g., ZFC, Russell-Whitehead type theory), haven't been in focus at all.[134] A formalization of arithmetic with an ideology of *numbers* (an intended model of numbers) suffices to provide the formalization needed for an informal rigorous *arithmetical* practice – on the derivational views I've been concerned with. Church's thesis (going beyond functions of natural numbers via reinterpretations of numbers) accommodates axiomatic pluralism. The version of Hilbert's thesis I borrowed from Kripke (2013) in Sect. 4, however, requires changes to enable its application beyond the language of first-order predicate calculus with identity. Notice: Although any Turing machine formalism can be *represented* in the language of first-order predicate calculus with identity – that's a mathematical result about Turing machines – this result doesn't straightaway yield a first-order-predicate-calculus-with-identity version of Hilbert's thesis.

These preliminaries aside, recent work by Hamami (2019) defends what he describes as "orthodoxy," or "the standard view," and he traces it (historically) back to Mac Lane and Bourbaki. This is that "a mathematical proof P is *rigorous* if and only if *P* can be *routinely translated* into a formal proof," where such a proof

[133]I committed myself to axiomatic pluralism (without using that label) in Azzouni (1994, Part II).

[134]One may well doubt, in light of the richness of contemporary mathematics, whether any straightforward ideologically nonneutral foundational project is possible. Such can't be ruled out, of course, because there can always be rather unexpected approaches – based on relative consistency proofs – to embedding branches of mathematics in one another, and therefore grounding such in specified axiomatic systems.

"is (or could be) written out in the first order predicate language L($\in$) as a sequence of inferences from the axioms ZFC, each inference made according to one of the stated rules."[135] As I've just indicated, I think this version of a derivational account cannot accommodate contemporary mathematics because it isn't ideologically neutral. Let us, accordingly, broaden it. Further, let us distinguish (as Hamami (2019) and Avigad (2019) both do) an epistemic/descriptive version of the derivational account from a normative version of that account. The epistemic/descriptive account is required to use the existence of formalizations to explain the epistemic properties of informal rigorous mathematical proof. The normative version instead defines a mathematical proof as "rigorous" if it can be routinely translated to a formal proof. No explanation of the epistemic qualities of informal mathematical proof is required.[136]

Consider the descriptive version of the derivational approach, and recall Tanswell's condition *Content* (Sect. 3). The task *Content* poses to descriptive derivational approaches, pretty much, is to require them to show how the materials, *already present in informal proofs*, indicate their formal transcriptions. I attempted, in Azzouni (2004) and Azzouni (2006), to defend this approach by giving an open-ended set of informal-mathematical tools – inferential abbreviations and shortcuts, meta-proof considerations, etc. – many of which mathematicians have learned, that I hoped would provide sufficient content to informal proofs to show how they indicate the relevant derivations.[137] It strikes me that, insofar as Hamami (2019) considers the descriptive strategy, this is what he offers as available for this – although he stresses more strongly than I did the idea that mathematicians come to the task with certain background competences.

Here is Avigad's (2019) excellent (and approving) description of Hamami's account of informal proof:

> According to Hamami, we accumulate not just theorems but inferential patterns and procedures throughout our mathematical education, and we put them to good use towards understanding an informal proof. When a competent practitioner reads such a proof, the inferential cues and context trigger algorithmic processes that expand the inferential steps to smaller ones. These, in turn, are recognized as applications of prior theorems or lemmas, or at least patterns in memory that have been previous justified.

[135]The first quote is from Hamami (2019); the second is his approving quotation of Mac Lane (1986, 377). "Rigorous," here is specialized terminology; it doesn't mean what it means in the phrase, commonly used (and used by me throughout this chapter), "informal rigorous mathematical proof."

[136]Hamami (2019) writes: "[A] *descriptive account* of mathematical rigor provides a characterization of the mechanisms by which mathematical proofs are judged to be rigorous in mathematical practice; *a normative account* of mathematical rigor stipulates one or more conditions that a mathematical proof ought to satisfy in order to qualify as rigorous" (italics his).

[137]Strikingly, the meta-proof considerations include those where shifts occur during the course of a proof to explicitly notational considerations – for example, that the indexes on such operators have such-and-such properties. These notational considerations are ones, of course, about notation occurring in the informal rigorous proof.

The algorithmic-device view agrees that "inferential cues and context trigger algorithmic processes," but these needn't (and often don't) lead to expansions of inferential steps; they often lead to just seeing the result. More important, they usually *don't* point *past* informal proving to a formal transcription.[138] That's because algorithmic competence is at back of all of this, but algorithmic competence, as I've been stressing throughout this chapter, *doesn't* epistemically *require* formalization. Church's thesis, coupled with the mathematical result that any Turing-machine computation, can be represented formally in a first-order predicate language *does not* translate to an epistemic requirement of a formalization of this sort explaining our grasp of any intuitively effective bit of reasoning.

Avigad (2019), on the other hand, although officially accepting Hamami's approach, attempts to give the *normative* version of the derivational account some teeth. He tries to show, that is, that a number of the virtues that good informal mathematical proofs (and proof practices) have – for example, being based on sound analogies, reasonable generalizations, and a wide collection of examples – supply *good guarantees* that an informal proof will have a formal correspondent. Avigad means to show that the existence of corresponding formal derivations is thus an appropriate standard for informal proof practices: the gap between formal derivations and informal proofs isn't a reason to reject derivations-as-standards precisely because good informal proof-practices *raise the likelihood* that an informal proof has a formal correspondent.

I worry (as I have for a long time), however, that "good guarantees" – raising likelihoods in these ways – aren't good enough to explain the epistemic strangeness of informal rigorous mathematical proof. That is, informal mathematical proof practices are *too good* to be explained this way. Recall the quotation from Manders (1995) in footnote 19; for that matter, here's a quotation from MacKenzie (2001, 322–323)[139]:

> . . .many rigorous arguments in ordinary mathematics have been replaced successfully by formal proofs, using automated theorem provers and proof checkers, especially the AUTOMATH and MIZAR systems . . .. What is most remarkable about these many replacements of rigorous arguments of mathematics with formal, mechanized proofs . . . [is that] it is a conservative process. Applied to programs, hardware designs, and system designs, efforts at formal, mechanical proof frequently find faults and deficiencies that have not been detected by other means . . .. Applied to rigorous arguments within mathematics, however, efforts at mechanized proof nearly always suggest at most the need to remedy matters that a mathematician would regard as basically trivial, such as typographic errors or failures to state the full range of conditions necessary for a theory to hold.

[138] They certainly *don't* point past informal rigorous mathematical proofs with one kind of content – arithmetic, say – by virtue of being "decomposable" (Hamami's phrase) into proofs with a strikingly different ideology, that is, that of ZFC.

[139] I'm under the impression that, vis-à-vis various formalization projects, and their impact on informal rigorous mathematics, nothing has changed in the intervening years.

But Avigad's general-virtue approach to mathematical proof *should yield* the same result for programs, hardware designs and system designs that Avigad hypothesizes it yields with respect to informal rigorous mathematical proof. It clearly doesn't.[140]

I've suggested in earlier work (Azzouni 2009b) – in a way related to Avigad's (2019) approach to a normative role for formal derivations – that transcribability to a formal derivation has, in the contemporary setting, become a norm for informal rigorous proof. I want to end this section by revisiting considerations that cut against that idea.[141] The problem is that there are informal rigorous mathematical proofs that are *counterexamples* to the normativity thesis. Consider, for example, the proof in footnote 118. (Visual proofs like that one are the best counterexamples, but there are many similar ordinary-language-based ones.) Phenomenologically – notice – this proof is *utterly convincing* as it stands. Furthermore, there is no sense in which it looks like it needs to be completed or filled in. It's true of many informal rigorous mathematical proofs that they look like they're missing steps; but this is *not* one of those.[142] That is, neither epistemically nor normatively does this proof and many other informal rigorous proofs (those in the Euclidean tradition, e.g., Venn diagrammatic proofs – but *many* other informal rigorous mathematical proofs as well) need supplementation of any sort. Further, although Hilbert's thesis indicates that these proofs can all be formalized (and indeed, as I've illustrated by citation from the literature, many of them *have been*), they themselves don't indicate the existence of formalizations that, in turn, justify why they're true: their content, that is, does nothing of this sort.[143]

The epistemic process, rather, is the exact *reverse* of what normative and descriptive derivational accounts hypothesize. The intuitively effective procedures such proofs exhibit right on their surfaces, when preserved formally, simultaneously preserve the epistemic qualities (the phenomenology) of those informal proofs. The formalization inherits, that is, what it is about the informal proof that convinces us – what *justifies* our being convinced of the result of the proof. It's not, that is, that the formalization reveals what's convincing about that proof or that the formalization justifies that proof. This is enough to show that – at least with respect to *many* informal rigorous mathematical proofs – derivation accounts are intrinsically misleading.

Nevertheless, compatibly with how I've just described the phenomenology of some proofs that formal derivations correspond to informal proofs might *still* be a (general and newly acquired) norm. Whether such a correspondence *is* a norm is,

[140]Compare this response to Avigad with my earlier (Azzouni 2009b, 16, footnote 12) response to Rav (2007, 317).

[141]I first raised this objection to my earlier norm view in Azzouni (2013c) – but this discussion goes beyond that one.

[142]That to formalize this proof would involve something like translating visually seen spatial areas into complex axioms about areas isn't to "fill in" the original proof. It's not even to "make explicit" what's tacit in the proof, as it stands. That's an interpretation that treats, by fiat, a language-based transcription of something we see visually, as therefore (on those grounds alone), "more explicit."

[143]The fact that other proofs of the same form may be misleading is irrelevant.

ultimately, a sociological matter. Consider, however, the possibility of a flourishing diagrammatic tradition that – contrary to Hilbert's thesis – can't be transcribed to a language-based formalization. More dramatically, consider a flourishing informal diagrammatic tradition (involving proofs, say, as phenomenologically compelling as the one in footnote 118) that can't be formalized *at all* – diagrammatically or otherwise. Rather than there being a norm that would fault this proof-tradition, it seems, rather, that generalized versions of Hilbert's thesis, and, in fact, Church's thesis, would be *overthrown.* Indeed, that these are regarded as *theses* is, in fact, the sociological evidence that formalizability of any sort *isn't* a norm of informal rigorous mathematical proof.

16 Conclusion

I've covered far too much territory for an *article.* I'll nevertheless try to summarize (some of) what I've done here in a couple of concluding paragraphs. The problem this chapter opened with is the epistemic strangeness of mathematical proof. This is a (psychological/sociological) claim about informal rigorous mathematical proof – that there is a widely shared experience of "it must be this way" that proofs in mathematics sometimes have (and that long proofs exhibit, usually, only in part) as well as "aha – I see why this must be" epiphanies. That is, mathematical proof, in full, is a complex heterogeneous experience, and that experience (involving short-cuts, invocations of authority, "aha"-epiphanies, and so on) is hardly a seamless impression of a priori inference. The algorithmic-device view explains this phenomenology: algorithmic devices – diagrammatic and language-based – exploit our ability to execute some intuitively effective recognition procedures – ones that are cognitively embodied in us and that we can apply to mathematical problems.

I'll put the point more picturesquely: A mathematical proof is like a stew with chunks of reasoning governed by algorithmic devices plus lots of other – and some looser – stuff. Usually, but not always, algorithmic devices are derived from recognition procedures we normally use (to navigate our world visually, for example) and then we feel the "aha"-epiphany when we apply them. But we don't otherwise – for example, if we use an abacus for certain calculations, or engage in a difficult computational maneuver with integrals.

We cognitively embody many kinds of algorithms. When applying these to the topics they naturally apply to, we effortlessly experience inference processes, often as immediate inferential insights about things. Successful diagrammatic practices notationally hijack these processes and thus enable us to apply these inference packages to subject areas that such inference packages wouldn't otherwise apply to.

The algorithmic-device view of mathematical proof, unlike derivational approaches, explains the epistemic properties of informal rigorous mathematical proof in terms of the mathematical machinery that's *visible* in informal rigorous mathematical proof *itself.* It doesn't explain these properties via a transmutation of informal rigorous mathematical proof to formal algorithmic systems – diagrammatic or otherwise. In turn, other properties of informal rigorous mathematical proof

(e.g., Tanswell's "agreement," "correctness") are explained by the fact that the phenomenology of informal rigorous mathematical proof is based on inference packages and various conventions that are held in common and applied in common by appropriately trained mathematicians.

Nevertheless, transmutations of informal rigorous mathematics into one or another formal system are always possible, via generalizations of Hilbert's thesis. In particular, any natural-language reasoning with diagrammatic algorithmic devices can be formalized in a heterogeneous formal system. Any such formal heterogeneous system, in turn, can always be recast as a language-based formal system because all diagrammatic operations on higher-dimensional grid systems can be recast in one-dimensional concatenation systems – and indeed, as Turing machine calculations. Phenomenologically faithful embeddings of informal rigorous mathematical proof into formal systems retain the apparent content of the mathematical statements – at least insofar as there remains an intended model for the formal systems in question. Respecting this apparent content also explains why the formal systems in question are always based on something in the neighborhood of classical bivalent logic. That classical mathematics is couched in a logic in the neighborhood of the classical first-order predicate logic despite its taking place in natural language which is *not* governed by such a logic is the result of a complex historical process.[144] That means the process is contingent: we could (in the future) find ourselves – collectively – deserting classical logic, as we, in effect, have already with respect to pure mathematics. So too, we might desert ZFC as we, in effect, also have with respect to pure mathematics. This latter possibility turns, largely, on the empirical-science needs that mathematics meets. But discussion of that involves a different set of considerations I can't pursue now; my only point – again – is to stress that our philosophical understanding of ordinary rigorous mathematical proof, certainly as it is and has been pursued in this and the last century, requires axiomatic and informal mathematical pluralism.

Abstract

Philosophical theories of counterfactuals have had relatively little to say about counterfactual reasoning in mathematics. Partly this is because most mathematical counterfactuals seem also to be counterpossibles, in that their antecedents deny some necessary truth. In this chapter, I delineate several different categories of mathematical counterfactual (or "countermathematical") and then examine in

detail a case study from mathematical practice that features counterfactual reasoning about "spoof perfect" numbers. I argue that reasoning about spoof perfect numbers presents both a challenge to philosophical analyses of counterfactuals and a resource for thinking more productively about the role of counterfactual reasoning in mathematics.

Keywords

Counterfactuals · Counterpossibles · Mathematical practice · Perfect numbers

1 Introduction

It has been suggested that a good "philosophical heuristic," when trying to attack a proffered analysis, is to look at extreme cases (Hàjek 2016). When the analysis in question concerns counterfactual conditionals, one class of extreme cases are counterfactuals with impossible antecedents – so-called "counterpossibles" (It has been pointed out to me (by Ralph Wedgewood) that the term "counterpossible" here runs counter to the analogy with "counterfactual." If the antecedent of a counterfactual denies an actual fact, should not the antecedent of a counterpossible deny a possible fact? In other words, a more appropriate term for these impossible counterfactuals is "counternecessary." Unfortunately, current usage is too entrenched at this stage to be open to being changed). As is well-known, the standard possible-worlds analysis of counterfactuals delivers the verdict that all counterpossibles are true. Vacuously true, one might say, since it matters not what the content of the consequent is. Nor is this the only route to vacuity. Syntactic approaches, based on the derivability of the consequent from the antecedent, will also class all counterpossibles as uninterestingly true, if the background logic is classical.

So what? A full analysis of counterfactuals may need to say something about counterpossibles. But does anything substantive hang on what is said? In particular, can it be shown to be a liability for an analysis to classify all counterpossibles as vacuously true? In his 1974 book, *Counterfactuals*, David Lewis devotes several pages to the issue of counterpossibles. Here is an excerpt:

> [O]ne sometimes asserts counterfactuals by way of *reductio* in philosophy, mathematics, and even logic. . . . Their antecedents deny what are thought to be philosophical, mathematical, or even logical truths, and must therefore be thought not only false but impossible. These asserted counterphilosophicals, countermathematicals, and counterlogicals look like examples of vacuously true counterfactuals. (Lewis 1973, p. 24)

In the above passage, Lewis simultaneously coins (at least I am not aware of any earlier usage) the term "countermathematical" for the class of counterpossibles that have mathematical subject matter and makes explicit the implication of his analysis that all counterpossibles are vacuously true. On Lewis's definition, a countermathematical is a conditional whose antecedent denies a mathematical truth. In order to come up with a definition which hinges less on the realism/

antirealism debate in the philosophy of mathematics, let us drop reference to truth and adopt the following definition:

(1) A *countermathematical* is a subjunctive conditional whose antecedent denies an accepted mathematical claim. (I plan to ignore, for present purposes, the question of what degree of agreement across the mathematical community is required in order for a mathematical claim to count as "accepted.")

As is well known, Lewis is a champion of a possible-worlds analysis of counterfactuals. According to his analysis, a counterfactual $A \mathrel{\square\!\!\rightarrow} B$ is true if and only if the closest A-worlds to the actual world are all B-worlds. But if A is impossible, then there are no A-worlds, so the standard analysis makes all counterfactuals with impossible antecedents vacuously true. Note that there are also other routes to this conclusion that have nothing directly to do with possible worlds. For example, consider any analysis of counterfactuals rooted in classical logic which makes the consequent of a counterfactual true if it can be deduced from the antecedent together with appropriately amended auxiliary hypotheses. If the antecedent is contradictory, then every consequent is deducible, regardless of what other hypotheses are added. In what follows, I shall use the term *vacuist* for any analysis according to which all counterpossibles are vacuously true, and *nonvacuist* for any analysis which makes room for some counterpossibles to be true and others false. (Although I shall not pursue the issue in this chapter, I think that most of what I say below against the vacuist position would apply equally well against the converse view that all counterpossibles are vacuously false (or that all counterpossibles lack a truth-value). The point of the examples from mathematical practice is that any uniform classification of counterpossibles is insufficient.)

Pressure on the vacuist account comes from three main sources. However, or so I shall argue, a compelling case against vacuism has yet to be made. First, some philosophers have argued that classifying all counterpossibles as trivially false does violence to our intuitions concerning specific examples (and especially pairs of examples with appropriately contrasting consequents). The problem with this line of objection is that our intuitions about extreme cases tend to be weak to the point of uselessness, and easily manipulated by peripheral contextual factors.

A second source of pressure on vacuism is the increasing use of nonvacuist accounts of counterpossibles to do substantive philosophical work, especially in the analysis of mathematical explanation. Recent work by Sam Baron, Mark Colyvan, David Ripley, Alexander Reutlinger, and others has sought to extend a difference-making account of scientific explanation to cover mathematical explanation. This involves making sense of mathematical facts "making a difference," and a natural way to do this is to consider what would be the case if a certain mathematical fact were different. For this analysis to work, the resulting counterpossibles must be nontrivial, hence it requires some kind of nonvacuist account. This approach has been explored both for mathematical explanation in science (Baron et al. 2017; Baron 2020; Reutlinger et al. 2020) and for intramathematical explanation of one mathematical fact by another (Baron et al. 2020). Although important progress has

been made in fleshing out this analysis, there remains much work to be done in clarifying just how the counterpossibles featuring in mathematical explanations ought to be evaluated. Some general guidelines have been proposed, but without further grounding in mathematical practice there remains the issue of overreliance on vague and only partially articulated intuitions.

This brings us to the third – and in my opinion most crucial – source of pressure on the vacuist view, which is that counterpossibles play a substantive role in actual mathematical practice. If this claim is correct, then it not only casts doubt on the cogency of vacuism by exposing its tensions with practice, but it also bolsters the first two sources of pressure on vacuism. On the one hand, patterns of acceptance and rejection of counterpossibles in mathematical practice can provide a firmer scaffolding for our intuitions about individual cases. On the other hand, this same kind of evidence from practice can flesh out a positive analysis of mathematical explanation within mathematics, and potentially also in science. The problem, however, is that the evidence provided to date of the role played by counterpossibles in mathematical practice is equivocal at best. Although some examples have been given, in many cases – as we shall see – they turn out either not to involve genuine counterfactuals, or not to be significantly linked in to broader aspects of mathematical practice.

My focus in this chapter is on counterpossibles with mathematical content, and in particular arithmetically oriented examples. I shall argue that cases of this sort can be found in actual mathematical practice and that their role in this practice constitutes a *prima facie* challenge to mainstream contemporary accounts of counterfactuals. My principal targets are accounts that are vacuist, in the sense defined above, because such accounts make it particularly difficult to accommodate any interesting role for counterpossibles in practice. But I think that the examples discussed also pose a challenge for existing nonvacuist accounts. Accounts of this latter sort can allow for true counterpossibles and false counterpossibles, but this is not much use in itself if it is not accompanied by workable guidelines for evaluating the truth or falsity of particular examples. Broadly speaking, then, the challenge for the vacuist concerns analysis, and the challenge for the nonvacuist concerns evaluation. ("We can ask two types of questions about counterfactual conditionals: What is the meaning of the statement, and how do we determine whether it is true or false?" (Lewis-Beck et al. 2004).)

I am not the first to look to mathematics for examples of counterpossibles, nor the first to stress "practice-based" examples as a way to put pressure on certain analyses of counterfactuals. However, as I shall argue in the next section, the purported examples of countermathematicals that have been discussed in the philosophical literature to date fail to stand up to scrutiny.

2 *Reductio* Arguments Are Not Countermathematicals

I have argued that one way to advance the debate over the proper analysis of counterfactuals is to find examples of counterpossibles from nonphilosophical practice. But does not the beginning of the Lewis quote from the previous section

indicate one area, straightforwardly distinct from philosophical practice, in which such examples can be found in abundance, namely in proofs by *reductio ad absurdum*? In the first part of this section, I shall argue, against what is the prevailing view in the literature on counterfactuals, that *reductio* arguments are not countermathematicals and thus, more generally, that they are not counterpossibles either. Then, at the end of this section, I shall show that even if I am wrong and *reductio* arguments are counterpossibles, they still cannot be used to put any real pressure on the vacuist position.

The core of my argument against *reductio* arguments being counterpossibles is that they are not even counterfactuals. Counterfactuals are subjunctive conditionals, but *reductio* conditionals do not function as subjunctives. For example, consider the following condensed argument:

(2) Assume (for purposes of *reductio)* that there is a largest prime *p.* Then (*p!* + 1) is prime.

This is true because we can derive the primality of ($p!$ + 1) from known facts about divisibility – in particular, that ($p!$ + 1) leaves remainder 1 when divided by any number less than or equal to *p.* Hence ($p!$ + 1) has no prime factors less than or equal to *p.* This is in sharp contrast to the corresponding claim expressed as a subjunctive conditional. If there *were* to be a largest prime, then (intuitively) all sorts of other established mathematical facts might be different too. But, if so, then we cannot just "automatically" appeal to any such other established mathematical fact in trying to derive a contradiction from the assumption that there is such a *p.* One might argue, for example, that if there were finitely many primes then there would also be only finitely many numbers. In particular, the following might be an acceptable subjunctive conditional,

(3) If there were a largest prime p, then there would be a largest number q such that $q < (p! + 1)$.

But if this is right, then it is false that if there were a largest prime p then ($p!$ + 1) would be prime. It is false because in these circumstances there would be no number ($p!$ + 1). (It is striking that Lewis uses the subjunctive formulation when discussing this exact example in his 1973, p. 25.)

It is enough for present purposes to show that *reductio* arguments are not "disguised" subjunctive conditionals. For, if they are not subjunctive conditionals, they are not counterfactuals, and if they are not counterfactuals then they are not counterpossibles. Are *reductio* arguments "disguised" conditionals of some other sort? I used to think that *reductio* conditionals are more like indicative conditionals. But this now does not seem right to me either. If there *is* a largest prime, then I have been radically misled by the various proofs I have seen which purport to establish the contrary result. So who knows what I should accept as a (mathematical) consequence of this assumption! (This connects with the behavior of indicative conditionals in other contexts. I might accept the subjunctive conditional, "If I hadn't vacationed in

France last summer then I would have vacationed in Spain," but this does not commit me to accepting the corresponding indicative conditional, "If I didn't vacation in France last summer then I vacationed in Spain." If I did not vacation in France, then something very strange is going on because I have lots of vivid memories of doing just that.) (More generally, the role of this conditional in the context of a reductio proof is very different from the normal role of a counterfactual. Roughly speaking, we are interested in the "reductio conditional" only as a means toward demonstrating the falsity of the antecedent. By contrast, our interest typically in a conditional, whether indicative or subjunctive, is in exploring the ramifications of the truth of its antecedent. So, even when there are conditionals in the context of reductio proofs, they do not have the normal role of counterfactuals.)

My thesis that *reductio* arguments do not involve counterpossibles is, I acknowledge, controversial. Fortunately for the broader debate over counterpossibles, there are independent grounds for thinking that the case of *reductio* arguments is not especially useful in settling the issue of how properly to analyze counterfactuals. Consider how an argument against the vacuist analysis of counterfactuals might proceed. The basic form is as follows:

(1) The standard possible-worlds analysis makes all counterfactuals with impossible antecedents vacuously true, since if A is impossible then there are no A-worlds.
(2) *Reductio* arguments in mathematics start from impossible premises. [e.g., the assumption that there is a largest prime number, p].
(3) But not all conclusions advanced in the context of a *reductio* argument are mathematically acceptable.
(4) Hence, there are mathematically unacceptable claims of the form "If P then Q" where P is impossible.
(5) Hence, not all counterfactuals with impossible antecedents are vacuously true, so the standard analysis is untenable.

The typical response to the above argument, for those who favor a possible-worlds-based analysis of counterfactuals, is to make a distinction between what can *truly* be asserted and what can *appropriately* be asserted. In a 1997 paper, Daniel Nolan argues that for a proof to be acceptable it is not enough that it be formally valid; it must also be *obviously* formally valid. Thus a defender of the standard analysis of counterfactuals can argue that the problem with "If $\sqrt{2} = a/b$ then 42 is prime," is not that it is false but that the steps from premise to conclusion have not been made clear. Nolan concludes that "*reductio* proofs do not show the need for nontrivial reasoning about impossibilities" (Nolan 1997, p. 538). (The above line of defense draws a distinction between mathematical acceptability and truth, but not in a way that presupposes any particular background philosophy of mathematics. It should be noted that antirealists about mathematics have independent reasons for rejecting the original argument because on their view mathematical acceptability does not even aim for literal truth.) In this way, the vacuist can hold onto the claim that all countermathematicals are vacuously true, but add that a countermathematical is (mathematically) acceptable if and only if a derivation is provided of its

consequent from its antecedent using other demonstrable mathematical facts. This is in contrast to the nonvacuist, who holds that some countermathematicals are not just mathematically unacceptable but also false.

Can this debate be moved forward, and – if so – how? I think that it can, and one of my main aims in this chapter is to indicate why and how. The key to making progress is to realize that there are other examples of countermathematicals which play a role in mathematical practice but are not part of *reductio* arguments.

3 Classifying Countermathematicals

Recall our earlier definition, that a *countermathematical* (henceforth, CM) is a subjunctive conditional whose antecedent denies an accepted mathematical claim. Before proceeding to look at some case studies, it will be useful to have in place a preliminary classification of different types of CM. I do not claim that the taxonomy that follows is either optimal or exhaustive, but hopefully it will allow for a more focused discussion of different examples.

3.1 Metamathematical

Some mathematical claims are not claims of a particular mathematical theory but claims *about* the properties of a theory. The denial of some established metamathematical claim is a *metamathematical* CM (or, perhaps, a *countermetamathematical*). For example,

(4) If ZF set theory were a conservative extension of Peano Arithmetic, then Goodstein's Theorem would be provable in PA.

It is unclear to what extent metamathematical CMs play a role in mathematical practice. Sometimes, metamathematical CMs are used in *reductio*-style reasoning, for example, showing that if a certain formal theory were complete and consistent then it would be strong enough to embed arithmetic, and hence Gödel's Incompleteness Theorem would be violated. I would be inclined to resist classifying such cases as CMs for the reasons canvassed in Sect. 2. Another reason for distinguishing this category from "genuine" CMs comes from stressing the division between mathematics and metamathematics. Perhaps reasoning of this sort is not "internal" enough to mathematical practice, and too often bound up with broader issues in logic or philosophy.

3.2 Axiomatic

An *axiomatic* CM is a conditional whose antecedent denies an established axiom of an established mathematical theory. For example,

(5) If the Axiom of Choice were false, then there would be sets S and T of incomparable size (i.e., neither can be mapped in a one-to-one fashion onto a subset of the other).

Evaluating the truth or falsity of axiomatic CMs seems relatively straightforward, at least in principle. It is a matter of determining whether the consequent is a theorem of the amended theory produced by replacing the axiom in question with its negation. Jonathan Bennett has argued – convincingly, I think – that evaluation is possible in this sort of case, despite the lack of analytical support, precisely because the axioms of a given theory provide a framework for carving up logical space in a specified manner;

> Consider . . . how counter*logicals* are handled. . . . [A] speaker can say things of the form 'If conjunction were not commutative, then C would be the case,' and be right for some values of C and wrong for others, just so long as he is talking about the power structure of some *system* of logic – some set of rules and independent axioms – and saying that C is a theorem in the system that results from the original one by deleting its commutativity axiom. Such conditionals are saved from triviality by being made relative to some *formulation* of logical truth. (Bennett 2003, pp. 228–229)

Independence does seem to be a crucial feature of what makes axiom-based CMs relatively unproblematic to evaluate. It means they can be dropped (or even negated) without having to alter any other axioms of the theory (Although I agree with Bennett's general point here, the specific example in the given quote does not work quite as he claims. If all that is done is that the denied axiom is "deleted," then the new system will be weaker than the old system. To get any new results, the negation of the deleted axiom must be added in its place. Otherwise, the most we could legitimately say would be along the lines of, "liven if conjunction were not commutative, C would still be the case."). Another way of putting this point is that there is another (logically) consistent theory in the vicinity which can be used as a framework for evaluation.

Even if it is conceded that evaluation of axiomatic CMs is straightforward, there remains the issue of how such CMs are to be analyzed. It is true that this may raise problems for platonists, for example, if the Axiom of Choice is necessarily true, then what can be meant by drawing conclusions from the supposition that it is false? (Nolan 1997) Nonetheless, I doubt that axiomatic CMs will provide good case studies for the debate over counterpossibles because this problem of analysis does not extend across other positions in the philosophy of mathematics. Indeed, even some other versions of mathematical realism, for example, Quinean indispensabilism, will have no problem with conditional claims that deny the truth of established axioms.

3.3 Stipulational

A CM is *stipulational* if its antecedent asserts that a "borderline" case (or cases) of some mathematical concept be reclassified in a different way. One of the clearest

examples of this sort concerns the nonprimality of 1. Here is a sample quote taken from a mathematics textbook (there are also plenty of more technical examples, "Take the Euler Fi-function for example. it can be shown the $Fi[p] = p - 1$ when p is a prime. If 1 was prime that wouldn't be true for $Fi[1] = 1$"):

(6) If 1 were prime, then the Fundamental Theorem of Arithmetic, which says that every whole number greater than one can be written uniquely as the product of prime numbers, would be false.

The most natural way of reading this example, I suggest, is as contradicting not actual mathematical *facts* but actual mathematical *terminology.* Since the mathematical facts can therefore be left untouched, evaluation is again relatively straightforward. Each old theorem mentioning primality (or a property defined using primality) must be retranslated using the new terminology and then assessed to see if it remains true. Some do (for example, the theorem that there are an infinite number of primes) and others do not (for example, the theorem about the uniqueness of prime factorization).

Crucial to this reading is that the reclassified cases be borderline, otherwise the new concept becomes too far removed from the original one. Compare (6) above with.

(7) If 4 were prime, then some composite numbers would have no prime factors.

As things stand, 4 is a paradigmatic example of a nonprime number. If the meaning of "prime" were altered to the extent that 4 is counted as prime, then it becomes unclear what would happen to related terms such as "composite" and "factor," and this interferes with the evaluation of (7).

In light of the above remarks, there is a sense in which stipulational CMs are not really counter*possibles* at all. A platonist, for example, can entertain the antecedent of (6) without supposing that anything is different in the realm of mathematical abstracta. This suggests that even the vacuist can allow for such conditionals to be nontrivial by focusing on change of terminology rather than change in intrinsic facts about mathematics. (Perhaps there is a way to make the distinction between stipulational CMs and other sorts of CM in terms of Kripke's rigid designator/nonrigid designator distinction.) If so, then stipulational CMs cannot provide a definitive challenge to competing analyses of counterpossibles.

3.4 Counterarithmetical

Our discussion of the above two categories suggests that the most effective examples of CMs are likely to be neither axiomatic nor stipulational. A further desideratum is that the CM feature in an area of mathematics in which there is a single, well-established theory, and about which there is little debate among mathematicians

concerning the correctness of its basic results. Penelope Maddy has usefully distinguished areas of mathematics in which there is a presumption of a single correct theory in terms of a background maxim she calls UNIFY (Maddy 1997). In an area not governed by this maxim, such as group theory, it seems that subjunctive conditionals do not generally correspond to counterfactuals. For example, consider the conditional:

(8) If the operator of the group Z_6 were not commutative, then the group would form the symmetry group of an equilateral triangle.

This is best read, I suggest, is simply shifting the focus from an abelian group of order 6 to the (only) nonabelian group of order 6, namely S_3, and making a true assertion about a feature of this latter group.

For our purposes, a good place to look is arithmetic since it seems to have the above feature; moreover, there is little doubt over its core axioms and theorems. (According to Maddy, set theory is one paradigm area of mathematics where UNIFY is operative. However, although there may be a presumption of a single correct theory, there is ongoing debate about which set-theoretical axioms ought to be included (especially in the area of large cardinal axioms).) I coin the term "counterarithmetical" to cover the special case of a CM which pertains to arithmetic. More precisely:

(9) A *counterarithmetical* is a subjunctive conditional whose antecedent denies an accepted arithmetical claim. (Rather than trying to build into the above definition some distinction between CAs and the previous two categories, I shall just accept that some CAs are axiomatic (e.g., "If there were a number without a unique successor then there would be a largest prime number."), and some CAs are stipulational (e.g., (8) above).)

Linking examples of counterarithmeticals to mathematical practice is crucial here, and it is in this emphasis that I part company with what prior discussion there has been of the topic. Various examples of counterpossibles with arithmetical subject matter have been given in the philosophical literature, but these "philosophical" examples tend to bear little relation to mathematical practice and hence must be evaluated almost entirely on the basis of intuitions that are typically fairly weak, even conflicting.

For example, Almerindo Ojeda asserts in passing, while arguing against the standard possible worlds analysis of counterpossibles, that

(10) If 3 were even, 4 would be odd

is intuitively true, but that

(11) If 3 were even, 4 would be prime

is intuitively false (Ojeda 2005, p. 31). Beyond the bare appeal to intuition, Ojeda's argument is brief. Roughly, his idea is that the successor of an even number need not be prime, so if 3 were even this would not "force" 4 to be prime. The problem with using intuitions as the sole data for philosophical analysis is that it provides no guidance when faced with conflicting intuitions. For example, I happen not to share Ojeda's intuition that the second of the above counterarithmeticals is false. In support, I offer the following argument: I accept that if 3 were even then 4 would be odd. But if 4 were odd, then it would not be divisible by 2 (from the definition of oddness). Also, 4 would not be divisible by 3, because 3 would be even and only even numbers are divisible by other even numbers. So 4 would not be divisible by any smaller number except for 1. Hence, 4 would be prime.

I am not claiming that my argument is decisive. In fact my whole point is that one cannot expect either decisive arguments or robust intuitions concerning such "free-floating" CMs. For this reason, it is unlikely that concocting philosophically motivated examples of CMs will provide a firm enough basis for undermining the standard view. This applies not just to CMs but to any counterfactual conditional with an "extreme" antecedent. (Another class of extreme counterfactuals are those whose antecedents deny a law of nature. For an interesting analysis of such "counterlegals," (see Kvart 1986, p. 208). Also, for an attempt to link counterlegals to certain global kinds of mathematical counterfactual (such as "If there were no mathematical objects, then. . ..") via Quinean indispensability considerations, see Baker (2003).) One problem is that our intuitions concerning counterfactuals tend to weaken as the counterfactual conditions increase in breadth (the scope and magnitude of discrepancies from the actual world) and depth (the modal strength of the actual claims being denied). A second problem is that extreme antecedents do not tend to feature in everyday counterfactual claims. Outside of the philosophy classroom, people rarely go around making assertions about what would be the case if there were round squares, or if some objects were both blue and red all over. Hence, there is little in the way of extraphilosophical "commonsense" usage to measure our analyses against.

It is here, I think, that consideration of counterarithmeticals in particular has the potential to cast light on the broader debate over counterpossibles. For – as we shall see in the next section – there are examples of mathematicians asserting counterarithmeticals in the course of normal mathematical practice, in what appears to be a philosophically unselfconscious manner. Looking at the pattern of acceptance and rejection of counterarithmeticals by practicing mathematicians may provide a potentially important body of data from a source external to, and no less reliable than, philosophy itself.

4 Spoof Perfect Numbers

A natural number is *perfect* if and only if it is equal to the sum of its proper divisors, including 1. Perfect numbers have been an object of interest for mathematicians since ancient times, and the Greeks in particular attached mystical significance to

them. Partly, this is because of the rarity of perfect numbers. Just 5 perfect numbers were known to the ancient Greeks, and even with the aid of today's powerful computers fewer than 50 more have been added to that list. There are also several quite basic questions about perfect numbers which remain unsettled. These include whether there are infinitely many perfect numbers, and whether there are any odd perfect numbers.

It is this latter question which provides the starting point for our first example. In 1638, Descartes corresponded with Mersenne concerning the issue of the existence of odd perfect numbers. Descartes argues that there are likely to be odd perfect numbers, writing at one point that

> I think I am able to prove that . . . there are no odd perfect numbers, unless they are composed of a single prime number multiplied by a square whose root is composed of several other prime numbers. But I can see nothing which would prevent one from finding numbers of this sort. For example, if 22,021 were prime, in multiplying it by 918,009, which is a square whose root is composed of the prime numbers 3, 7, 11, 13, one would have 198,585,576,189, which would be a perfect number. (Quoted in Crubellier and Sip 1997)

As Descartes was well aware, 22,021 is a composite number (its prime factorization is $19^2.61$). Focus for the moment on the core claim which Descartes makes here, namely

(12) If 22,021 were prime, then 198,585,576,189 would be perfect.

This is a subjunctive conditional whose antecedent denies an accepted arithmetical claim, in other words, it is a **counterarithmetical.** In recent years, number theorists have become interested in numbers of this sort, which they have termed *spoof perfect numbers.* Specifically, a spoof perfect number is defined to be a number that is perfect if you assume, contrary to mathematical fact, that one or more of its composite factors are prime.

To make the mathematical side of the discussion more tractable, I shall henceforth focus on a much smaller example of a spoof perfect number:

(13) If 4 were prime, then 60 would be perfect.

At first blush, one might wonder what difference it makes whether a certain factor is prime or not. After all, the perfectness of a number depends on the sum of *all* its factors, regardless of primality. The idea of the spoof antecedent condition is that the spoof prime number, in the above case 4, is now assumed not to break down into any smaller factors. Under this hypothesis, there are fewer factors of 60, because only factors expressible as multiples of 3, 4, and 5 are permitted. Thus, for example, 10 would no longer count as a factor of 60. The "eligible" factors of 60, under the hypothesis that 4 is prime, are 1, 3, 4, 5, 12, 15, and 20. These sum to 60, hence 60 is *spoof perfect.*

My core argument against the vacuist account of counterpossibles can now be formulated:

1. Spoof perfect numbers are a mathematically interesting subset of the natural numbers.
2. Each spoof perfect number is defined using a counterarithmetical.
3. If all counterpossibles are true, then counterarithmeticals do not define a mathematically interesting subset of the natural numbers.
4. Hence, not all counterpossibles are true.

The remainder of the chapter will be devoted to potential ways of responding to this argument on behalf of someone who holds a vacuist view of counterpossibles.

5 Vacuist Responses: Analysis

5.1 Mathematical Practice Is Irrelevant

Perhaps, the most extreme response to the above challenge is to dismiss it entirely on the grounds that appeal to mathematical practice ought to carry no weight in the debate over the proper analysis of counterpossibles. I shall be brief here, and not just because this response effectively puts an end to the present discussion. It is a widely held belief among both contemporary metaphysicians and contemporary philosophers of mathematics that mathematical practice is entirely relevant to the evaluation of competing analyses of concepts which appear within the borders of mathematics, which is not to say that practice overrides all other factors. But if a philosophical analysis implies that significant portions of the mathematical community are systematically wrong about some area of mathematical discourse, then this is – and should be – taken to be a serious drawback for the analysis in question.

The earlier discussion of *reductio* reasoning in mathematics as a potential thorn in the side of the vacuist account of counterpossibles was predicated on the assumption that if it were to be shown that mathematicians use counterpossibles in a way that conflicts with vacuist account, then it would be a problem for the latter analysis. And David Lewis, an archetypal vacuist about counterpossibles, has made numerous remarks about the importance of respecting mathematical practice as a condition of adequacy on philosophical theorizing. One of his better-known proclamations is the following,

> Mathematics is an established, going concern. Philosophy is as shaky as can be. To reject mathematics for philosophical reasons would be absurd. . . . I'm moved to laughter at the thought of how presumptuous it would be to reject mathematics for philosophical reasons. (Lewis (1991, pp. 58–59). The intervening passage between the two quoted segments reads, "If we philosophers are sorely puzzled by the classes that constitute mathematical reality, that's our problem. We shouldn't expect mathematics to go away to make our life easier. Even if we reject mathematics gently – explaining how it can be a most useful fiction, 'good without being true' – we still reject it, and that's still absurd. Even if we hold onto some mutilated fragments of mathematics that can be reconstructed without classes, if we reject the bulk of mathematics, that's still absurd.")

5.2 "Spoof Perfect Number Theory" Is Not Part of Serious Mathematics

A second line of counterargument is to not only acknowledge that systematic patterns of reasoning exhibited in mathematical practice do carry weight, at least in principle, but also to argue that the investigation of spoof perfect numbers is not a legitimate part of "mainstream" mathematical practice. If so, then the core argument may perhaps still be dismissed.

It is true that discussions of spoof perfect numbers are uncommon, even within number theory. On the other hand, results and conjectures concerning spoof perfect numbers can be found in "respectable" mathematical publications – for example, in R.K. Guy's influential survey of open questions in number theory (Guy 2004), and refereed journals such as *Integers and Mathematical Computation* (Nielsen (2003, 2015) and Dittmer (2014). For additional recent work focused specifically on spoof perfect numbers, see also Arnaldo and Dris (2017), and BYU Computational Number Theory Group (2020)).

What about links between spoof perfect numbers and other issues of demonstrable significance in number theory (or indeed elsewhere in mathematics)? Links of this sort are one aspect of what G.H. Hardy has termed the "seriousness" of a piece of mathematics. (A chess problem is genuine mathematics, but it is in some way "trivial" mathematics. However ingenious and intricate, however original and surprising the moves, there is something essential lacking. Chess problems are unimportant. The best mathematics is serious as well as beautiful – "important" if you like, but the word is very ambiguous, and "serious" expresses what I mean much better (Hardy 1940, p. 16).) Unsurprisingly, the area to which research into spoof perfect numbers is most commonly connected is research into perfect numbers *simpliciter*, and in particular odd perfect numbers. As already mentioned, whether there exist any odd perfect numbers is an important and open question in number theory. The consensus seems to be that it is unlikely that there are any odd perfect numbers, partly because various increasingly strong constraints have been proved concerning the size and properties of any such number. For example, it is known that if any odd perfect number must be larger than 10^{1500}, it must have at least 101 (not necessarily distinct) prime divisors, and it must have the form $p^{4a+1}\, m^2$, where $p = 1 \pmod 4$ is prime. (For these and further conditions on odd perfect numbers, see Holdener and Rachfal (2019, p. 541). The nineteenth-century mathematician Sylvester is quoted as saying that "the existence of [an odd perfect number] – its escape, so to say, from the complex web of conditions which hem it in on all sides – would be little short of a miracle.") In Sect. 6 below, I shall discuss an example where results concerning spoof odd perfect numbers are used to draw conclusions about "genuine" odd perfect numbers.

A third indicator of the mathematical interest of spoof perfect numbers is the extent to which the basic notion of spoofness has been generalized or modified to yield other potentially fruitful mathematical concepts. One generalization of Descartes' notion is to that of a *multispoof perfect number.* As the name suggests, these are numbers which are perfect if **two or more** of their composite factors are assumed to be prime. For example,

(14) If 4 and 6 were prime, then 840 would be perfect. (This example is due to Wang (2002). The full "prime" factorization is 840 = 4.5.6.7. It is straightforward (though tedious) to verify that the various combinations of these factors sum to 840, as required.)

Moving even further in this direction, a number is *completely spoof perfect* if it can be expressed as a product of composite numbers, and it would be perfect if **all** of these composite factors were prime. For example,

> 390405312000= 4.8.9.10.15.22.46.94.95 is an even spoof perfect number if you suppose incorrectly that all these factors are primes. (ibid)

Reformulating this in conditional form yields the following counterarithmetical:

(15) If 4 and 8 and 9 and 10 and 15 and 22 and 46 and 94 and 95 were prime, then 390,405,312,000 would be perfect.

Another extension that is worth mentioning, partly because it is more radical in nature, is to *negative spoof perfect numbers.* This involves allowing negative numbers as potential prime factors, for example, when we write $6 = (-2.).(-3)$, thus opening up a whole new class of cases. An example of a negative spoof perfect number is given by Voight. $N = 22{,}017{,}975{,}903 = 3^4 7^2 11^2 19^2(-127)$ "is perfect if we are willing to ignore the fact that −127 is negative" (Voight 2003).

Finally, there are various theorems and conjectures concerning spoof perfect numbers, results that we will discuss in more detail in the next subsection. These provide more evidence, at least *prima facie*, that the topic – though small in scope – is of genuine mathematical interest.

Lurking in the background here are broader questions concerning the relation between mathematical practice and philosophy. What force does appeal to evidence from mathematical practice have in attacking or defending philosophical claims about mathematics? And can distinctions be made between different sorts of mathematical practice? Ought we to privilege "serious" academic mathematics over recreational mathematics? Published mathematics over unpublished? Statements made in the course of a proof over "stage-setting" introductory remarks? At this juncture, I will limit myself to a fairly modest claim: that there is enough going on in the mathematical investigation of spoof perfect numbers for it to deserve to be taken seriously as data for the analysis and evaluation of counterpossibles.

5.3 Mathematically Acceptable Spoof Perfect Numbers Are Interesting

What about responding to the core argument by borrowing one of the vacuist strategies from the discussion of *reductio* reasoning, and making a pragmatic distinction between truth and mathematical acceptability? The idea is to take aim

at Premise 1 and argue that, strictly speaking, the set of spoof numbers is not interesting, because (so the vacuist maintains) all counterarithmeticals are true. However, what mathematicians are picking out in their examples of spoof perfect numbers are part of a subset of *mathematically acceptable* spoof perfect numbers. And these may well be quite interesting. What makes a particular spoof perfect number mathematically acceptable? Just as in the *reductio* case, acceptability hinges on the availability of a step-by-step derivation of the consequent (that the number is perfect) from the antecedent (that a particular composite factor is prime).

There are at least a couple of reasons for thinking that this pragmatic strategy will not be as effective here as it was for *reductio* conditionals. First, it turns out that there is always a simple derivation of the consequent from the antecedent available, because – unlike in typical *reductio* proofs – we already have the negation of the antecedent in our stock of basic theorems and results. (Of course, if the claim being proved by reductio has already been proved by some other method, then we may indulge in the pretense that is not available as a theorem that can be introduced during the course of the new proof. Nonetheless, the canonical case of reductio reasoning proceeds from genuine ignorance over the truth-value of the initial assumption.) For example, we can quickly prove that 59 is spoof perfect as follows.

(1)	4 is prime	Assumption
(2)	So 4 is prime or 59 is perfect	1, Addition
(3)	4 is not prime	Theorem
(4)	Hence, 59 is perfect	2, 3, Disjunctive Syllogism

Clearly, this same pattern of reasoning can be applied to prove the literal truth of any claim about spoof perfectness. So the vacuist is in a bind because it is not just the truth of all counterarithmeticals that is uninteresting but also the trivial easiness of proving individual cases.

Second, and more important, present in the mathematical literature are theorems and conjectures concerning the existence of spoof perfect numbers of various sorts. Many of these results concern completely spoof perfect numbers (recall from the previous section that a number is completely spoof perfect if it would be perfect under the assumption that all of its composite factors are prime). For example,

Theorem 1: For a given number of composite factors, the number of even completely spoof perfect numbers is finite.

Theorem 2: Every completely spoof perfect number has at least six composite factors.

Theorem 3: 907,200 is the smallest even completely spoof perfect number.

The details and proofs of these theorems can be set aside for the moment. What is crucial is that they each make claims that are simply false if – as the vacuist

maintains – *all* numbers are spoof perfect (and multispoof perfect, and completely spoof perfect).

Not only does the vacuist position render the above "theorems" literally false, but it also settles in a trivial manner certain conjectures which are taken by the number theoretic community to be open (and interesting). For example,

Conjecture: There is no odd completely spoof perfect numbers.

To summarize, the inclusion in number theoretic practice of theorems and conjectures of the above sort brings the pragmatic strategy of the vacuist into direct conflict with mathematical practice. If all counterarithmeticals are indeed literally true, then the bulk of these theorems are literally false. And no appeal to a mathematical acceptability/unacceptability distinction will get around this fact.

One glimmer of hope does remain for the proponent of a pragmatic vacuist strategy. She could attempt to formalize the notion of "interestingly true counterarithmetical" and then interpret the above theorems as making claims that are implicitly restricted to the class of "interesting" spoof perfect numbers (I owe this suggestion to Bill Childs). However, the burden of proof is then on the vacuist to come up with an adequate characterization of "interesting." I shall postpone discussion of this option until we have some more technical apparatus in place.

5.4 Vacuously True Counterarithmeticals Do Not Imply That All Numbers Are Spoof Perfect

This response on behalf of the vacuist takes aim at Premise 3 of the core argument. The idea is to question the inference from vacuously true counterarithmeticals to all numbers being (trivially) spoof perfect. As we shall see, there is something to this idea, depending on how exactly one decides to define spoof perfectness. But even on a definition which allows for some numbers not to be spoof perfect, even for the vacuist, the resulting set of numbers still seems to have little independent mathematical interest. Hence, the overall core argument is unaffected.

The point of this response is to focus on the precise definitional link between spoof perfect numbers and counterarithmeticals. Recall the sorts of cases that have been presented, for example,

(16) If 4 were prime, then 60 would be perfect.

The weakest way of defining spoof perfectness is to say that a number is spoof perfect if and only if it features in the consequent of a counterarithmetical of the above sort. More precisely,

Definition 1: A number, *n*, is **spoof perfect** if and only if there is some *m* such that (If *m* were prime, then *n* would be perfect) is true.

On this definition, a vacuist account of counterpossibles implies that all numbers are spoof perfect. However, we could also put further constraints on the conditional claim. One obvious constraint is to add that the conditional in question be a counterfactual, in other words that *m* not be prime. In itself, this does not reduce the extent of spoof perfect numbers. But it does if we combine it with a further plausible constraint that *m* be a proper divisor of *n*. Adding these twin constraints yields the following alternative definition:

Definition 2: A number, *n*, is **spoof perfect** if and only if there is some composite *m* such that *m* is a proper divisor of *n* and (If *m* were prime, then *n* would be perfect) is true.

It is worth noting that for the nonvacuist, the only difference between these two definitions is whether actually perfect numbers are counted as spoof perfect since, in Definition 1, presumably only *ms* that are proper factors of *n* will feature in true counterfactuals about the perfectness of *n*. But for the vacuist, the difference between the two definitions is more significant. Whereas Definition 1 implies that all numbers are spoof perfect, Definition 2 restricts the spoof perfect numbers to those which have at least one composite proper divisor (since this is just the condition placed on *m*).

So, to summarize, there is nothing to stop the vacuist from picking Definition 2 and thus making room for not all numbers being spoof perfect. However, it is easy to see that the resulting set consists of all and only those numbers that have at least one composite proper divisor, in other words numbers with at least three prime factors. Even on this refinement of the vacuist position, therefore, spoof perfect numbers must be equated with a much more basically defined set, leaving no reason for mathematicians to characterize them in such a convoluted, counterarithmetical way. I conclude that the refined vacuist position still does not fit with mathematical practice and hence that this response on behalf of the vacuist is insufficient.

5.5 Spoof Perfect Numbers Need Not Be Defined Using Counterarithmeticals

Thus far, we have looked at challenges to Premise 1 and to Premise 3 of the core argument, as well as attempts to dismiss the force of the argument outright. I now want to turn to possible attacks on what is in many ways the crucial claim of the argument, encapsulated in Premise 2:

2. Each spoof perfect number is defined using a counterarithmetical.

In the original formulation of the core argument, this premise was left intentionally vague. In particular, the "is" in Premise 2 could be read (in increasing order of strength) as

. . . **may be** defined using a counterarithmetical.
. . . **is always** defined using a counterarithmetical.
. . . **must be** defined using a counterarithmetical.

The idea behind challenging this claim is to argue that the counterfactual locutions that tend to be used when introducing the notion of spoof perfect number – "if 22,021 were prime," "if 4 were prime," etc. – are rhetorical "fluff." Not only *can* they be dispensed with when giving a more precise and explicit definition of spoof perfectness, but they *ought* to be also dispensed with. If it turns out that precise definitions can be given which make no use of counterpossibles, then the vacuist would seem to be off the hook. Vacuous counterpossibles can then happily coexist with a contentful role for spoof perfect numbers in mathematics.

6 Paraphrasing Away Counterarithmeticals

6.1 Sigma Functions

What has been presented at the end of Sect. 5 is a program for a defense against the core argument, not a defense in itself. Its success will depend crucially on whether counterpossible-free definitions of spoof perfect number, multispoof perfect number, and so on can be formulated. The approach I shall consider here is based on the apparatus of sigma-functions. I have chosen this approach for two reasons. First, the use of sigma-functions is already well-entrenched in the theory of perfect numbers. Second (and relatedly), it is to sigma-functions that mathematicians most often turn when explicating the more intricate aspects of spoof perfect numbers (see Nielsen (2003, p. 9) and Guy (2004, p. 72)).

Definition: The *sigma-sum* of a natural number, n, written $\sigma(n)$, is the sum of all of the proper and improper divisors of n.

It will be useful for subsequent discussion to note the following theorem concerning sigma-sums:

Theorem: If the prime decomposition of a number, n, is $p_1^a \cdot p_2^b \cdot \ldots$, then $\sigma(n) = (1 + p_1 + p_1^2 + \ldots + p_1^a)(1 + p_2 + p_2^2 + \ldots + p_2^b)(\ldots)$.

The proof is too involved to give here, but the result is intuitive if one thinks of the divisors of a number being made up of all possible combinations of the elements of its prime decomposition. It can be seen that multiplying out the σ product yields each divisor as one element of the final sum.

Lemma: n is a perfect number if and only if $\sigma(n) = 2n$

This follows immediately from the above Theorem, since by definition a number, n, is perfect if it is the sum of all its divisors other than itself. Hence, the sum of all its divisors and itself is equal to $2n$.

The basic strategy for defining spoof perfect numbers is to construct a new "sigma*-sum" corresponding to each counterarithmetical antecedent, such as "If 4 were prime." The sigma* function corresponding to this assumption treats 4 as if it were a prime number for the purposes of calculating sums of divisors. This involves first expressing the number whose spoof perfectness we are investigating as the product of powers of 4 together with a product of prime factors. (In order to guarantee uniqueness, the highest power of 4 possible must be included in the factorization. For example, $16 = 22.4$ would not be a legitimate "4-factorization.") For example, $20 = 4.5$; $24 = 4.2.3$; $75 = 3.5^2$; $80 = 4^2.5$, and so on. If the components of such a factorization are $c_1^a.\ c_2^b.\ \ldots$, then $\sigma^*(n) = (1 + c_1 + c_1^2 + \ldots + c_1^a)(1 + c_2 + c_2^2 + \ldots + c_2^b)(\ldots)$. As can be seen, this directly mirrors the Theorem for sigma-sums that applies to (purely) prime factorizations. If $\sigma^*(n) = 2n$, then n is spoof perfect.

For illustrative purposes, let us run through the above procedure with 4 as our "counterarithmetical prime" and 60 as our number being investigated. $60 = 4.3.5$, so $\sigma^*(60) = (1 + 4)(1 + 3)(1 + 5) = 5.4.6 = 120$. So $\sigma^*(n) = 2n$, and 60 is spoof perfect. With this apparatus in place, we can agree to accept as correct those counterarithmeticals which correctly describe a σ*-function of this sort. So "If 4 were prime then 60 would be perfect" is correct, but "If 4 prime then 59 would be perfect" is not correct (The latter counterarithmetical is not correct because the 4-factorization of 59 is 59, so $\sigma^*(59) = 1 + 59 = 60$ ((2.59)). The counterarithmeticals are not to be read literally (since, given the vacuist account, they are all trivially true) but rather as gesturing at the corresponding claims about σ*-functions.

All that remains is to define the absolute notion of a number being spoof perfect, when this is not tied to any particular counterarithmetical claim. If we introduce subscript notation to indicate the composite number whose primality is being assumed, so $\sigma^*_4(n)$ is the σ*-function for n under the supposition that 4 is prime, then we can define spoof perfectness as follows:

Definition: A number, n, is **spoof perfect** if and only if $\exists m$ such that m is a composite proper divisor of n and $\sigma^*_m(n) = 2n$.

What about the other varieties of spoofness that were mentioned earlier? I will not pause at this point to formulate a sigma-function definition of *multispoof perfect number*, though I think it would be quite straightforward to do so. As for *completely spoof perfect number*, this requires extending the σ^* notation to allow for multiple subscripts. Recall that a number is completely spoof perfect if and only if it can be expressed as the product of composite factors and would be perfect under the assumption that all of these composite factors are prime. So, for composite numbers $a, b, c, \ldots$, let the $(a, b, c, \ldots)$-factorization of n be a factorization into the product of powers of $a, b, c, \ldots$ (This involves abandoning uniqueness of the result of the σ*

operation because in many cases there will be more than one way to express a number as the product of given composite factors. For example, consider factoring 1024 into a product of the composite numbers 4 and 16. Not only $1024 = 4.162$, but also $1024 = 43.16$. It can be verified that these two factorizations yield distinct σ*-sums). Then define $\sigma^*_{a,b,c,\ldots}(n)$ to be the σ*-function for n under the supposition that a, b, c, ... are prime.

Definition: A number, n, is **completely spoof perfect** if and only if $\exists a, b, c, \ldots$ such that a, b, c, ... are composite proper divisors of n and $\sigma^*_{a,b,c,\ldots}(n) = 2n$.

Finally, to illustrate the expressive power of the sigma-notation approach, we shall show how one of the theorems concerning spoof perfect numbers that was mentioned in subsection (III) above can be "translated" into the language of σ-functions.

Theorem 2: Every completely spoof perfect number has at least six composite factors.

Theorem 2 (σ* version): $\forall n \; \forall a, b, c, \ldots$ (If a, b, c, ... are composite proper divisors of n, and if $\sigma^*_{a,b,c,\ldots}(n) = 2n$, then the number of composite factors of $n \geq 6$).

6.2 Discussion

It is clear, I think, that the sigma-function approach sketched above provides the vacuist with a powerful tool for resisting the force of the core argument. It uses apparatus that is already quite familiar from mainstream number theory, and it allows definitions and theorems concerning spoof perfect numbers to be formulated without involving any countermathematical elements. No proof has been given that this method of "sigma-paraphrase" can *always* be applied to claims concerning spoof perfect numbers, but there is no reason to think that it cannot, and plenty of reason to view this is a quite general method for eliminating reference to counterarithmeticals from mathematical presentations of spoof perfect numbers.

The vacuist sees the core argument against their position as resting on a claim of indispensability: Spoof perfect numbers *must* be defined using counterarithmeticals, hence if counterarithmeticals are vacuous then spoof perfect numbers are uninteresting. Let us grant for the moment that the vacuist has succeeded in undermining this indispensability claim. Does this eliminate this challenge to the vacuist position?

Talk of indispensability and of paraphrasing things away brings to mind the Quine-Putnam argument for the existence of mathematical objects, and nominalist challenges to the argument such as Hartry Field's *Science Without Numbers* (Field 1980). The presumption of this debate is that the goal for the nominalist is to come up with an adequate, mathematical-object-free formulation of our best scientific

theories. However, there is another strand of antinominalist argument, advocated by neo-Fregeans such as Crispin Wright, which questions whether even a successful recipe for paraphrasing away mathematical objects would bolster the nominalist position. Consider one area where it does seem to be straightforwardly possible to eliminate explicit quantification over mathematical objects, namely in using (finite) numbers to count objects. As is well known, the reference to number in an expression such as.

(17) The number of cows in the field is 3

and can be eliminated, using just first-order logic with identity, by re-expressing (17) as

(18) $\exists x\ \exists\ y\ \exists\ z[Cx\ \&\ Cy\ \&\ Cz\ \&\ x \neq y\ \&\ x \neq z\ \&\ y \neq z\ \&\ \forall\ w\ (Cw \supset (w = x \vee w = y \vee w = z))]$

The nominalist takes this to show that utterance of (17) does not ontologically commit us to numbers. The neo-Fregean reply is that if (18) really has the same content as (17), does this not – conversely – show that (18) *has* ontological commitment to numbers?

Returning to the case of spoof perfect numbers, the analogous question concerns the precise relationship between a counterarithmetical assertion about spoof perfect numbers, such as

(19) If 4 were prime, then 60 would be perfect,

and its "sigma-paraphrase"

(20) $\sigma^*_4(60) = 120\ (= 2.60)$.

The issue of what to say about the relation between (19) and (20) presents something of a dilemma for the vacuist. If, for example, she postulates some strong sort of equivalence between the two, then this would seem to conflict with her broader commitment to the vacuous truth of all counterpossibles. For this would in turn imply that, strictly speaking, all claims of the form of (19) are true, whereas clearly many assertions concerning the value of σ^* functions are false. In other words, the vacuist cannot rationally maintain both that spoof counterarithmeticals are equivalent to claims about sigma-functions *and* that all spoof counterarithmeticals are true.

A second, more appealing option, is to drop any claim of equivalence between (19) and (20) and say instead that (20) gives the literal meaning of what is expressed, in rhetorical and mathematically imprecise language, by (19). In other words, the model for the relation is more like that which putatively holds between an expression such as "Bob had butterflies in his stomach" and its more literal explication, "Bob felt nervous." Does this literal / metaphorical distinction give the right kind of relation between (20) and (19) for the vacuist's purpose?

The answer to this question depends partly on how the vacuist intends her claims to link to mathematical practice. On the one hand, she might be claiming that what mathematicians *really mean* when they assert a spoof counterarithmetical such as (19) is a claim about sigma-functions along the lines of (20). Following John Burgess's terminology (Burgess 1983) (in the context of the platonism-nominalism debate), call this *hermeneutic vacuism.* On the other hand, the vacuist might be claiming that what mathematicians *ought to do* when making assertions about counterpossibles is to replace claims such as (19) with their more mathematically precise analogs such as (20). Call this *revolutionary vacuism.*

Each of these alternatives faces some difficulties. The hermeneutic vacuist must face the fact that many appearances of spoof perfect numbers in the mathematical literature are not accompanied by any mention of sigma functions. Even more seriously, the original example from Descartes **predates** the development of the sigma-function formalism (by Euler) by over one hundred years! What has the hermeneutic vacuist to say about such cases, where mathematicians make spoof counterarithmetical claims without having any awareness of the sigma-function alternative? This would seem to indicate that mathematicians' understanding of spoofness is not *dependent* on translation into sigma notation. (Or should we say that Descartes was writing purely metaphorically in his letter to Mersenne . . .?)

The revolutionary vacuist faces a different sort of difficulty. For, unlike the hermeneutic vacuist, he is advocating that mathematicians change certain aspects of their practice. In particular, they should stop using counterarithmetical locutions in introducing and specifying spoof perfect numbers. But another way of viewing this call for revision is as a *conflict* between revolutionary vacuism and mathematical practice. And – although this is not a fatal flaw – this is enough to cast serious doubts on the cogency of this brand of vacuism.

There is much more to be said here on both sides, but hopefully enough has been done to show the connections between this issue and some broader debates in metaphysics concerning indispensability and ontological commitment. I shall close this section with a separate objection to the sigma-paraphrase strategy, namely that it fails to account for a certain kind of use to which mathematicians put spoof perfect numbers. In a 2003 paper, Pace Nielsen proves an upper bound on the size of an odd perfect number, expressed in terms of its number of distinct prime factors. At the end of the paper, Nielsen discusses Descartes' spoof odd perfect number (and shows its spoof perfectness using sigma-function notation). He then makes the following remarks:

> To demonstrate . . . the weakness of the bound above, we have the following: . . . If we restrict ourselves to numbers that can be expressed as a power of 22021 and other factors relatively prime to 19 and 61, and if we replace σ by σ^*, then the proof of the above theorem [on upper bounds] still goes through. So it should be true that for $N = 3^2.7^2.11^2.13^2.22021$ we have $N < 2^{1024}$. In fact $2^{1024}/N \approx 4.407 \times 10^{317}$. This demonstrates one of the difficulties in proving the non-existence of odd perfect numbers. (Nielsen 2003, p. 9)

What Nielsen does here is first show that the upper bound he has proved gives a very weak result for Descartes' spoof odd perfect number, since the bound is larger

than the number itself by a factor of 10^{317}. He then uses this fact to motivate the claim that the bound is likely also to be very weak for *nonspoof* odd perfect numbers. To be sure, this latter move is not a formal proof of the weakness of the bound. But the use of investigations into the properties of spoof odd perfect numbers to cast light on the properties of genuine odd perfect numbers (if any there be) is not uncommon in this area of mathematics. The question for the vacuist, then, is whether this sort of "heuristic" use of spoof perfect numbers can be justified once everything has been translated into sigma-functions.

There are at least a couple of reasons for thinking this might be a problem for the vacuist. First, the sigma-function approach is rather formalistic in nature. It is true that the relevant $\boldsymbol{\sigma^*_m}$-function can be precisely defined, for each composite number *m*, but why should the values of these $\boldsymbol{\sigma^*_m}$-functions have any bearing on the regular σ-function expressing the sum of divisors? Second, the sigma-function approach abandons any role for the property of being a genuine perfect number in defining the notion of spoof perfect number. This is in contrast with the counterarithmetical approach, which defines spoof perfectness by pointing to a counterfactual situation in which the given number is **literally** perfect. This encourages the view that spoof perfect numbers are closely connected to genuine perfect numbers – they almost were perfect! – and hence provides motivation for heuristic arguments such as Nielsen's which apply conclusions from one to the other.

7 Nonvacuism and the Evaluation Problem

Thus far, I have deliberately focused attention on the vacuist account of counterpossibles because the challenge posed by spoof counterarithmeticals in mathematical practice is most immediate for views which classify all counterpossibles as vacuously true. However, I think that the counterarithmetical examples presented earlier also offer resources for nonvacuist analyses of counterpossibles. In this section, I shall briefly outline why.

To make the discussion more concrete, I shall use a specific nonvacuist analysis to illustrate the general problem. Consider an analysis along the lines proposed by Daniel Nolan and others, which adds impossible worlds to the Lewisian framework (Nolan 1997). The idea is to keep the form of Lewis's definition of counterfactuals, but to save counterpossibles from vacuity by allowing their antecedents to pick out the closest impossible worlds. A counterpossible is false if its consequent is false at one of these closest impossible worlds. In allowing for false counterpossibles, this analysis makes room for nontrivial counterarithmeticals and thus for a mathematically interesting class of spoof perfect numbers. So far so good, but the nonvacuist is not yet off the hook. Ideally, we would like not just a framework for analyzing counterpossibles but also guidance about how to evaluate the truth or falsity of specific examples.

It is important not to set the bar unreasonably high here when we ask the nonvacuist for guidelines for evaluating counterarithmeticals. If the framework is one of impossible worlds, then counterpossibles will be evaluated at those

impossible worlds that are most similar to the actual world. Thus the request is mainly for guidance about how to assess comparative similarity. And the issue of how to cash out similarity is a thorny problem for possible-worlds approaches in general. Nonetheless, there are reasons for thinking that counterarithmeticals present two distinctive extra difficulties, stemming from their contradictory antecedents and from their mathematical subject matter. For the moment, I will focus just on the second of these features.

One approach to giving guidance is to provide rules of thumb for assessing relative similarity between two worlds. David Lewis provides some such rules in a 1979 paper (Lewis 1979, p. 472):

1. It is of first importance to avoid big, widespread, diverse violations of law.
2. It is of second importance to maximize the spatio-temporal region throughout which perfect match of particular fact prevails.
3. It is of third importance to avoid even small, localized, simple violations of law.
4. It is of little or no importance to secure approximate similarity of particular fact, even in matters that concern us greatly.

There are several reasons why applying these rules to counterfactuals with mathematical subject matter is problematic. For example, is there an intuitively clear divide in mathematics between "laws" and "particular facts"? Distinguishing laws in terms of their modal status clearly will not work, since "All even numbers are divisible by 2" and "7 is a prime number" are both necessary, if either is – nor will making a distinction in terms of generality, or being universally quantified in form. (Compare, "All numbers between 6 and 8 are prime," which is universally quantified but seems nonlawlike, and "0 is a natural number" which seems both particular *and* lawlike.) A second problem is how to make sense of – or provide analogs for – notions of spatiotemporal matching for mathematical facts. (See Baker (2003, pp. 256–260) for more discussion of how to apply Lewis-style rules of thumb to counterfactuals with mathematical subject matter.)

Perhaps, it will be possible to come up with rules of thumb for assessing similarity between worlds where different mathematical facts obtain. But at present, this is an open question, and – as such – a challenge to the nonvacuist position. Note also that to be useful in the context of evaluating spoof counterarithmeticals, such guidelines will need to answer quite specific questions, concerning, for example, whether a world in which 6 is prime and 6 is a factor of 12 is more similar to the actual world than a world in which 6 is prime and 6 is not a factor of 12. (The difficulty is that if 6 is a factor of 12, then (presumably) $12 = 2.6$. But also $12 = 2.2.3$, so this implies that uniqueness of prime factorization does not hold.)

It may be that some alternative, nonsimilarity-based analysis will be more effective in analyzing counterarithmeticals. Baron et al. (2020), for example, consider an approach inspired by counterfactual analyses of causation in which a distinction is made between "upstream" and "downstream" facts. They briefly consider a number of ways of trying to flesh out these notions in the mathematical case, where no causal notions are in play, but end up acknowledging that they are

leaving "the distinction between upstream and downstream facts at an intuitive level" (Baron et al. 2020, p. 8).

8 Conclusions

I hope to have shown in this chapter how the role of counterarithmetical reasoning in mathematical investigations of spoof perfect numbers presents both a *prima facie* challenge and a potentially valuable resource to philosophical theories of counterfactuals. To be adequate, any such theory must have something to say about counterpossibles – counterfactuals with impossible antecedents. If the analysis implies that all counterpossibles are vacuously true, then the challenge is to explain the systematic patterns of acceptance and rejection of different arithmetical counterpossibles by practicing mathematicians. If the analysis allows for non-vacuously true counterpossibles, then the task is to provide guidelines for evaluating arithmetical counterpossibles that are precise enough to underpin their role in actual mathematical practice.

Abstract

Mathematics can be viewed through complementary lenses as structure or as process. The latter point of view which is taken in this chapter (and this volume) emphasizes "doing mathematics" and so is tied to learning and creativity.

Mathematics is not just any process but a rational one and this chapter investigates what is meant by reason in mathematics. A look at the way mathematics is actually done leads to an expansion of the usual understanding of reason by integrating of intuition and creativity into the rational process. This leads us to take another look at what we mean by objectivity in mathematics. We identify

weak and strong varieties of objectivity (analogous to weak and strong AI) and claim that mathematics is objective in the weak sense but not the strong. As a consequence of this and the central place we give to process, mathematics is inescapably tied to human culture and thus never absolutely objective, true, or eternal

1 Introduction: What Mathematicians Do

Mathematics is what mathematicians do! In this statement there is "what mathematicians do" and then there is the mathematics. They are two sides of the same coin, each defining the other, each side indispensable to the other. Without mathematicians there is no mathematics and vice versa. If you try to make logical sense of the statement, it looks perfectly circular, and since we have been trained to frown upon circularity our instinct is to reject it. We normally demand linear arguments from hypotheses to conclusion and this may be the way it needs to be in ordinary mathematical discourse but, in trying to discern what mathematics is all about, perhaps circularity is not the problem that it appears to be. In fact, circularity may actually point us in the right direction. It may help us to see that mathematicians and mathematics, mathematical process and content, are fundamentally intertwined, and thus that any definitive separation is ultimately artificial. They are two perspectives on one and the same phenomenon. It is a matter of convenience and perspective as to which one we choose to consider at any given time.

Remember that the great mathematician Bill Thurston said, "What we (mathematicians) are doing is finding ways for people to think about mathematics" (Thurston 1994), which is circular in much the same way as my statement above yet says something important about the interrelationship of mathematics and mathematical activity. After all mathematics is a creative process in which new results lead to new questions which lead to further progress in a kind of endless spiral.

I spent the good part of a book (Byers 2007) discussing the kind of situation in mathematics in which there are two equally valid perspectives that appear to clash with one another. In the present situation the two perspectives are process and structure. I referred to this kind of situation as ambiguous, an ordinary word that I appropriated to describe a fundamental aspect of mathematics that is normally overlooked. Normally ambiguity is viewed negatively and suppressed but I choose to emphasize its constructive aspects. Coincidentally a terrific book appeared in the same year which was also about such positive ambiguities (Grosholz 2007).

In this chapter I intend to investigate the process/content ambiguity of mathematics and the ambiguity of mathematics and the mathematician. There is a considerable amount of confusion concerning this situation that I hope to shed some light on. Mathematics is not just about stuff; it is also about how the stuff comes about, how it is understood, and how it is learned. Process and content appear to inhabit logically distinct domains but the point of view taken in this chapter is that they cover the same ground and thus should be thought of as complementary – two valid ways of describing the same thing. Each perspective brings its own insights.

However, these two points of view do not currently have the same status. For the most part, mathematics is considered to be identical to its content. Thus it is unconventional, to say the least, to consider the perspective that would take "process," the doing of mathematics, as primary or that we should consider process as being prior to content. Of course "prior" here does not necessarily mean chronologically so much as it refers to ontological status.

Let us consider for a moment what it would mean to prioritize the process dimension over the dimension of structure. It would root mathematics in the activity, the doing, or the learning. How would this work? For one thing it might force us to expand our definition of mathematics to include what today is called informal mathematics. In addition to the usual formal world that consists of objects and structures, there would also be an informal world that forms the ground out of which the formal is created. The formal, then, would be the crystallization of the informal. Objects would arise from process through what is called reification, which is, for example, the process whereby infinite summation becomes a real number or subtraction becomes a negative integer.

Of course, this is not the way we learned to think about mathematics. It is the opposite of Platonism where you have ideal objects at the most fundamental level. In fact it is not the way we think about science nor, for that matter, the way we think about the human condition. We tend to think of objects as primary and some of these objects as elementary, the "atoms" of our theory. We are most comfortable with these sort of "atomic" ways of organizing the world.

The objects whether they are actual atoms or else molecules, cells, people, or numbers are the primary focus. We start with elementary objects and then consider their relationship to each other and the ways in which they combine and interact to produce new, more complex, objects. That is the way we structure the world. Even our language (but not necessarily every language) is structured in this way. Things (nouns) appear to come first and thus have priority over actions (verbs). We imagine that the world has this structure and that language reflects this reality but it is also possible that the reverse is true, that language comes first and the structure of language determines how we think and has given us a theoretical approach in which the world and various scientific disciplines are structured in this, object-oriented and atomistic, way. For the most part this object-oriented way of looking at things has been handed down to us from the ancient Greeks.

2 Looking at Mathematics from the Perspective of Process

The alternative, a process approach, has something in common with the way one looks at things in quantum mechanics in which it is insufficient to think of an electron, say, only as a particle, that is, an isolated object with clear boundaries and a definite location in space-time. It takes the collapse of the wave function to "create" a particle, that is, bring it into being. The wave is the particle before the collapse of the wave function.

There is also a "collapse" in the process of reification. Process, which is open and fluid, collapses, or crystallizes, into the reified object which appears to have definite boundaries or a formal definition and therefore seems to be solid and permanent. The process world is chaotic and that is how things are "at the beginning," in the informal dimension of the mathematical adventure. Process, which has no permanent form, certainly exists, but not in quite the same way as form does. The manner in which it exists resembles in some ways the process of informal thinking or free association where ideas keep flitting by and we have to be very alert to grab the significant ones and write them down so as to give them a kind of permanence. We sometimes do this by giving names to the ideas that we deem to be significant, and this highlights the connection between language and the process of creating structure. When most people use the word "mathematics" they are normally talking about the world of mathematical structure. When I use the word I will mean both worlds: the fluid one of process and the solid quasi-static world of structure.

This fundamental assumption about how mathematics and, more generally, scientific disciplines should be organized is ultimately in question here. Perhaps objects are not the fundamental and permanent building blocks of reality. Objects change – even what we mean by specific mathematical concepts like continuity change; they come into being under certain circumstances and change or even disappear when they are no longer relevant. If change is fundamental and universal, then one key question would be the manner in which objects, including mathematical objects, come into being both for the individuals doing mathematics, for the larger culture of mathematics, and for society in general. Thus the manner in which a process becomes an object, reification, is central.

However, there is also the inverse process, namely, the manner in which structure disintegrates, is modified, or gives rise to process. That process can come from structure is simple. When you have numbers you can then do arithmetic. But how do structures change? How does a simple structure give rise to a more complex one? One way this happens is in response to problematic elements that inevitably crop up in any theory and only appear after the structure is investigated by the mathematician. Thus you cannot divide in the system of the integers. Or there are the famous unsolvable problems in Euclidean geometry such as the trisection of the angle. These problems reveal certain inadequacies of the system in question. Their resolution often requires the creation of a new system that extends the old. But before the new structure can appear it is necessary that the way of thinking that comes with the old system, and in which the theorems are considered to be absolute truths, breaks down. Only this provides a space in which a new way of thinking can emerge. In this new

theory the original truths are seen as relative (to the set of axioms used, for example) and not absolute. A good example of this is the movement from Euclidean to non-Euclidean geometry, or simply making ratios into rational numbers.

Thus there is reification, which is the way structure is constructed from process and what you might call "deconstruction," the melting down of old structures to make room for new. One goes from process to content, the other moves in the opposite direction, from structure to process and then to new structure. Both directions involve mathematical creativity, although deconstruction and reframing are not always recognized as fundamental aspects of mathematics. It is important to bear in mind that both construction and deconstruction are human activities. Reification involves the birth of concepts, and deconstruction is essential to reframing an old concept in a new way.

Let us think for a moment about what it would mean to take "mathematics is process" as a place to begin the discussion of the nature of mathematics. Of course, this would not mean that mathematics is only process. It means that you must start with process (and with an understanding of reason which I go into below) when you describe mathematics. You do not start with mathematical objects such as number systems, for example. You do not even start with axioms, not even with a system of logic such as the propositional calculus. These traditional approaches view process as, for example, the unraveling of the properties of mathematical objects that are implicit in an axiomatic system. Learning and creativity are bracketed off from "real mathematics" and only considered in separate disciplines such as education and psychology. Not even the history of mathematics gets treated as a "mathematical" discipline and so even advanced students tend to be quite ignorant of the history of their own discipline. We tend to ignore process in our teaching so students get little training in problem solving or even training in the process whereby one becomes fluent with a difficult mathematical concept. As a direct consequence of the mathematical community's approach to the nature of mathematics, process is neglected and even reason is not seriously investigated other than to identify it with logic. There is a sense in which all traditional approaches are fundamentally static.

Yet at its very origins mathematics is an activity: counting, measuring, comparing, estimating, and so on. For example, we might be interested in investigating "quantity" or "amount." We begin by trying to answer the question, "Which is more?" or equivalently, "Which is larger?" To consider such questions it is necessary to structure quantity by inventing a language. We require abstract carriers of quantity and that is how we get to the concept of "number." "Number" is a reification of the various activities that were mentioned above.

Even though it may not be possible to go back in the history of mathematics to isolate the first emergence of number, we can look at the development of the number concept in infants which will give us some hints. The situation is surprisingly complex. It seems that infants (and some animals) have a latent "numerosity," which could be defined as a rudimentary ability to recognize number, a built-in capacity to develop the number concept. This does not mean that this latent capacity need necessarily be activated in the same way that other genetic traits can remain latent until some environmental stimulus turns them on so to speak. So the capacity

for number leads to various activities that require an enriched and refined sense of number which leads to a more sophisticated number sense in a spiral of development that ends up with the very complex number systems with which that we are familiar.

It is interestingly that educators have long observed that students learn by doing. Then they learn to give names to bits of mathematical activity, creating in this way a structure which becomes the scene of further, higher level, activity. Thus a fraction starts as a problem in long division and ends up being a number just as the negative numbers arise from the process of subtraction. Thus processes get reified out as conceptual objects. Then in the formal recapitulation we begin with the objects and reintroduce processes of various sorts. We are reluctant to begin with process because objects seem so much more precise and easier to get your hands on. Of course a given process could conceivably be reified in more than one way and lead to different formal systems. Possibly we move in certain directions because of certain tendencies that are built-in.

There are other ideas that flow directly from ordinary activities that find their way into mathematics. Ideas such as "chance, "continuity," "nothing," and "infinity"? All of these arise out of activities, out of solving problems. These and a host of other questions begin at a level that is concrete and experiential; they arise in the ordinary activities of human beings.

Of course, thinking about mathematics in this way may make some people a little uncomfortable, maybe even bring on a feeling of disorientation. We have become habituated to the metaphor of mathematics as an enormous and intricate edifice of eternal truth. In this view even though mathematics may have been created by human beings, nevertheless it transcends the human condition and inhabits a mystical, Platonic realm that lies beyond time and space. We love the idea that even if individual human life is finite, the mathematics that we create will live forever because its truths are eternal and immutable. It is a comforting place to inhabit whereas mathematics as process brings us back to the contingency and uncertainty of life, something that may appear to recede as we contemplate the grandeur of the great mathematical theories.

3 Mathematics Is What *People* Do

To go back to the statement "mathematics is what mathematicians do," note that it has an emphasis on process but also that it emphasizes that mathematics is an activity that is carried on by human beings. The late neurologist Oliver Sacks said, "Science is a human enterprise through and through, an organic, evolving human growth,. . ." (Sacks (2019), quoted in the review of his posthumous book). The same could and should be said about mathematics.

It is particularly appropriate to look at mathematics from this point of view in this chapter since this volume celebrates precisely the change from structure to activity. This change can be traced back to two remarkable books: *Proofs and Refutations* (Lakatos 1976) by Imre Lakatos and *The Mathematical Experience* (Davis and Hersh 1981), by Philip Davis and Reuben Hersh. Both of these books turned our

attention away from the structure and content of mathematics and toward what is actually going on when mathematicians do mathematics. This shift involves moving from a view of mathematics as consisting of static, permanent structures in the form of definitions, theorems, and proofs but also as algorithms, and various methods of computation to a view in which mathematics is always changing and coming into being, to mathematics as a dynamic, creative, and thus human process. This necessitated a critique of the prevailing framework for mathematical activity, namely formalism and Platonism, and this volume is a search for a replacement.

4 Understanding and Learning

Thurston and many others have identified "understanding" as the basic mathematical activity. Mathematicians try to understand the mathematical phenomena that they encounter in their professional lives. But what do we mean by understanding? I recall a comment made by a student concerning some very dry derivation of the consequences of the axioms of a topological space, "I follow the argument but I don't understand it." Following involves a step-by-step process of verifying that each step follows logically from the previous one. Understanding is more global or holistic. It usually happens suddenly and may happen more than once for the same material, that is, there are depths of understanding. It often appears suddenly and one says something like, "Aha! I see what is going on here." Understanding a proof, for example, often means that the idea behind the proof is revealed. Even a fairly complex proof may be the elaboration of an idea which can be stated quite succinctly. But understanding a subtle mathematical idea like real numbers, continuity, or randomness is a significant accomplishment that, in a certain sense, is never complete. There is a continuum of understanding which moves from the first glimpses of understanding by the young student to the sophisticated understanding of the research mathematician.

It is worth emphasizing that both research and learning involve understanding. Doing mathematics involves learning (about) mathematics. We would have a much more profound appreciation for education if we realized that learning at the most profound level involves the same mechanisms as doing research. (Of course not the same level of complexity.) Learning is not the passive accumulation of facts. Learning involves mastering ideas, that is, conceptual understanding. Learning and understanding are both creative activities.

Though mathematicians and math educators do not normally communicate with one another because they live in different disciplinary compartments, educators are well placed to understand the difference between being content or process oriented. Educators and teachers need to focus on process because it is evident that learning is a process. Today, influenced by a view of knowledge as mere data, there is a tendency to think of learning as the accumulation of facts and techniques. But this is not what I mean by learning or doing mathematics and has little to do with becoming fluent with a particular mathematical world.

I can remember a first-year graduate student in one of my classes. I asked him what mathematics he had studied and he answered that he had read such and such a book on analysis and could quote the theorems and proofs from memory. Very impressive! Unfortunately he was unable to answer or even to approach the questions in the first assignment because it turned out that he had never actually done a problem before. This student knew no mathematics at all, and this illustrates what I mean by saying that mathematics is not primarily about content. Both learning and research are processes whereby human beings "find ways . . .to think about mathematics," where "thinking about" could be taken to mean "understanding."

The shift from viewing mathematics as structure to viewing it as process is a radical change in perspective. We were all brought up to consider the content of mathematics as what is real and defines the subject. It I as though every area in mathematics could potentially be written down in some sort of definitive textbook which, of course, would never be complete. In this view a subject would consist of a compendium of facts and research involves adding to this collection. In this view learning would involve getting familiar with those facts in the manner of the graduate student I caricatured. Of course this is not what learning means at all. It really means becoming fluent with the material, understanding the main ideas and concepts, and being able to apply them in an intelligent way. Just as fluency with language implies the ability to produce sentences that may have never existed before so fluency in mathematics means being able to work with situations that one has never encountered previously.

The shift from facts to process is crucial for the philosophy of mathematics because facts seem to be solid, objective, and potentially eternal. Process, on the other hand, carries the connotation of impermanence, of coming into being and then disappearing. Process also seems to have elements of subjectivity. There is always someone who is creating or learning. Of course we could imagine that the agent behind the process is an algorithm or computer program, which gets us into questioning the possible role of artificial intelligence in the process of mathematics. I shall have more to say about this later in the chapter.

5 The Process of Reason

Of course, mathematics is not just any process. It is a rational process and, in particular, it is an intelligent process. People *do* mathematics; they *learn* mathematics. So in order to find a way to talk about mathematics as process we must define what we mean by a rational process. What is reason? I will give a kind of definition a little later on but, whatever reason turns out to be, it must involve intelligence, that is, mind. And, as far as we know, this is why mathematics is a human activity – mathematics is about *people* learning to think about mathematics. As we go along we shall see that this implies what machines do and can do is not mathematics. Artificial intelligence is not rational intelligence; it merely mimics certain aspects of rationality.

It follows that what I have called elsewhere "the dream of reason" (c.f. How Mathematicians Think p. 12 or 84) does not hold, partially, as we shall see, because we misunderstand the word "reason." We identify reason with logic and divorce it from intelligence. Then we imagine that "reasoning" involves following the rules of logic, in particular, that it is rule-based in the same way that a computer algorithm is rule-based.

The traditional dream of reason is, of course, that we can produce mathematical and scientific theories that are certain, objective, and identical to what they model. In particular we imagine that a theory is static and eternally true. We feel that truths can never and will never change. In the dream of reason the theory stands alone liberated from reason, mind, and humanity. Understood in this way the dream of reason is a bad dream because the humanity of the dreamer has been lost or ignored. If this dream is not valid, then there is no "final theory" of physics, economics, or any other science; there is not even a theory of the stock market that works over an extended period of time. In our subject it is clear that mathematical activity will continue without end.

This chapter will propose a new way of thinking about rationality as process. On this basis we might be able to rehabilitate the dream of reason and reclaim it for humanity instead of a way of replacing human beings by machines and human reason by sophisticated, but intrinsically limited, algorithmic processes.

6 Formalism as Process

As a precursor to a discussion of the rational process let us consider the nature of formalism. Formalism identifies mathematics with a process, namely, the axiomatic method that operates within the context of a set of axioms, definitions, and operational rules of logic. It is still the dominant way of thinking about how doing mathematics works and so let us go back and revisit the nature of an axiomatic system and the process of working within it.

Here are a few questions regarding axiomatic systems that reveal the limitations of the way we normally think of it.

1. What does Thurston's comment mean when applied to an axiomatic system, that is, what does it mean to understand such a system as a whole or even to understand some particular theorem that follows from the axioms? In particular where is understanding to be found – is it part of the system or extraneous to the system? In other words, what is understanding and where is it located?
2. Given a choice of some particular set of axioms why are some results interesting while others are not? Why do we often make statements like "that result is deep" or "this result is trivial." Can the basis for the judgments "deep," "trivial," and "interesting" be found within the system or are they outside the system? Or are they merely subjective with no objective meaning? Are these judgments even part of mathematics at all? If they are not, then how do you decide whether or not to publish some article in a prestigious research journal?

3. Suppose you are trying to prove a result which has been found to be plausible empirically. Where does the idea for the proof come from? Does the mathematical idea exist within the system or is it extraneous to the system? In general, what is the relationship between the concepts and ideas of the subject and the axiomatic structure?

These questions and others demonstrate that when we discuss the axiomatic system we focus on certain aspects to the exclusion of others. There is a great deal more going on than mere deduction from axioms. Another way of putting this difference consists in saying that the rational process involves much more than applying logical inference to a set of a priori truths.

What I have to say will be clarified if we take a new look at what is happening in the axiomatic system. In order to make things concrete I shall take a quick look at Euclidean geometry as a prototype of an axiomatic system and give a more complete account of what is going on. What are the answers to the three questions I listed above in the case of Euclidean geometry? What, in short, does it mean to look at Euclidean geometry as a rational process?

7 The Discovery of Reason by Doing Euclidean Geometry

Euclidean geometry is one of the foundational elements of Western civilization and the root of the technological revolution that is currently sweeping over us. I am thinking about Euclidean geometry these days because I am teaching the subject to my 13-year-old grandson in order to give him a little intellectual enrichment. It is not taught in schools any more but friends and colleagues who are scientists and mathematicians all concurred that the subject had been important to them in their intellectual development. Why was that? In other words why study Euclidean geometry?

Most people regard Euclidean geometry as the prototype of a deductive system – definitions, axioms, and theorems deduced through pristine logical thought. They may believe that the subject is algorithmic so that it could be done by a computer. In other words they imagine that Euclidean geometry could be done without human intervention in exactly the same way that some people believe that AI systems can operate independently of human beings. So is Euclidean geometry a matter of pure deductive logic?

The significance of Euclidean geometry to the mathematician goes beyond its theorems. It includes the means through which these results are obtained. Euclidean geometry was such a significant part of the education of scientists, physicians, and mathematicians of my generation because it taught us how to think. In particular it showed us that thinking involves a deep connection between logic, intuition, and insight.

Even though Euclidean geometry is held up as the prototype of a deductive system, which may appear to be abstract, in reality it is concrete and geometric. It

is concerned with the structure of two- and three-dimensional (flat) space. In fact for the Greeks, Euclidean geometry *defines* space. It is not only about proving theorems but also about developing an intuition for the geometry of space and fitting these intuitions into a system of verifiable truths. Doing Euclidean Geometry involves logical thinking but it also involves the nonlogical procedures of intuition and insight that I will describe below.

Imagine that you are studying Euclidean geometry from scratch. Imagine that it is an area of research. "Doing" Euclidean geometry would work like this: First of all you have to think up some geometrical statement (or potential theorem) that is interesting and accessible on the basis of current knowledge (the axioms you have agreed on and the theorems you have established so far). (This is akin to deciding which hypothesis to test in a scientific experiment.) Then one has to guess whether the statement is true or not. If you guess "no," you try to find a counterexample. If you guess "yes," you try to construct a proof. The proof itself does not come into existence through a series of purely logical statements. A proof (or counterexample) is built around some idea (which may turn out to be a geometrical construction). In other words you have to know *why* it is true before you try to prove it. Actually the idea for the proof is usually what you mean by "understanding" the result.

Where does the idea or the understanding come from? Obviously it comes from the mathematician. It is only at this stage, after the idea has revealed itself to you, that you attempt to write down a proof and this is the only step in the procedure that is strictly logical.

Thus doing geometry involves **intuition** (developing the hypothesis and guessing true or false), **insight or creativity** (coming up with the hypothesis and the idea for the proof), and **logical argumentation** (for the purposes of verification and communication).

All three are essential parts of a deductive system, and this is how it feels to work on such system *from the inside*. This is how it feels to *do* mathematics. The further you go the less value you ascribe to the third, logical, part. Thurston said, "When the idea (behind a result) is clear, the formal setup is usually unnecessary and redundant." Creative scientists are basically interested in new insights, original ideas. Creativity is the very essence of science and mathematics.

8 What Is Rationality?

Let us *define* the rational process by abstracting my description of Euclidean geometry. Thus, *rationality involves intuition, insight, and logic.* Logic is just one of the steps not the whole ball of wax. This gives us a working definition of the rational process. Intelligence, on the other hand, is a concept that is very subtle and hard to get your hands on. Maybe we could think of it as the capacity for problem solving and thus for reason. I propose that we substitute "rational process" for "intelligence" whenever we can. (For example, maybe we should talk about "artificial rationality" rather than "artificial intelligence.")

9 Intuition or Fast Thinking

Intuition is thus an essential aspect of the process of reason. The Nobel Prize-winning psychologist and economic theorist Daniel Kahneman is famous for demonstrating that the economic actor is not only logical. In fact according to Kahneman human beings are capable of two kinds of thinking that he calls fast and slow. Slow thinking is what many people think of as logical thinking. They forget that fast thinking, which is involved in intuition is also essential to rational thought. Fast thinking is what the "leader of the free world" calls his "gut" and he is a disastrous example of the damage that can occur when fast thinking is unchecked by slow. You can read the history of rational thought as the attempt to control fast thinking with slow thinking but, in my opinion, that would be a mistake for reason has room for both of these modes. AI takes slow thinking, puts it into an algorithm, and uses a machine to speed it up. It remains a kind of victory of slow thinking over fast thinking but comes with a cost. Rational thinking involves a synthesis of intuition and systematic, rule-based procedures.

10 Reason or Revelation?

I have heard it said that the Ancient Greeks contributed their ideals of reason and harmony to modern civilization. The ancient Hebrews, on the other hand, contributed the ideal of revelation, which you can think of as the voice of God speaking to Moses from the burning bush but, more prosaically, as the discontinuous emergence of a new and powerful idea. In other words, the aha! experience. Anyone who has done any research in mathematics or even mastered some nontrivial mathematical concept like real numbers or limits will have had this moment when things began to come together and make sense.

The confusion I mentioned above concerning the true nature of the rational process comes from reducing reason to logical inference, on the one hand, and ignoring the role of revelation on the other. Logic is rule based, orderly, and predictable whereas creativity is not predictable and does not seem to follow any system of a priori rules. By reducing reason to logic we can easily conclude that the role of the human mind in mathematics could be replaced by some kind of artificial intelligence. The problem with this is that what I (a bit dramatically) called revelation is an essential part of the process of doing mathematics and even of learning mathematics (There is much more about this in my book, *Deep Thinking: What Mathematics Can Teach Us About the Mind*, World Scientific, Singapore, (2015).). The way toward a more complete view of mathematics involves accepting that reason is a lot more than logic and includes both intuition and insight. Only then will it be possible to respond to Poincaré's question – the perpetual mystery of power of mathematics to penetrate so deeply into the reality. The power comes from mathematics' ability to harness all aspects of the rational process.

11 Creativity and Insight

Creativity is not to be confused with the production of what is new. It involves insight, by which I mean the discovery of a new way to "see" some situation. We understand some event or situation by placing in a context, that is, framing it. Then the most basic creative act involves *reframing*, that is, coming up with a new way to understand a given situation or event. So "getting the idea" often means finding a new point of view from which to look at some situation. In science a frame is called a paradigm and reframing is referred to as a paradigm change. I am thinking, for example, of the way Einstein reframed our understanding of gravity.

But to remove the idea of creative reframing from the rarified atmosphere of genius let me supply a more down-to-earth example that applies to everyone.

According to developmental psychologists like Susan Carey (2009) children are born with two primitive but vastly different conceptual systems for number. An early conceptual task for children consists of combining these two systems into their first learned number system – the system of the counting numbers: 1, 2, 3,. . .. That development is a child's first creative learning experience in mathematics. However, because we are here concerned with the rational, I want to focus on the next step children take a few years later – the reframing of "number" from the frame of the counting numbers to the new frame of fractions or rational numbers. Initially fractions are introduced in terms of relative areas. We all remember that two-thirds was given meaning by dividing a pie into three parts and choosing two of them. Notice that this kind of example does not yet make two-thirds into a number but merely a ratio, that is, a relationship between the numbers two and three.

12 Creativity as Reification

The crucial but nonobvious question concerns why 2/3 is a number at all? If it is a number, then by what process does it become one? The child must come to see 2/3 as a single object, that is, she must reify the ratio of two to three into a new kind of number. When this happens with respect to two-thirds the child can do the same thing for other fractions. She has then undergone a total conceptual reorganization, a reframing of her understanding of number. Reification of pairs of whole numbers, which brings the fractions into existence, is nothing less than a paradigm shift and yet almost every child goes through this shift sooner or later. Of course we do not call it reframing, we call it learning. We have all been there but we have forgotten and so for us it is "obvious" that fractions are numbers. We forget what a significant development this was. But there is no reason a priori that fractions should be numbers that extend the system of counting numbers. Moreover there is no reason why the set of ratios should make up a new number system for which the old operations of arithmetic still make sense. You can see what a big deal it is when you think about the extravagant claims that the Greeks made for the rational number

system (which they seem to have identified with reason itself) and how profoundly shocked they were when confronted by the existence of irrationals. The creation of the rational number system in human culture or in the mind of a child is a prototype of an act of creativity.

One crucial point about this example. The two number systems, counting numbers and factions, are incompatible (or incommensurate, as the philosopher of science Thomas Kuhn would have it) with one another in the following sense. If you ask a child who lives in the world of counting numbers how many numbers there are between 2 and 3, she will say none. But a child who made the creative leap to the world of rational numbers will say that there are lots of them. And of course they would both be correct within their respective frames or conceptual systems. In other words correct and incorrect are *relative* terms, relative to context, of course.

Within a conceptual system like the integers or the rational numbers one insists on consistency and thus the absence of things like contradiction and ambiguity.

A well-designed theory has no place for such logically problematic things. However, it is precisely these problematic elements that drive paradigm change, the movement from one conceptual system to another. In Greek geometry there were "unsolvable problems" like trisecting an angle and squaring a circle. To solve them, you need to change the context of the discussion, that is, reframe the problem. An even more subtle problem concerned the status of the parallel postulate in Euclidean geometry. Questioning its status as an axiom and therefore "obviously true" leads ultimately to the development of non-Euclidean geometry.

One does not leave one's present paradigm willingly or easily; you need to be driven out by a problem that you cannot solve in the old system. For the move from the counting numbers to the rationals the problem might be that the division of whole numbers is not closed within the system of counting numbers. In other words though you can divide 7 by 3 in the counting numbers (and get an answer of 2 with remainder 1), the answer is not a number in the system you started with.

This leads me to say that *creativity transcends logic.* It involves the sudden leap to a higher point of view. A problem that was intractable in the original frame becomes transparent when looked at in the new.

One further comment is brought out by this example. In mathematics there are many kinds of numbers: counting numbers, rational numbers, real numbers, complex numbers, and many others. This whole hierarchy is built on the primitive idea of "number." Yet "number" in the abstract is never defined in mathematics. We all have a feeling for number because even a 6-month-old child has two separate conceptual systems for number. Nevertheless this "feeling for number," what I called numerosity earlier, is informal and thus never defined explicitly. The specific kinds of numbers I mentioned are, in comparison, well-defined. In this way the conceptual world of mathematics (and physics) emerges out of an informal world. Number is not special in that regards. What I said also applies to the concepts of time, space, energy, randomness, and many other concepts. In fact all of the building blocks of science have informal roots. Mathematics lives in both formal and informal worlds. Intuition functions very well in the informal world and creative reframing often has

to go back there but logical processes live exclusively in the formal world where things have explicit meanings.

13 Strong and Weak Objectivity

The power of mathematics and science lie in their claim to "objective" truth. In this section I would like to take a few paragraphs to repeat a point that I have made elsewhere (Byers 2017) concerning the nature of objectivity. Most people believe in a kind of objectivity which I shall call "strong objectivity" and define below, which is analogous to what is meant by "strong AI."

We sometimes say that something is "merely" subjective when we mean that it comes from personal prejudice or idiosyncratic opinion. Thus we would object to a mathematical theorem or scientific experiment being influenced by religion, race, or gender. Objective means that such matters, as well as many other cultural factors, do not influence the result. Of course some people consider mathematics itself to be a culture but within mathematics the criterion of independence from arbitrary opinion might serve as a minimal way to differentiate subjectivity and objectivity – we could call this *weak objectivity.*

However, there is another possible meaning of objectivity. Something is objective in this sense if it does not depend on mind or intelligence. You could say that it is objective in this sense if it would continue to be true even if there were no human beings around. This must have been the idea behind putting a diagram of the Pythagorean theorem on Voyager 1 in the hope that the truths of Euclidean geometry were universal and would be recognized by any intelligent being. Is the Newtonian theory of gravity objectively true? Most people would say that it is even if that truth is only an approximate one. Is the relativistic theory of gravity objectively true? Is it an eternal truth? Maybe it is but the jury is still out. At any rate a scientific theory is objective in this sense if the theory exists independent of the scientist who formulates or studies it. So some believe that the scientist *discovers* what is already there, that the rules of the universe and of mathematics are built-in, so to speak. Let us call this *strong objectivity.*

I believe that mathematics is objective in the weak but not the strong sense (This is what I take away from the writing of Reuben Hersh in books like (1980) *What Is Mathematics, Really?*, Oxford University Press, and is, I believe, the essence of the point of view that is celebrated in this volume.). This implies that the truths of mathematics are human truths not Platonic truths. So the truths of Euclidean geometry are objective in the weak but not the strong sense. In exactly the same way one could subscribe to the hypothesis of "weak AI" and not "strong AI." Notice that the "weak" position depends on an essential connection between human thought and science; the "strong" position on the other hand holds that once the theory (or technology) is established, human beings are redundant. One holds that the process of rationality can operate independent of human beings, the other that human beings are the essential measure of rationality for rationality is the process by which human being understand the world and themselves.

14 Contradiction and Ambiguity

Because we conflate reason with logic and are oblivious to the role of paradigm change in mathematics, we tend to be hostile to the presence of contradiction, paradox, and ambiguity within mathematics much less to be open to their constructive uses. Most people believe that mathematics and science are free of ambiguity, contradiction, and paradox and yet I wrote a long and well-received book about the constructive uses of these things. To give an elementary example, the number zero was unacceptable to the Greeks because of its contradictory nature – something that represents nothing as one author put it. The contradictory nature of zero remains but this has not stopped us from using it productively in science and technology. The same thing could be said for *infinity* (remember mathematics has been called the science of infinity), randomness, and many other basic concepts of math not to speak of the idea of complementarity in Quantum mechanics which makes what appears to be a paradoxical situation into a foundational principle.

The human mind has discovered creative ways to make use of contradictory elements. Indeed the legendary physicist Niels Bohr distinguished between two kinds of truth. "An ordinary truth is one whose opposite is a falsehood. A profound truth is one whose opposite is also a profound truth." Not only is he saying that something can be contradictory and true at the same time but he is further asserting that containing an inner contradiction may be an indication of its profundity.

Thus there is a vast difference between what I have been calling human rationality and logical, rule-based argumentation. The human mind is extraordinary! It can create something profound out of nothingness or chance. It can make constructive sense out of what appears to be meaningless, create something out of nothing. It can create regularity out of the very lack of regularity, that is, randomness.

This gaping hole in the prevailing philosophy of mathematics arises because of the view that identifies mathematics with its formal structure and ignores informal mathematics and process in general. In order to accomplish this it has been necessary to elevate rule-based logical argumentation to a kind of foundational principle, which is, of course, what formalism does. In this way process, creativity, and learning not to say history have been banished from the way the subject is described and understood.

A key element in all of this is a misunderstanding of the meaning and the role of ambiguity. The conductor and composer Leonard Bernstein once said that the richness of music is proportional to its ambiguity and the same can be said of mathematics. A measure of how deep a result is can be given by the number of ways it can be understood, the number of different contexts that it fits into. We continually look at particular mathematical concepts from multiple points of view. For example a matrix can be thought of as an object, a rectangular array of numbers, or a process, a linear transformation. Notice that a reified structure is ambiguous since it is both process and object. And you choose to look at it from one or the other perspective depending on your needs at any given time. In fact we think of the matrix in both ways at the same time and move freely from one context to the other. The point here is that the ambiguity, thought of as the ability to look at one situation from

a multidimensional point of view, contributes to the power and creative potential of an idea. When you start to think about things in this way one quickly sees that ambiguity crops up everywhere in mathematics and moreover that it is a generator of the process of deepening our understanding of a particular subject. Logic may have no place for ambiguity but rational thought uses it productively all the time.

15 Logic, Algorithms, and the Human Mind

Rationality is best understood as the cognitive function of the human mind. One isolates and abstracts some particular aspect of cognition, logic for example, and then the case is made that one can reconstruct all of human cognition from that one property. There was the famous attempt by Russell and Whitehead to reconstruct all of mathematics starting with the rules of logic. Of course that attempt failed but it was interesting and was used for later developments like the Incompleteness Theorem of Gödel. In the long run extreme reductionism never works. You cannot capture the full potential of the human mind using one particular model of mind. The mind is just too large and free for that to be possible. Logic and algorithms are one way the mind functions but not the only way.

The way to see this conclusively is to look at the history of science and mathematics. This history consists of the development of paradigms, conceptual systems, or ways of understanding aspects of the world. Inevitably, as the subject progresses, anomalies or inconsistencies develop. The response of the scientist is ultimately to develop a new theory that contains the old theory but expands it so as to explain the anomaly. Thus the nonrationality of the root of two is resolved by moving from the rational numbers to the geometric numbers, the problem of trisecting the angle or squaring the circle ultimately leads to the real number system. In just his way the problem of subtraction (2–5 is undefined in the counting numbers) leads to the development of the (positive and negative integers). The problem of division (is 123 divided by 47 a number?) leads to the rationals.

The process of (human) rationality has room for, and even thrives upon, the problematic in the form of ambiguities, contradictions, and even paradoxes. It would be a great shame and a loss to our collective humanity to reduce human rationality to a process that eliminates the problematic and focuses exclusively on one particular form of argumentation.

16 Conclusion

This volume commemorates a change in the philosophy of mathematics that is long overdue, a fundamental change in the way we think about the nature of mathematics. This change involves elevating the role we ascribe to process. Process, doing mathematics, then becomes part and parcel of what we consider mathematics to be. The mathematician cannot be separated definitively from the mathematics he or she produces. Far from living in some remote Platonic realm, mathematics is seen to

be a vital part of human culture and society. Thus we can and should study the interactions between the mathematical culture and the larger scientific and general cultures. One consequence of this change is that the world of mathematics becomes less isolated from the larger culture. In particular mathematicians would stop thinking of mathematics as a self-contained world of its own. At this time when we are both benefitting and suffering from the effects of digitalization, it is imperative that people who know something about mathematics take the time to think about the assumptions behind the technological revolution that we are living though today and, moreover, speak out about their conclusions.

These considerations lead me to emphasize once more the essential role of human creativity in mathematics and elsewhere. I will repeat that learning properly understood and the creation of new mathematics are both based on what is essentially the same mechanism – human beings infinite capacity for creativity and innovation. Reason is our birthright as human beings and reason is no more and no less than the means by which human creativity finds expression. Our job as mathematicians is to develop our own creativity, nurture it in our students, and resist the temptation to reduce the adventure of creativity to something mechanical and ultimately sterile.

Abstract

The chapter advances a reformulation of the classical problem of the nature of mathematical objects (if any), here called "Plato's problem," in line with the program of a philosophy of mathematical practice. It then provides a sketch of a platonist solution, following the same perspective. This solution disregards as nonsensical the question of the existence of abstract, and specifically

mathematical, objects, by rather focusing on the modalities of our access to them: objects (in general, both concrete and abstract) are regarded as individual contents that we have (or can have) a *de re* epistemic access to. The question of the existence of mathematical objects is then replaced by that of the modalities of our *de re* epistemic access to individual mathematical contents.

Platonism · Nominalism · Mathematical objects · Plato's problem · *De re* vs *de dictum* epistemic access

1 Preamble

Mentioning platonism and *de re* (attitude) in the title of a chapter of a handbook about philosophy of mathematical practice might surprise some adepts of the latter. While platonism might be seen as a metaphysical option, the distinction between *de re* and *de dicto* attitudes might appear as proper to the analytical philosophy of language. These two facts might be considered enough for making the philosophy of mathematical practice principally alien to these notions. In echoing this view, while reporting on a previous version of my chapter an anonymous referee has qualified it as "an ultra-conservative piece in the philosophy of mathematical practice." The reason for this is that it would have told "nothing about mathematical practice, divorcing itself starkly from the aspirations of some philosophy-of-mathematical-practice pioneers such as the PhiMSAMP (Löwe and Müller 2010) members, nor does it agree with Mancosu's (2008) conservative understanding of PMP as exploration of new philosophical questions about mathematics."

This report made me decide to write the present preamble, in whose absence some readers might have been tempted to agree with this judgment, by misconstruing the very purpose of my chapter.

It is certainly true that I hereby explore a traditional (or "ultra"-traditional) question for the philosophy of mathematics: so traditional to date back to ancient Greek philosophy. However, being new is a required value neither for good philosophical questions nor for fruitful philosophical approaches. A philosophical investigation is often made valuable and innovative because of the way traditional questions are restated and tackled and of the tentative answers that stem from time-honored approaches. It is certainly not for me to say whether the investigation I present here is a valuable and innovative one. What I can say is that it aspires to be so because of this reason: since it aims at using a well-established distinction, as that between *de re* and *de dicto* attitudes, to answer a traditional question in a purportedly original way.

It is also certainly true that I hereby explore no specific aspect or episode of mathematical practice. Promoting and arising similar explorations is not, however, the only purpose of philosophy of mathematical practice (as I understand it, at least). Another equally important purpose is accounting for some essential general feature

of this practice, by so insisting that the term 'mathematics' in 'philosophy of mathematics' should stand for it: for the human activity of doing mathematics. This activity has social and material aspects, but it is not because of them that it is mathematical. What makes it so are the modalities of its being an intellectual activity. This makes it necessary for the philosophy of mathematical practice to engage with the purpose of accounting for the specific feature of that intellectual activity that we perform by doing mathematics, namely, with the question of wondering what makes an intellectual activity mathematical in nature. This is just the question I explore in this chapter (even if only partially, of course). And it is just because of such that I take this chapter to be, in the full sense of the term, a piece of philosophy of mathematical practice – whether (ultra-) conservative or not, I leave to the readers to decide.

More than having a history, mathematical activity is (or generates) a history. Since I in no way think that the philosophy of mathematics should have any normative duty concerning mathematics itself, I take this history to be, properly speaking, what the term 'mathematics' should stand for in 'philosophy of mathematics.' Establishing what and how mathematics should be is a question for professional mathematicians, not for philosophers. Even less, it is a duty of philosophers to establish whether something is there or not. In particular, philosophers of mathematics are entitled to decide neither what is actually there (or has happened and happens) that one would consider as mathematical, nor what is genuinely mathematical and what is not so, among all that is there (or has happened and happens) that mathematicians and professional historians of mathematics call by this name.

In my view, philosophy essentially aims at accounting for independent realities (unless it is some sort of metaphilosophy, which it might of course legitimately be, in some cases). This is even obvious, it seems to me, when it is the philosophy of something, as the philosophy of mathematics clearly is, since, in order for philosophy to be the philosophy of something, this something should be available to its inquiry. This inquiry can (or even cannot avoid to) shape this something, just as science does for the reality it studies. But this shaping is just an essential part of accounting for it, of explaining how it is, and of spelling it out, not of establishing how this should be, or what is there to form this reality, and what is not there.

Arguing from these theses is, in my view, just the same as promoting a practical turn in philosophy, if there is one that one might promote. Hence, if philosophy of mathematical practice is to be part of this turn, it has to tell us of which something that is there and is called 'mathematics' it is intended to be philosophy of. When I say that the term 'mathematics' in 'philosophy of mathematics' should stand for the historical fact of mathematical activity, I simply mean that this something should be nothing but this historical fact: what this activity has been and is today. This fact makes the intersection of history and philosophy of mathematical practice not only quite strict, but also essentially constitutive: The philosophy of mathematical practice is, to my mind, the philosophy of a historical fact.

Still, there is no need, I hope, to refer to Croce (the historicist philosopher *ex excellentia*) for remarking that history (*res gestæ*) is not the same as historiography (*historia rerum gestarum*). This constitutive connection does not make philosophy

of mathematical practice the same thing as the history of mathematics, in the usual sense where 'history' wrongly stands for 'historiography' (and, then, philosophers of mathematics the same thing as historians of it). History (in this sense, i.e., historiography) reconstructs relevant facts and accounts for their specific and detailed aspects. Philosophy accounts for general features, the way of being, and the peculiarity that makes them mathematical facts. The former can be done without the latter (though possibly not very lucidly). The latter cannot be done without the former, since the former provides to the latter with the reality which it is the philosophy of (since history, properly called, only appears to us through the lens of historiography: We have no direct access to it). This is another way to say, in the language of Lakatos's *dictum*, that historiography of mathematics without philosophy of mathematics is certainly blind, but can still subsist, while the philosophy of mathematics without the history of mathematics (and therefore its historiography that provides it to us) is so empty that it cannot subsist unless as a caricature of itself.

Another important clarification is suggested by the same referee of a previous version of my chapter. What I am arguing for is not at all that the philosophy of mathematics cannot but consist of a collection (or even an organic system) or case studies. My point is precisely the contrary. A collection (or system) of case studies cannot but be what it is, namely, a more or less ordered configuration of particular inquiries devoted to single neighborhoods in the space of history. Philosophy is much more and much less than this: It is an account of the space itself. While the former accounts for some elements in a quite large set, the latter defines a structure based on this set and studies it as such. This is why the reader will find no case study in what follows (while some of them can be easily found in other, more properly historical essays I have written), but rather a reflection of what makes the historical fact of mathematical activity mathematical in nature.

I conclude my preamble with a proviso. Though I will be naturally brought to mention a few philosophers of mathematics and some of their works, my purpose here is not that of discussing the opinion of this or that colleague or master. Rather it is that of promoting a general philosophical option, and rejecting some others, by presenting the former in my personal (and I hope, original) guise. Any reader that would like to have more bibliographical information about the present discussion in the philosophy of mathematics that I shall deal with should look for it elsewhere. I contributed to offering a survey of some of these discussions (in Panza and Sereni 2013), and (apart fort the most recent developments, elapsed after its publication) I can certainly refer the reader to this work.

2 A Misconception

Philosophy goes with many temptations. And the philosophy of mathematics is not without them, too. The most dangerous one is taking the latter as a mere extension of the former, due to the possibility of using mathematics as a testbench for philosophical theses, as a storehouse of examples and problems on which to measure the mutual merits of opposite philosophical views. There are two kinds of philosophers: those that have problems and look for solutions for them, and those that have

solutions and look for problems to solve them with. The philosophers of the latter kind are victim to a misconception, I contend. The dangerous temptation I am alluding to is a form of this misconception. One of the ways it takes place in the philosophy of mathematics is using mathematics and/or mathematical examples to measure the mutual merits of realism and nominalism, understood as general metaphysical theses, the former asserting and the latter denying the existence of abstract objects.

In the course of this chapter, realism, or, more precisely, the particular version of it that is often called 'platonism' – which I write, as is often done (following Parsons 1964, p. 275), with a lowercase 'p,' for disguising it from other theses more faithful, also in their intention, to Plato's philosophy – is presented as the thesis that "there exist mathematical objects" (Balaguer 1998, p. 1). More precisely, it is the thesis that, independently of our course of action and thought, there exist abstract objects in their own right, which are intrinsically mathematical in nature, and that mathematics deals with them, and aims at describing them, by so revealing how they are and how they are related to each other. Mathematics would, then, be successful when what it asserts of these objects is true, that is, when it truly describes them and their world as they are, in fact. It follows that a mathematical theory is good if and only if its theorems are true of the relevant objects. Among these objects, there are sets, numbers, and geometrical figures, or, possibly, only sets, starting with the empty one, according to the most reductionist ones among these realist self-styled philosophers of mathematics.

These, or other, less radical, partisans of ontological reductionism are certainly ready to admit that good mathematical theories can include theorems that are not literally true, or are so only if the relevant terms are properly understood according to appropriate reductionist clauses. Still, once the reduction is finally complete, or these clauses are fully operative, there is no more need for rephrasing: The theorems of these theories plainly mean what they appear to mean *prima facie*, and what makes them true of the relevant objects is that these objects just are and stand to each other like these theorems literally say that they are.

Nominalism is presented as the opposite thesis that denies the existence of abstract objects, and, *a fortiori*, of mathematical ones. It denies, for instance, "that numbers, functions, sets, or any similar entities exist" and, by consequence, "that it is legitimate to use terms that purport to refer" to them (Field 1980, p. 1). To avoid the most classical of paradoxes, this cannot but be understood as the thesis that the concept of an abstract object is empty, which immediately entails that this is also so for the concept of a mathematical object (provided it be admitted that mathematical objects could not be but abstract). These two concepts cannot be taken as ill-formed of course, since, if they were so, it would be hard to sensibly claim that they are empty. The same is even more clearly the case for more specific mathematical concepts, as that of a number, a set, or a function. These concepts are so defined to make some particular mathematical items purportedly fall under them. It follows that either a nominalist is prepared to also argue that these items are not objects (but, then what?), or cannot avoid to conclude that the usual mathematical language is both well-formed and empty, making mathematical statements either literally false, or only vacuously true.

Supposing that the doubtful distinction between mathematical items and objects is dropped out, it follows that appropriately understanding a mathematical statement depends on two possible moves, locally alternative to each another, but possibly operating together within a more general program aiming at a global understanding of mathematical discourse. On the one side, one might require, in a Quinlan vein (inaugurated in Quine 1939, but pursued in many subsequent works), that mathematical statements be paraphrased as statements on nonabstract, and then nonmathematical, objects. Once the paraphrase is complete, these statements would become, finally, literally true or false. This would allow one to say that a mathematical theory is good if its theorems admit a paraphrase making them literally true, but no more mathematical, statements. One might also require, on the other side, as suggested in Field (1980), that mathematical theories be added to empirical ones, which only deal with concrete objects to generate conservative extensions of them. Though remaining literally untrue and not necessarily admitting any paraphrase making them true, the theorems of a good mathematical theorems would then have a very welcome virtue: that of making it easier (or even practically possible) to establish empirical truths.

Both the partisans of platonism and nominalism so conceived may easily find, within the mathematical storehouse, many examples appearing, at first sight, favorable to one or the other party.

A nominalist might easily observe, for example, that a sentence like 'Mars has two moons' can be faithfully rephrased as 'There are x and y such that they are distinct to each other and both moons of Mars, and for any z, either it is not a moon of Mars or it such that either $z = x$ or $z = y$', where no reference is made to any number. The use of the term 'two' might, then, be taken as a *façon de parler*, simply used for short.

A platonist might concede this, after all, but observe that the former sentence does not express, in fact, a (purely) mathematical statement, and that the simplicity of such an example vanishes, when we speak of numbers as such, rather than of the numbers of the moons of Mars, or of pears or apples. When we say, for instance, that 2 plus 3 is 5, we do not speak at all of two particular things and three other particular things that, when put together, result in five things. At most we speak, in agreement with def. VII.2 of Euclid's *Elements* (Euclid, TBEH), of two units and three units, that, when put together, result in five units. But units are certainly not, as such, in all their generality, concrete objects. This makes it impossible – the platonist might conclude – to follow the same strategy used above to restate the sentence to avoid any reference to abstract objects. Indeed, this would make it loose its generality, which is a salient feature of mathematical statements.

The nominalist can try to replay by suggesting a new paraphrase that would be too long to write here. It will be enough to say that it might try to render the generality of the original sentence by replacing the reference to units either by appropriate universal quantifiers ranging on the totality of concrete objects, or by a talk of concrete objects whatsoever. At this point, the platonist might either present another simple example, as that of the sentence there are infinite prime numbers, by challenging the nominalist to suggest a faithful nominalist paraphrases, or, go for a much more general strategy and remember Plato's distinction between vulgar and

knowledgeable (or philosophical) arithmetic, respectively concerned with "unequal units [μόνᾳ ἄνισος]," such as "two armies" or "two oxen," and with "countless units [μόνᾳ μυρίαι]," none of which differs from each other (*Philebus*, 56d-e; see *Theaetetus*, 195e–196a). The nominalist might retort, in turn, under Quine's authority (Quine 1986, p. 400), that the latter arithmetic is merely "recreational" and should in fact be ignored by naturalized (and, then, good) philosophy, to the effect that an example as the last one just mentioned should be taken as perfectly immaterial for such a (good) philosophy.

This last move might also open the road for the second nominalist strategy, in which the recourse to paraphrase is replaced by the talk of conservative extensions of scientific, and, then, nominalistic, theories. Faced with this strategy, the platonist would have no reason to surrender, since there would be still room to argue: (i) that scientific mathematized theories are far from nominalist, in fact, since mathematics is constitutive of its objects; and (ii) that pure mathematic is far from recreational and should constitute the appropriate text-bench for deciding the realism versus nominalism dispute.

Who is right? It might appear that there are good reasons for both sides.

For instance, there is no need to invoke the number two, as an abstract object, to count the moons of Mars if counting objects (or transitive counting: Benacerraf 1965, pp. 49–50) is understood as such, that is as an intellectual operation on these objects (rather than as the establishment of a bijection between them and the numbers), which is all that is needed for all scientific purposes. There is no more any need to invoke numbers to decide whether there are more planets or moons in the solar system. Using them is surely quite convenient; it makes things simpler. However, it is not indispensable. If one had to work on much bigger collections, one would probably need to pass through numbers, but this would be only a practical need. In principle one could avoid them. This might appear to be a strong enough reason to think that number words enter our statements concerned with these empirical practices only as useful, but dispensable, *façons de parler*, as the nominalist suggests.

But is it the use in such empirical practice that decides the nature of mathematics? For making the realist win over the nominalist on the testbench of mathematics, it does not seem at all necessary that no occurrence of mathematical words might be explained as the nominalist suggests. It seems enough that some occurrence cannot be so explained. But then, the case of the infinity of prime numbers might become decisive: Either the nominalist can explain it nominalistically, or the platonist has a point, after all, unless, in a last and decisive gasp, the nominalist succeeded in excluding this case from the relevant testbench.

3 An Ill-Posed Question

But, then, again: Who is right? Neither one, I contend. Since the question the two parties offer opposite answers to is simply ill-posed.

Even supposing that the realist versus nominalist dispute has any sense, in general, it does not extend to mathematics in these terms, at least if such an extension has to take the form of a philosophy of mathematics. Since, if philosophy of mathematics is to be about mathematics, it has to start from mathematics itself, and reflect on it, rather than begin elsewhere and come to mathematics by accident, by reproducing on it the same general questions and answers already looked over outside it, with the mere replacement of schematic place holders with mathematical ingredients. In other terms: It is not enough to replace 'abstract' with 'mathematical' in the general question 'do abstract objects exist?' to get a sensible question for the philosophy of mathematics.

Let us be a little bit more precise. Let us assume that the word 'abstract' is the only schematic word in this general question. This means that the replacement of this word with any other word of the same type within this question is not to go together with a corresponding replacement of any other words such as 'objects' or 'exist,' or, at least, with a corresponding particular understanding of them. This being granted, suppose, for the sake of the argument (and only for that), that, when it is so understood, such a general question has a clear sense. The point is then the following: Also under these provisos, it would still remain that the mathematical instance of the question – 'do mathematical objects exist?' – is not a genuine question for philosophy of mathematics, or, at least, it is not so if it is also admitted that philosophy of mathematics is actually to be about mathematics.

Of course, philosophers are perfectly allowed to have no particular interest for mathematics, as well as for any other field of knowledge. But we, philosophers of mathematics, are also allowed, and to my mind, even required, to regard the philosophy we practice as a genuine enterprise only if it reasons on mathematics as an external material that it takes as given as such, before beginning its work.

If this is admitted, there is room to argue that the very question 'do mathematical objects exist?' is nonsensical. Or, at least, it is so, if mathematics is supposed to be given, and it is granted that the words 'objects' and 'exist' designate primitive notions, asking for no appropriate elucidation depending on mathematics itself. Consequently, the connected question 'is mathematics about its own objects?' also becomes nonsensical, under similar conditions.

This makes any putative answer to these questions, advanced in agreement to such conditions, not only doubtful, but inevitably misleading: a claim that is not so far, after all, at least for its form, from Kant's claim about dogmatic metaphysics.

A symptom of this nonsensicalness is the difficulty of answering (and in agreeing on the good answer) to a connected question: 'what could be conceived of as an evidence for the existence, or nonexistence, of mathematical objects?' If mathematics is taken as given, it should include such evidence. Of course, this might be very well hidden, quite far from the surface that immediately appears to an inexperienced observer. This would make discovering and exhibiting such evidence quite hard. But it should be, in any case, possible to clearly say how it might be like. Since the question 'do mathematical objects exist?' presents itself as a factual question, deciding which is the right answer to it should be a matter of fact. Moreover,

assigning a clear meaning to this question, by making it sensible, should require clearifying how this matter of fact could become manifest to our understanding. We should, in other terms, be able to say what would make us unquestionably aware that mathematical objects do or do not exist.

I know only two attitudes face to this last crucial question, which might appear plausible, at last at first glance.

The first is only available to nominalists: The burden of providing evidence for deciding about the existence of mathematical objects is only on the platonist side, since platonists are the only ones that make a positive claim. Here is how the point is made by C. Cheyne (2001, p. 108), for instance,

> [. . .] it is a contingent matter whether numbers exist with mathematical necessity in the actual world. The claim that this could be decided by purely a priori methods becomes dubious. Discovering whether or not this world is favored by the existence of entities that might not exist would seem to be a matter of observation. But how could we observe such entities if they lack causal powers? The burden of proof is [. . .] on platonists [. . .].

The nominalist's burden is then nothing but that of accounting for the available evidence in a way that does not suppose the existence of abstract, and, then, mathematical objects. This is not properly an answer to the question; it is instead a move for turning the absence of any answer in favor of the nominalist side. But the move is weak enough. For it turns this absence in favor of an agnostic attitude, at most, by so making clear that the nominalist thesis is, in fact, a *petitio principi*. The nominalist might retort by appealing to the Ockham razor, and claim that, in the absence of any positive evidence, all that can decide whether mathematical objects exists or not is whether it is necessary to postulate their existence in order to account for the available evidence. However, this inverses the burden of proof, since it now requires the nominalist shows that this is not necessary. In J. Burgess' words (Burgess 1983, pp. 95–96):

> Actually, the burden of proof is on such enemies of numbers [. . .], to show either: (*a*) that science, properly interpreted, already does dispense with mathematical objects, or (*b*) that there are scientific reasons why current scientific theories should be replaced by alternatives dispensing with mathematical objects.

The problem becomes, then, that the nominalist account, both in terms of paraphrases and in terms of conservative extensions, is partial, at most, if not largely unsatisfactory. Possibly, it accounts for some scant evidence. But it does it at the price of declaring this evidence untrustworthy, that is, of tacking it as a fake appearance of a hidden reality that our language is often incapable to describe faithfully, or can only describe in a quite entangled and odd way.

The second attitude is that of some platonists: The required (positive) evidence is provided by the truth of some appropriate mathematical statements involving terms that purportedly denote mathematical objects. In B. Hale and C. Wright's words (Hale and Wright 2001, p. 8):

> [. . .] no more is to be required in order for there be a strong prima-facie case that a class of apparent singular term have reference, than they occur in true statements free of all epistemic, modal, quotational, and other forms of vocabulary standardly recognized to compromise straightforward referential function.

The point here is that a statement about certain objects is true only if these objects exist. Fair enough. But this leaves other questions open: What evidence do we have for the truths of the relevant mathematical statements? What evidence do we have that these statements are actually about the objects they seem *prima facie* to be about? Even more crucially: Are we really sure that mathematical truths require existence?

The second of these three questions brings grist to the mill of nominalists. Considering the third one would bring us too far from the purpose of the present chapter. So, I limit myself to the first. A possible answer to it is that the relevant truths are logical truths, or, at least, logical consequences of so innocent assumptions that we could not reject them as untrue. This was essentially Frege's strategy, and, in a different version, is still the neologicist one (as defended in Hale and Wright 2001, for instance). But it has problems, in turn, and not only because of the difficulty of deriving suitable mathematical statements from consistent systems of innocent enough assumptions. But also, among other things, because of the doubt one can raise about the fact that the innocence of these assumptions entails their truth, or, better, an appropriate kind of truth for supporting existence. One might, of course, redefine existence in terms of (the relevant kind of) truth. But this would violate the condition mentioned above, about the presence of a single schematic word in the question about the existence of abstract objects, making the platonist thesis essentially different from a simply application to mathematics of the realist one. Under this guise, the thesis would rather involve a claim about a peculiar notion of existence, proper to mathematics. It should, then, be supported, not by a general metaphysical attitude, but by a specific inquiry about the nature of mathematics, which is exactly what I am encouraging.

4 Plato's Problem

I can stop the *pars destruens* of this chapter here. It was aimed at critically describing an attitude that no sort of philosophy of mathematical practice might share, to my mind. Still, arguing that the philosophy of mathematical practice might not share this attitude is not the same as arguing that the question it deals with, though nonsensical, as such, is not rooted in a relevant and perfectly sensible genuine problem about mathematics (which philosophy of mathematical practice is certainly not only entitled, but also required to tackle). What I wanted to suggest is that the trouble with this attitude is much less due to the opposite answers that it suggests for this question, than to the question itself, better to the way this question renders the crucial problem that stays at the roots of it. The point at issue is that this way makes this question essentially external to mathematics, by so making hard to decide which evidence, coming from mathematics itself, might count as a justification for an answer to it, whatever this answer might be.

In Panza and Sereni (2013), A. Sereni and I designated the problem I am referring to as Plato's one. A way to address it is by quoting a famous passage by the *Republic* (527a–b), in an appropriate translation:

> This <. . .> will not be disputed, at least, by those that <are> even a bit acquainted with geometry, that this science [αὕτη ἡ ἐπιστήμη] is in full opposition [πᾶν τοὐναντίον] with the language spoken within it by its adepts <. . .>. Since <the way they> speak <is> as much ludicrous as necessary [μάλα γελοίως τε καὶ ἀναγκαίως]: they shape all their discourses as if they were operating in practice and in the purpose of practice [ὡς γὰρ πράττοντές τε καὶ πράξεως ἕνεκα πάν-τας τοὺς λόγους ποιούμενοι]; [they] speak of squaring, applying and adding, and they all say this way, whereas all <their> learning is somehow suited for the purpose of knowledge [τὸ δ' ἔστι που πᾶν τὸ μάθημα γνώσεως ἕνεκα ἐπιτηδευόμενον]. <. . . > [This is] knowledge about that which always is, and not that which now comes into being and now perishes.

Contrary to the way this passage has been often understood (and consequently translated), this is in no way a criticism of the language and practice of geometers (the point has been firstly made *mutatis mutandis* by M. F. Burnyeat 1987). Plato notices that this language seems to be shaped "πράξεως ἕνεκα [in the purpose of practice]," whereas geometrical learning is "γνώσεως ἕνεκα [for the purpose of (theoretical) knowledge]" of eternal (and abstract) matters. He takes this language to be not only "ludicrous [γελοίως]," but also "necessary [ἀναγκαίως]." He seems then to acknowledge that there is no other option than using such a practical, ludicrous language for theorizing about such an abstract matter.

This is exactly the opposite of the nominalist claim: Mathematics does not use an abstract language for speaking of concrete objects, by calling for appropriate nominalist paraphrases; it rather speaks of *abstracta* as if they were material artifacts, by so calling for an appropriate understanding. The ludicrous (or metaphorical) aspect of its language does not consist in its surreptitiously dealing with concrete objects by *prima facie* speaking of abstract ones, but in its (having no other option than) using a language originally fashioned to speak of the former objects for reasoning about its abstract matter.

But this is no more the same as plainly asserting that there are abstract objects that mathematics is about and call with their proper names. If it were so, there would be no opposition, no necessary ludicrousness. At most, the problem would be that of inventing a new language, just fashioned for speaking of these abstract objects, just as the vulgar one had been invented to speak of concrete ones.

According to Plato, mathematics is certainly not about "ideas [εἴδη]." It cannot depend on the exercise of νοῦς but rather depends on that of διάνοια, or, possibly φαντασία, as Proclus will say later. The soul can contemplate, at most, the idea of a triangle, or that of a number, possibly those of even and odd, but mathematics requires more, or less, than that: It requires triangles, and numbers; not single ideas, but pluralities of items. What do these pluralities consist of? How can we conceive of these items? More in general: How can we account for the intellectual exercise that mathematics pertains to?

Such is Plato's problem. And this should be the ontological problem of the philosophy of mathematics. Not whether there are μαθηματικά or not. But how

can we account for our reasoning on them? Since it is of them that mathematics is reasoning, unless one wanted to argue, *contra* Plato, and because of a biased and preestablished misconception, that its form is fictitious and is to be amended by true philosophy (which would just be the opposite of philosophy of mathematics, being rather philosophy against mathematics).

Take this statement 'Any vector space has a basis'. What is it speaking of? The most obvious answer is that it speaks of vector spaces and its bases. Does it not? Why not? Possibly since vector spaces must be abstract objects and abstract objects do not exist? I suggest a nominalist supporting this answer to explain it to any working mathematician, and consider the reaction. I suspect that it would be better not to describe it. But, does this mean that the platonist described above has finally won? Does this prove that vector spaces exist and have bases? And that there is nothing more to say on that matter, except, possibly, for adding that this makes the statement true, and its proof a justification for its truth?

Suppose to work within ZF, i.e., whiteout the axiom of choice. The proof that any vector space has a basis does no more hold. But what does the axiom of choice say? Let us consider one of its most usual formulations (all equivalent to each other in appropriate frameworks): "For any set of pairwise disjoint non-empty sets, there exists at least one set that contains one and only one element from each set in the former set." What is it speaking of? Again, the most obvious answer is that it speaks of (nonempty) sets, or, more specifically, of sets of (nonempty) sets. Our platonist would say that these sets exist (let us avoid asking him/her whether this makes the set exist formed by all sets). But, then, is this statement true of them? If it were not, I suppose the same platonist should maintain that it is false. Then its negation should be true. But, based on this negation, we might now prove that there are vector spaces with no bases. Hence our previous statement would be false. The former statement ('any vector space has a basis') is, then, true only if the latter (the axiom of choice) is so. But how might we prove the latter? We might certainly prove it, in ZF, by grounding on another equivalent or even stronger statement, for example, on the former one (which is provably equivalent to the latter over ZF). But this would only displace the question. What is it if it is not a proof that justifies the axiom of choice? And if we have no justification, how can we be sure that it is true? And if we cannot be sure that it is so, how can we be sure of it for the former statement, about vector spaces? So, possibly the two statements are not true: Possibly vector spaces exist, but some of them have no bases. All that we can know, then, according to our platonist, is that vector spaces exist and either all of them have a basis, or some do not. Or, possibly, this is not so, since, in fact, we have, after all, a clear justification of the axiom of choice: We see that sets are as it says; we see it with our insightful eyes of mathematicians, even, if we cannot make other eyes see it, even eyes of other (nonclassical or constructivist) mathematicians.

The problem with both conclusions is that they do not follow from any evidence coming from mathematics itself. They do not really provide a solution to Plato's problem (relatively to the particular fragment of mathematics that it is concerned with) but merely dissolve it. If these conclusions hold, the problem would simply not arise; it would be solved before being posed, since, what causes the problem is just

that mathematics speaks of vector spaces just like geography speaks of lakes, mountains, or towns, whereas vector spaces are not like lakes, mountains, or towns. So, how can mathematics speak of them this way? The previous platonist conclusions simply deny the root of the problem: They merely presume that vector spaces are just like lakes, mountains, or towns, at least at the insightful eyes of (classical) mathematicians.

5 On the Platonist Side

Let us restate the problem, then, in a more general setting. Mathematics results from a quite peculiar intellectual activity, or it is such an activity when it is considered as an enterprise rather than as a corpus. This activity appears to be twofold. It seems to consist both in the creation from noting of eternal and immutable items, and in the attribution of (some) properties and relations to them. Though these items appear to be eternal and immutable, their creation is the work of human beings (not of Gods or God), and it takes place in time, or even in history (not before any time). These human beings have, moreover, no other way for justifying their attributions of properties and relations to these items than proving statements that assert that these items are and stand to each another accordingly to these attributions. The proofs of these statements start from other statements of the same sort, some of which have necessarily to be admitted both without grounding on a similar justification, and without having acquaintance with these same items. How can we explain it?

This is not at all a problem about existence, about what exists or does not exist. What exists is clear: It is mathematics, and this existence is made manifest by history and actual experience (of teachers, students, and professionals), just as it happens for the existence of other intellectual enterprises and social phenomena, as well as for their products and, *mutatis mutandis* (but not *mutandis* so much), for empirical middle-size objects. The problem is rather about how this existence should be better accounted for. As such, this is a genuine, even crucial problem for a philosophy of mathematical practice, since this existence is just that of mathematical practice itself and of its outcomes.

When one looks at the problem this way, the theses that the platonist and nominalist I have described above try to test (or, better, confirm) on the testbench of mathematics are invested in another light, and they appear, then, dramatically naive and implausible. The platonist thesis becomes the thesis that this evident reality is to be explained by postulating the existence of another reality, inaccessible and unverifiable, but somehow (either causally or not) operative enough so as to make it possible to take the former existence as a more or less deformed imagination of the latter. The nominalist thesis becomes the thesis that this evident reality is not as it looks, since what appears is a theater performance disguising a much more trivial reality, not dissimilar in nature from our everyday life. When a serious philosophy of mathematical practice tackles the problem, it cannot but reject both these preposterous answers.

To my mind, the rejection should not be symmetric, however, since these theses are not so: whereas the former aims at explaining the available evidence through a

far-fetched assumption, the latter aims at denying this evidence in the name of a preconception. If I had to take a side in the dispute, though judging it misleading, I would have, then, no doubt in taking the platonist side. Since this is the side which aims at accounting for mathematics as it appears to be, rather than as it is required to be in agreement to an independent preconception. The purpose of the following considerations is to suggest a plausible way to stay on this side for a philosophy of mathematical practice: a way of being a platonist without recourse to the far-fetched assumption of the existence of mathematical objects.

One might argue that staying on the platonist side because of the reason I just advanced is still not the same as being a platonist. If it were so, the preceding pronouncement would be incongruous, since what comes after the colon would go far beyond what comes before it. Anyone that agreed with this would also probably find the position I will defend in what follows far from platonist in nature. Though I do not care so much about -ist and -ism-words, I regard this point as relevant, and I want to clarify why.

To my mind, this is not a purely terminological point, indeed. It rather depends on a judgment on what is essential in the platonist option, in all the different forms it has taken along the history of philosophy of mathematics. More than that, it also depends, in a sense, on what is considered to be the main task of philosophy. For many, this task is that of establishing what there is, and platonism is an important part of philosophy since it clearly claims that there are abstract objects. Not for me! I do not take this to be at all a task for philosophy. At most, it is one for positive sciences (whether they be physical, natural, biological, economical, or historical). I neither take the task of philosophy to say how what is there should be (if it could be in different ways). This is certainly a task for politics, but philosophy is not politics at all (though it could be useful for it). Philosophy should rather aim at providing the most appropriate conceptual categories to be used to account for what there is, or, better, what appears to be there.

This makes me think that platonism is a worthwhile option in philosophy of mathematics since it suggests that mathematics deals with the very contents that the language of mathematics speaks of, *prima facie*. In other terms, I take platonism, in the philosophy of mathematics, to be the quite general thesis that mathematical talk is to be literally understood as a talk of individual contents that provide the subjects of different forms of predication – in a word, as a talk of objects – and that this talk, so understood, consists of statements that hold as such, and as such have to be admitted and accounted for. My purpose, in what follows, is to articulate and better detail this general thesis in an appropriate way, along the line of a philosophy of mathematical practice.

6 Philosophical Purposes

Before doing that, an *excursus* is in order, however. It aims at shortly answering this further question: What should the purpose be, in general, of a philosophy of mathematical practice? Or even, more simply: What should such a philosophy be

like? I have already tackled the problem in my preamble, but it seems in order to come back to it now, in the light of the previous considerations.

Let us put the question this way: Should philosophy of mathematical practice be conceived as a reaction against a metaphysical, analytical, or foundational trend in the philosophy of mathematics? Or rather as an attempt to tackle new, previously unnoticed problems that, though strictly connected with the everyday work of mathematicians, do not strictly have a mathematical nature, being rather concerned with methodological choices, value judgments, or alike? Or, again, as an effort to rethink classical problems of philosophy of mathematics, restate them, and tackle them from a different perspective?

I do not like the first, purely antagonistic, option, and consider that the second one is simply not enough, since I think that classical philosophical problems are so, for they are good and difficult problems, though they are often conceived and restated in an ill-posed way. Plato's problem is an example of that: What makes it be, since Plato himself, a traditional problem for philosophy of mathematics is that it is a crucial problem that no serious philosophy of mathematics can dismiss, and even less if the dismissal is simply motivated by its being an old problem. This makes me think that the second option might be truly fruitful only if pursued as a complement of the third. It is, then, in the frame of this third option that I reason here.

When this option is joined with what I have said at the end of Sect. 5 above, it brings me to consider that a crucial task for the philosophy of mathematical practice is that of suggesting good conceptual categories to be used to account for the structural form of mathematics (intended as an existent reality), as it appears to be.

I say 'account for the structural form' for the sake of brevity, of course, in order to make clear that the relevant conceptual categories are not those required to describe the specific contents of mathematical theories, but rather some general features of these theories and contents, which are often characterized, by using a technical philosophical language, as logic, epistemic, ontological, etc. The specific contents of mathematical theories are also to be described, of course, using appropriate conceptual categories, but shaping these categories, and providing such a description, is a task for mathematicians rather than philosophers (though it would be wise for philosophers to try to understand this description, without falling into the opposite temptation to that mentioned in Sect. 2: the temptation of replacing mathematicians in this task, to provide a supposedly deeper description of these contents, which inevitably results much less profound than confused and defective; a temptation, it should be said, that some alleged philosophers of mathematical practice are not unfamiliar to).

In this framework, it seems to me that nothing might forbid philosophy of mathematical practice from embracing a platonist perspective, under the form of the thesis that the peculiar nature of mathematical activity is to (or, at least, might suitably) be accounted for as an intellectual activity dealing with (the) abstract objects (denoted by the usual terms figuring in the mathematical language).

This is still a very broad view, however, that can be declined in very different ways. One might wonder, for example, what one should mean in this context by 'intellectual activity,' 'dealing with,' 'abstract objects,' and, even, by 'objects' *tout*

court. I cannot enter all these matters, here, of course. I will, then, take for granted that my audience understands the term 'intellectual activity' more or less as I do. I only add that, according to the version of platonism that I would like to illustrate (and defend) here, 'dealing with x' means something like 'supplying (shaping, giving birth to) x, then studying it in order to describe it.' I also suppose, that this is enough to restrict my ongoing task to (quite programmatically) answer to the following single question: What should one mean, in the present context, by 'objects,' in general, and 'abstract objects,' in particular. The attention to the context is essential, since I am far from pretending to explain what can make an object abstract, in general. I shall limit myself to the case of abstract objects that one might take as mathematical ones.

My purpose, in what follows, will then be nothing but that of trying to make clear as the notion of an abstract (mathematical) object should be understood, in order to provide a good conceptual category to be used while describing mathematics as an intellectual activity dealing with abstract objects.

7 Objects by Reification

Objects are usually taken to be self-existing individuals, or, better, individual self-existing contents. An object is, then, taken to be abstract if this content is so, that is, as it is usually said, it is not spatiotemporally identifiable or determinable. An abstract object is, then, taken to be mathematical if (pure) mathematics involves putative reference to it (without receiving it from outside, for instance, from logic). If we understand an object this way, it becomes unavoidable to wonder how an individual content can exist (or have existed, or will possibly exist) without being spatiotemporally identifiable or determinable. It is just by taking this possibility for granted, without any further explanation, or, worse, in trying to provide quite improbable, and, often, even (quasi-)mystical answers to this question that platonism becomes generally implausible.

A way to avoid the problem is by ceasing to take existence, at least if intended as a primitive notion, as a necessary condition for objecthood. This is in no way an original perspective, and it is rather quite common in philosophy, also outside philosophy of mathematics. It goes, however, quite often together with some troubles, which is neither necessary nor possible to consider here in any detail. It will be enough to observe that a common move made to escape (some of) these troubles is taking abstract objects to be individual contents coming from reification of (first-level) concepts. This could go together with making the notion of an abstract object essentially independent of the more general notion of an object, namely, with renouncing at defining abstract objects as a particular sort of objects. What is important here is, however, not how this last task could be achieved, but rather how one can make the notion of reification of a (first-level) concept both precise enough, and such to avoid that the claim that mathematics deals with abstract objects becomes empty.

An example will make the point clearer. Let us take for granted that ordinary arithmetic deals with natural numbers. A very low-cost way to also grant that this

makes it deal with (abstract) objects is by providing a clear enough definition of the concept of a natural number, by means, for instance, of some appropriate version of Peano axioms, then taking natural numbers to be abstract objects just insofar as they are reifications of the concepts of the distinct items falling under this concept, reiteratively defined in turn, on the base of the definition of this last concept. The notion of reification of a concept is not very well defined here, but it does not seem *prima facie* implausible to consider, for instance, that taking the number one to be the successor of zero, by also admitting that the concepts of zero and successor are implicitly defined through the relevant version of the Peano axioms, be a way to take this number as the reification of a concept (that of successor of zero), and that the same also happens, in principle, for all other positive natural numbers.

Though certainly not perfectly crystal clear, this reasoning does not seem to me preposterous. But it would not help up to make the claim it supports – that arithmetic deals with abstract objects, understood as reification of concepts – anything more than an empty (though comfortable) claim, a contrived *façon de parler* to merely say that mathematics uses singular terms with a referential intent. If we want to make platonism an interesting philosophical thesis, we need to do much better than this.

Today's philosophy of mathematics presents at least two ways of doing it, each of which has unquestionable merits.

The first is provided by *Ante Rem* Structuralism (ARS), mainly advocated by Steward Shapiro (1997; a similar view that differs, however, from Shapiro's in many important details is advanced in Resnik 1997; other forms of structuralism are also available, which are not necessary to discuss here, since they do not openly adhere to the idea that mathematical objects result from a form of reification of concepts). To say it in general, the basic idea behind ARS is characterizing the appropriate form of reification by identifying a particular way, typical of mathematics, for defining concepts and organize them with the aim of fixing individual contents. This modality pertains to the identification of a categorical structure: The relevant abstract objects are identified with the poles (or places) in such a structure. They are, then, taken to exist insofar as the categorical structure they are poles of exists, and this exists, in turn, if and only if it is coherently defined, and obeys a general theory of structures, which (*mutatis mutandis*) mimics set theory.

Though much more might be said on ARS, this short account should be enough for making clear the way it answers to Platos' problem. What is important, indeed, is that it leaves to mathematics itself the task of defining categorical structures, and then insuring the existence of mathematical objects, though taking on it the task of indicating the appropriate way in which that has to be done (namely, by defining categorical structures). Leaving apart the usual, more technical objection about indiscernibles (originally advanced by Keränen 2001, to which Shapiro has replied, for instance, in Shapiro 2008), its main shortcoming comes, to my mind, from its being unapt to account for the historical evolution of mathematics, and, more in general, for large portions of past and present mathematics which are certainly not structuralist in nature, as well as for the current pervasive practice of transcendental proofs (proofs of theorems of a certain theory, involving tools from other theories).

The second way requires a more detailed explanation, since it appeals to less commonplace technicalities. It also adopts a much more descriptive (rather than normative) stance. It is provided by E. Zalta's Object Theory (Zalta 1983, 2021). The basic idea of this theory (or OT from now on) is providing a logical rendering of the very idea of reification of concepts in the shape of a particular form of predication, called 'encoding,' essentially distinct from that customarily in use in predicate logic. Formally, this depends on admitting two distinct forms for an atomic predicate formula, namely, 'Fa,' and 'aF,' where 'a' is a term and 'F' a monadic predicate, expressing the case where *a,* respectively, exemplifies (or has) *F*, and encodes it. Both forms of predication are embodied in a system of modal higher-order logic admitting types, but also working without them for simplicity. In its nontyped version, this system includes the following axiom

$$\Diamond[aF] \Rightarrow \Box[aF]$$

(where 'a' and 'F' are schematic letters, and '$\Diamond$' and '$\Box$' are the usual modal operators), asserting that *a* can encode *F* only if it encodes it necessarily. As the reciprocal implication also holds, of course, because of the usual properties of the modal operators, this renders that idea that *a* is the reification of *F* if and only if it is necessarily so.

This idea goes together with two further crucial ingredients of the system: the clause that an object encodes a (monadic) property only if it is abstract, and a form of comprehension asserting that, for any condition on monadic properties expressible in the formal language at issue, there is an abstract object that just encodes the properties that meet this condition (which allows an abstract objet to be conceived, in fact, as the reification of a bunch of properties).

The former ingredient is implemented by the introduction of the nonlogical monadic predicate constant '$E!$' denoting the property of being a concrete object, through which the two other monadic primitive predicate constants '$A!$' and '$O!$' respectively, denoting the properties of being an abstract and an ordinary one, are defined by

$$A! =_{df} [\lambda x \neg \Diamond \mathsf{E!x}] \quad \text{and} \quad O! =_{df} [\lambda x \Diamond \mathsf{E!x}].$$

It follows that any object considered in the system is either abstract or ordinary, and it is abstract if and only if it cannot be concrete, that is, it is concrete in no possible world, while it is ordinary if and only if it can be concrete, namely, it is concrete in some possible world. To these definitions, the following axiom-schema is added:

$$\forall \ldots \ [O!x \Rightarrow \neg \exists P[xP]],$$

(where '$\forall \ldots \ [\varphi]$' stands for the universal closure of 'φ'), asserting that an object is ordinary (and, then, not abstract) only if it fails to encode (is not the reification of) any (monadic) property. By contraposition, it immediately follows that an object

encodes (is the reification of) of a (monadic) property only if it abstract, as announced above.

The latter ingredient completes the picture. It consists of the following comprehension axiom-schema:

$$\exists x[A!x \wedge \forall P \ [xP \Leftrightarrow \varphi]]$$

where 'φ' is any formula in the formal language at issue in which 'x' does not occur free. Let, then, $\boldsymbol{P}$ be whatever (monadic) property already defined in the system. From this axiom schema, together with the first axiom mentioned above and a principle of identity for abstract objects making x the same abstract objects as y if and only if x necessarily encodes the same properties as y, we immediately get that

$$\exists!x\,[A!x \wedge \forall P \ [xP \Leftrightarrow \forall z \ [Pz \Leftrightarrow \boldsymbol{P}z]]],$$

which ensures that there exists a single abstract object that encodes (is the reification of) any (monadic) property coextensive with $\boldsymbol{P}$. Extensionally speaking, we can then say that for whatever (monadic) property $\boldsymbol{P}$, there is a single abstract objet that encodes (reifies) it and only it. But this is not all, since the formula 'φ' can be more complex than that. It can express any condition on (monadic) properties, which makes the schema ensure that for any such condition there is an abstract object that just encodes the (monadic) properties that meet it, as also announced.

With this formal apparatus at hand, and with the help of some further enrichments of the language of his theory – including the introduction of the definite descriptions operator '$\imath$' (such that '$\imath x\,[\varphi]$' is a term denoting the single object, if any, that meets the condition expressed by 'φ') – B. Linsky and Zalta himself have been able to provide a rigorous explicit characterization of an intratheoretic mathematical object (Linsky and Zalta 1995, 2006, 2019; the reason for I speak of an intratheoretic mathematical object, rather than of a mathematical object *tout court,* will become clear below). This is an object κ_{T} such that there is a mathematical theory T (identified, in turn, with an abstract object appropriately fixed within OT, so as to render an actual mathematical theory), such that this object encodes all and only the properties it has in T, that is:

$$\kappa_{\mathrm{T}} = \imath x \ [A!x \wedge \forall F \ [xF \Leftrightarrow \mathrm{T} \ [\lambda z F \kappa_{\mathrm{T}}]]],$$

where $[\lambda z F \kappa_{\mathrm{T}}]$ is the 0-place (or propositional) property that any object has just in case the world it belongs to is such that $F\kappa_{\mathrm{T}}$ (in Zalta's terminology, this is the propositional property "constructed out" of $F\kappa_{\mathrm{T}}$).

This is properly not a(n explicit) definition, of course. Its very logical form prevents it from being so, since the term 'κ_{T}' figures in it both in the left- and the right-hand sides. It is rather a "theoretical description," offered in OT's (rigorous) language. Whether there is a theory like T, if it is actually a mathematical one, how it its done, which individual contents (denoted by singular terms) it deals with, which of them are taken to have in it this or that property, and what makes they have them

are questions that OT neither can decide nor pretend to decide. It simply provides a formal setting making possible to rigorously claim that these contents are intratheoretical mathematical objects, and that nothing else is such an object. This entails that intratheoretical mathematical objects are all abstract, and are just the individual contents (possibly denoted by appropriate singular terms) that a mathematical theory deals with. More generally, each of them is the reifications of the concept of having all the properties that this theory assigns to it.

Just as Shapiro's structuralist definition, Zalta's characterization or "theoretical description" of intratheoretic mathematical objects is intrinsically unsuited for accounting transcendent proofs and extratheoretical contents, that is, for mathematical objects possibly studied by different theories and then independent of them. The problem is serious, since denying this possibility makes it impossible to maintain, for instance, if not quite informally, that different versions of arithmetic all deal with natural numbers, as a platonist account should be able to do, it seems to me. OT has however the resources for also characterizing extratheoretical mathematical objects.

On the one side, it accounts for the reference of singular mathematical terms in statements that make no (explicit) mention of a particular mathematical theory, as a reference to abstract objects that encode a relevant concept. Supposing we are able to deal with the concept of a triangle, however it might be fixed, it would be enough, for instance, to identify this concept with a particular concept, call it '$\boldsymbol{T}$', dealt with it within this theory, to easily render the statement of a natural or informal language 'a is a triangle' by the statement of such a theory '$a\boldsymbol{T}$'. This is the same as interpreting the 'is' in the former statement as an informal occurrence of the encoding operator. If it happens that the concept $\boldsymbol{T}$ is defined within a certain particular mathematical theory, be it formal or not (and this theory is, in turn, identified with an abstract object appropriately fixed within OT), we can prove (within this theory) that a encodes $\boldsymbol{T}$ if and only if a exemplifies $\boldsymbol{T}$. The statement '$a\boldsymbol{T}$' is then a statement about an intratheoretic mathematical object, and this makes it suitable for rendering 'a is a triangle' only if the same also happens for this latter statement. Still nothing forbids considering $\boldsymbol{T}$ (informally) fixed otherwise (by a way that OT is not required to specify), and still rendering 'a is a triangle' by '$a\boldsymbol{T}$'.

On the other side, OT also allows to define within it a quite weak, pseudofreegan set theory, and use it to define natural number *à la* Frege, as extensions of concepts (Zalta 1999). To this purpose, it is enough to take the extension $\varepsilon\boldsymbol{F}$ of a (sortal) concept $\boldsymbol{F}$ as the object

$$\iota x \ [A!x \wedge \forall P \ [xP \Leftrightarrow \forall z \ [Pz \Leftrightarrow \boldsymbol{F}z]]]$$

that just encodes $\boldsymbol{F}$, to define the appurtenance relation $\in$ (or its Fregean *alias* $\frown$) by

$$x \in y \Leftrightarrow \exists P \ [x = \varepsilon P \wedge Py]$$

and to adopt an appropriate modal principle to get second-order Peano axioms as Frege did (*mutatis mutandis*) in *Grungesetze*. According to Zalta, extratheoretical natural numbers can, then, be taken as the objects meeting these axioms (on which

no order relation, no addition, and no multiplication are defined yet), and the same can be done for other mathematical objects definable within the same weak set theory.

All this should be enough to make clear, in the same time, the great expressive (or descriptive and elucidatory) strength of OT, and its intrinsic and purposeful presumptive weakness. This weakness consists in its deliberately avoiding any endorsement in favor of a specific view about the nature of mathematics. The theory succeeds in providing a clear logical account of the reification process and the corresponding constitution of abstract objects. However, it purposely refrains from accounting for what distinguishes the mathematical form of reification and makes the intellectual exercise that mathematics pertains to result in such a powerful and stable corpus. This makes OT particularly suited as a theoretical context for advancing a pluralistic view about mathematics (Zalta forthcoming). But it makes it also unsuited to provide, alone, an answer to Plato's problem. This does not mean that it cannot contribute to provide this answer. It simply means that some other independent insight is required to achieve this task.

8 Object by *De Re* Epistemic Access

This is why I want to suggest another perspective here, essentially independent of ARS and OT. In particular, I suggest looking at an object, both concrete or abstract, as an individual content we could have (had) a *de re* epistemic access to.

If I say that a has the property $\boldsymbol{P}$, I can mean two quite different things, whose difference depends on the modality of my epistemic access to a. I can mean, of a, identified as such in advance, that it has the property $\boldsymbol{P}$, or I can mean that a, which has not been necessarily identified as such in advance, has the property $\boldsymbol{P}$.

I was born in Varese, a nice little town in the north of Italy, and lived permanently there the first 27 years of my life, and even now, though I live abroad, I try to come back to Varese anytime I can, spending time in the house where I grew up and lived for so many years. From the balcony of this house, one can see the Varese Lake, on the shores of which I went to walk and bike myriads of times. I also went boating many times on this lake, and, when I was a kid, pollution did not advise against swimming in it, and so I swam in it many times. Now, it just happened that I read on Wikipedia that the Varese Lake has a surface area of 14.5 km^2. Despite my familiarity with the Varese Lake, this is a new piece of information for me, and it is, literally speaking, a piece of information about the Varese Lake. It is about it that I got this information, which I did not have before (simply since I never thought before to look for it). Not having this information did in no way make me unable to perfectly know what the Varese Lake is, to understand what one was speaking about when speaking of it, and to locate it on the surface of the Earth, and the image of it in my memory: in few words, to have a perfect epistemic access to it. Because of this access, I now know what the new information that I got is about. So, if I now say, that the Varese Lake has a surface area of 14.5 km^2, I definitely mean, of the Varese Lake, that it has a surface area of 14.5 km^2.

After having got this new information about the Varese Lake, I opened another Wikipedia page and did read there that the "Eridania Lake is a theorized ancient lake [on Mars] with a surface area of roughly 1.1 million square kilometers [. . .][, a] maximum depth of 2400 meters [and a] volume[. . .][of] 562,000 km^3" I had never heard anything concerning the Eridania Lake, and never heard of the theory that there could have been lakes on Mars in the far past. I am, then, very much surprised that such a huge mass of water on Mars could have existed. This new piece of information is not about something I knew before having it and independently of it, that I was able to locate in the universe, and I had an image of in my memory. In few words, it is not about something that I had an epistemic access to, before getting it. This piece of information is instead, for me, constitutive of the Eridania Lake: It is what makes me have an epistemic access to it. So, if I now say that the Eridania Lake had a surface area of about 1,100,000 km^2, I cannot but mean, literally speaking, that the Eridania Lake had such a surface area, and this is what makes me now able to think of it somehow.

This illustrates the distinction I want to make between two radically different modalities of epistemic access to a content that works as a reference of a proper name. In the former example, I take my epistemic access to be *de re*. In the latter, I take it to be purely *de dicto*.

This having been said, let us come back to the latter example (the former seems to me clear enough for not requiring other considerations). Though no human being (and also no nonhuman animal presumably) has certainly never had any direct empirical experience of the Eridania Lake, it seems to me clear that it counts as an object, and even more so as a concrete one. What does make it so clear (at least to me)? I advance that the reason is this: The fact that nobody has ever had any direct empirical experience of the Eridania Lake does in no way make it logically impossible for someone to have had such a direct empirical experience. Moreover, even if (for some reasons that I am not frankly able to imagine) we were urged to consider such an experience as logically impossible, it would still remain that this would hardly depend on the intrinsic features of the Eridania Lake, but rather of the limitations imposed to our (or other animal's) capacity of empirical experience. As such, the Eridania Lake would have allowed anyone to have a direct experience of it, and this experience would have, in turn, allowed a human being to have a *de re* epistemic access to it. The (logical) possibility of such an access is, in my view, what makes the Eridania Lake count for us as an object. The fact that this is the possibility of an empirical experience is, instead, what makes this object count for us as a concrete one.

There is an important aspect of this argument that deserves clarification. What I just described are in no way conditions that make the Varese and the Eridania Lakes concrete objects *tout court*, but rather conditions that make them count for us as concrete objects. I am, in fact, not interested in the question of establishing what makes a concrete or an abstract object be so. I even consider this question perfectly meaningless. In agreement with the approach to philosophy that I described above, I am rather interested in the question of establishing what makes us consider an object

to be so. It is just to this question that I suggest answering by saying that this is nothing but the possibility of having (had) a *de re* epistemic access to it.

This having been made clear, let us come back to the main point. The two examples I advanced are both such to make the possibility of having (had) a *de re* epistemic access to a certain individual content depending on the possibility of a direct empirical experience of this content. This is just what makes these examples concern concrete objects. The next question is, then, this: Are there other sorts of epistemic relations with some individual contents that can make us able to have a *de re* epistemic access to them. The possibility of (sensibly) taking some individual content as an abstract object – rather than, merely, as the putative referential target of a proper name used in a statement that is admitted to hold – depends, in my view, on the answer to this question. Moreover, if the answer is positive, it is just the nature of these alternative relations that decides the nature we can ascribe to the object at issue, and whether it should count for us as an abstract object or a concrete one. This makes me replace the question of whether there are mathematical (abstract) objects with the question of whether there are forms of epistemic relations with individual (abstract) contents that are proper to mathematics (and differ, then, from direct empirical experience) that make it possible for us to have a *de re* epistemic access to these contents.

To better understand the question, let me try to better clarify it.

What makes my epistemic access to the Varese Lake *de re* is my capacity of identifying this content as such while ascribing a certain property to it, but fully independently of my doing it. This is, in other terms, my capacity of fixing this content in my epistemic horizon independently of recognizing it as the content having this property.

Now, it seems plain to me that this also happens very often with individual contents that we deal with in mathematics.

We can certainly identify the number 31 independently of ascribing to it the property of being the 11th prime number (in the usual order on natural numbers). Hence, properly speaking, we do not say that 31 is the 11th prime number; we rather say, of 31, that it is the 11th prime number.

In the same way, we do not properly say that the ratio of two successive terms of the Fibonacci sequence tends to the golden ratio, or even that this ratio is (equal to) $\frac{1+\sqrt{5}}{2}$; we say of the ratio of two successive terms of the Fibonacci sequence that it tends to the golden ratio, and, of this ratio, that it is equal to $\frac{1+\sqrt{5}}{2}$.

Despite naming it after Euclid, we do not properly say that the Euclidean closure of the rational numbers is the field of the numbers constructible by ruler and compass; we say, of the Euclidean closure of the rational numbers, that it is the field of the numbers constructible by ruler and compass.

Again, we do not properly say that 4 is the minimal number of colors required to color a map by avoiding that two adjacent regions be colored with the same color; we say, of 4, that it is the minimal number of colors required for so coloring a map.

We no more properly say that 18 is the Ramsey number $R(4, 4)$ (i.e., the smallest number of vertices of a graph containing either a four-cycle or an independent set

with four vertices), or that $43 \leq R(5, 5) \leq 48$; we say, of 18, that $R(4, 4)$ is equal to it, and, of 43 and 48, that they are the limits of the closed interval including $R(5, 5)$.

Finally, we do not properly say that $\frac{\pi^2}{6}$ is the limit of the series $\sum_{i=0}^{i=\infty} \frac{1}{i^2}$; we say of $\frac{\pi^2}{6}$, that it is the limit of this series.

Examples might be multiplied. Some of the previous ones might, by the way, also be inverted. We might perfectly say, for instance, of $\frac{1+\sqrt{5}}{2}$, that it is (equal to) the golden ratio, or of the limit of the series $\sum_{i=0}^{i=\infty} \frac{1}{i^2}$, that it is (equal to) $\frac{\pi^2}{6}$. The point is not which examples we consider, or what we consider to be, in each of them, the given content, and the property that we attribute to it. What is relevant is that these examples illustrate an important fact about mathematics: that in it, we can exhaustively fix individual contents in our epistemic horizon, independently of ascribing to them relevant properties that are rather ascribed to them *post festum*. In other terms: We can identify such contents without specifying all the properties they have in the very setting in which they are identified or in other settings. This fact is just what allows us to export individual contents from setting to setting, or, better, to deal with the same individual contents in different settings. Again, we can fix such contents in a certain setting, then extend the setting by defining appropriate relations or functions on these same contents, which allows us to ascribe new properties to them, without making them different contents. We do both things pervasively. And this is just what makes, to my mind, a sort of spontaneous (though often irreflexive) platonism so popular among working mathematicians.

This is, indeed, my own version of platonism for a philosophy of mathematical practice: Mathematics can be (is) suitably accounted for as an intellectual activity dealing with *sui generis* individual abstract contents, so fixed as to make us able to have a *de re* epistemic access to them. As it should be clear, this claim has strictly nothing to do with the existence of these contents (and the truth of some statements on them). Not only does it not assert the existence of mathematical objects, it also does not deny it. It rather assumes that the notion of existence of abstract objects is, when conceived as a primitive notion, simply nonsensical, by leaving open the possibility of defining this notion based on other ones, by so ending up recognizing that, yes, mathematical objects exist (and mathematical theorems are true of them), but in a new, derived sense. Among other things – particularly the admission that mathematical statements are to be understood *prima facie* – this assumption of nonsensicality essentially distinguishes the claim from any version of nominalism. It is, rather a claim for genuine platonism, though this is, as it were, a platonism without existence (and truth), at least if intended as primitive notion(s).

I say 'sui generis,' since the way the relevant individual contents are fixed is peculiar to mathematics. And it is just this peculiarity that makes this thesis not only compatible with the program of the philosophy of mathematical practice, but also dependent on this very program for its clarification and advocacy. Indeed, it is only by parsing mathematical practice and its history that we can identify the different ways these contents are fixed, so as to make such an epistemic access possible, and we can try to recognize what makes them mathematical in nature.

Such a project is structurally similar, in nature, to that of any empirical science: It is, so to say, the project of an empirical science of mathematical reality, this reality being not, however, that of self-standing objects, as a traditional platonist would argue for, but rather that of mathematical activity and production.

9 History, Cognition, and Logic

Of course, realizing this project is not something I can do here. Both the limits of space and the very purpose of this chapter force it to be essentially programmatic, in nature. What I can and want to do is delineating a philosophical perspective, a research program for a philosophy of mathematical practice able to answer Plato's problem. This only requires, for the time being, to briefly suggest three general sources (certainly not alternative, but rather complementary) for our ability to fix abstract individual contents so as to make possible for us to have *de re* epistemic access to them (and, then, to take them to be mathematical objects): history, cognition, and logic (or, more generally, formalization).

9.1 By History

Mathematics largely evolves by (conceptual) recasting (I borrow this term from several talks of Ken Manders). Theories are firstly (mainly informally) advanced, then variously restated, reorganized, and formalized. This important part of mathematical activity explicitly and essentially depends on the admission that these different forms of recasting conserve contents, that some contents (not only individual, of course, but crucially also individual ones) remain the same under the transformation of the setting in which they are defined and studied. This suggests to inverse the model-theoretic perspective.

According to this last perspective, mathematical objects are conceived of as the elements of the first-order domain(s) involved in the model(s) of a (formal) mathematical theory, namely, with the individuals forming the range(s) of the (different sorts of) first-order variables. What I mean by inverting this perspective is conceiving most mathematical theories as codifications – or, possibly, in some cases, formalizations – of a portion of available knowledge inherited from the history of mathematics (in the proper sense of 'history,' i.e., as *res gestæ*, rather than *historia rerum gestarum*), in which contents (not only individual, but crucially also individual ones) are crystallized, so as to make their transmission possible. What many mathematical theories would, then, do is taking some contents as given, and suggest a new conceptual configuration for them, possibly connecting them with other contents, historically crystallized in turn, but dissociated from the former ones, in the original piece of knowledge. This would make a mathematical theory be not about its models but about the contents it captures by recasting.

The availability of a single model, under isomorphism (and within a given semantic setting), would merely show that the theory captures these contents making them part of a univocal structure (within this setting). The presence of

nonisomorphic models would rather show that these contents are not so captured, leaving, then, space for alternative interpretations. This lack of univocality (or relative categoricity) can be certainly beneficial, since it can open new horizons of knowledge (the case of nonstandard analysis is symptomatic), but it says nothing about the original contents. It rather says something about new contents that, in this way, we become able to distinguish from the former, and study together with, or separately from them.

Here, the basic idea is that mathematical activity is intrinsically historical (as argued for in the preamble), though this characteristic and peculiar nature of it remains hidden to superficial regards. The reason of the concealment is that this historical nature manifests itself by a sort of (temporary) negation of itself, just due to recasting.

9.2 By Cognition

Mathematics requires (both common and specific) cognitive abilities. These are not the usual abilities to realize practical performances, often considered by alleged studies in mathematical (typically numerical) cognition, in order to display widespread forms of cognitive access to mathematical objects (typically small integer positive numbers), some of which would also be proper to human infants and some species of primates. These merely appear to me as mundane abilities to play some linguistic or prelinguistic games, which either involve mathematical words, or admit a retrospective description appealing to these words or the corresponding concepts. Subtilizing is only one among many other possible examples of these practical performances, which have, to my mind, no attested relation with mathematical theories and the contents they actually deal with.

What I am instead referring to are cognitive abilities that are required to crystallize intellectual contents involved in abstract reasoning. These are typically (but not limited to) abilities of recognizing an invariant structure within different (sorts) of exemplification of it, for example, the ω-sequence structure within the succession of Arabic numerals, or that of the reciprocal of the natural numbers, or the structure of a regular polygon within equilateral triangles, squares, pentagons, etc.

More generally, these are abilities of detecting abstract invariants, either individual or not (for instance, operational ones) and of both considering them as such, and working on particular instances of them, in order to identify general structural properties. In Kant's well-known terminology, this is the capacity of dealing with the "universal *in concreto.*" However flawed his conclusions may have been, both by a dramatically mistaken experimental practice and by a misleading confusion between ontogenetic and historical evolution, in his study of the cognitive development of children, J. Piaget famously tried to locate and isolate abilities like those.

Here, the basic idea is that performing mathematics activity depends of the (acquisition and) possession of cognitive abilities of different levels and sorts. These are the abilities that make us able to identify stable intellectual contents (either individual or not), which are both phylogenetically forged, and ontogenetically refined, also through cognitively complex and specific exercises (even if certainly not only through them).

9.3 By Logic (or Formalization)

Mathematical (conceptual) recasting mostly depends on a codification of language and intellectual acts, such as (stable or provisional) suppositions, inferences, definitions, constructions, etc. This codification is essentially logical, insofar as it depends on restrictions of the forms of expression and of the possibility of actions, in agreement with a number of general clauses to be applied in any specific occasion. These clauses might be seen as norms granting permissions, to be appealed to yield an argumentative setting that excludes all that is not allowed by them. A given setting is, of course, often extended, either occasionally, by unenvisaged admissions or acts, or systematically, by the addition of clauses granting further permissions. Moreover, different settings are frequently merged with each another. If Cantor was certainly right in claiming that "the essence of mathematics just lies in its freedom" (Cantor 1883, p. 564; my translation), this is essentially the freedom of fixing appropriate settings or, at most, of locally contradicting them by merely foretelling new permissions, rather than that of leaving anything go.

So broadly described, codification can result in either formal or informal theories. The border between the two cases is far from rigid and largely depends on historical or cultural conditions, branches of study, and methodological attitudes and sensibilities. What can be taken as formal within some mathematical communities cannot be taken this way within other communities. Even the criterion of (the possibility of a) computer implementation is much vaguer than it might appear at first glance, since it depends on the machine languages used and the interfaces with higher-level languages. Still, be it as it may, the crucial point is that any form of codification, as broad as it might be, goes together with identifying a delimited space of possibilities, involving some poles that can count as fixed individual contents.

Conceiving a particular codification as an act of recasting makes these individual contents count as particular occurrences of a more general content that they render within a certain setting. This is just what allows the last content to be taken, as such, as an available target for attributions of properties or the definition of relations or functions, which are in no way constitutive of it, either in general or within the particular setting at issue.

Fixing natural numbers as poles of the (relatively) categorical structure defined by Peano second-order axioms allows, for instance, both taking these poles as targets of a fist-order (uncategorical) axiomatization – which count, then, as an act of recasting within a different setting – and defining on them, within their own constitutive setting, a linear order, and an additive and a multiplicative law of composition, without changing their nature, but rather attributing to them, as such, a new bunch of properties. Moreover, making codification meet some appropriate conditions also allows its outcome to become, as such, the subject matter of a new mathematical inquiry, depending, in turn, on a metacodification. Such is the very well-known phenomenon of metamathematics, which is also a distinctive aspect of our capacity of having, in mathematics, a *de re* epistemic access to individual contents.

Here, the basic idea is that mathematics uses codified languages within delimited argumentative spaces. These spaces are not only suitable for fixing some appropriate

structures that are intended to render previously available pieces of knowledge, by bringing them to a new life. They also have specific structural properties that can be studied as such by new mathematical theories.

10 A Few Words, in Guise of Conclusion

When they are so conceived, as sources of our capacity to fix individual contents, so as to make possible having a *de re* epistemic access to them, history, cognition, and logic become crucial ingredients of a form of platonism. Its being independent of any talk of existence of abstract objects (and of truth of statements on them), if not appropriately redefined as derivative notions, makes the theses advanced by it perfectly factual claims.

Whether mathematics complies or not with such a form of platonism becomes, then, a pure matter of fact: a matter of fact that the philosophy of mathematical practice is not required to abstractly argue for, but rather to verify by an inquiry of this practice and its history. This makes this philosophy work, in turn, as a sort of high-level empirical science.

Abstract

The received Hilbert-style axiomatic foundations of mathematics has been designed by Hilbert and his followers as a tool for metatheoretical research. Foundations of mathematics of this type fail to satisfactory perform more basic and more practically oriented functions of theoretical foundations such as verification of mathematical constructions and proofs. Using alternative foundations of mathematics such as the univalent foundations is compatible with using the received set-theoretic foundations for metamathematical purposes provided the two foundations are mutually interpretable. Changes in foundations of mathematics do not, generally, disqualify mathematical theories based on older foundations but allow for reconstruction of these theories on new foundations. Mathematics is one but its foundations are many.

1 "Practical" Foundations of Mathematics and Foundations of Mathematics *Simpliciter*

Foundations of a theoretical discipline are traditionally conceived as a join between this discipline and its philosophy; accordingly, the philosophy of mathematics typically focuses on the foundations of mathematics (FOM) rather than on other areas of mathematical research. The philosophy of mathematical practice attempts, among other things, to enlarge the scope of philosophical analysis of mathematics by paying more attention to past and present mathematical developments beyond FOM and, more specifically, beyond the *Grundlagenkrise* that occurred in mathematics at the turn of the nineteenth and twentieth centuries and the related subsequent developments (Mancosu et al. 2008). Without trying to diminish the importance and philosophical relevance of mathematical practices and contents beyond FOM, I would like to stress that the mismatch between theory and practice in mathematics, which provides a rationale for distinguishing the philosophy of mathematical *practice* into a separate area of research, concerns FOM in the first place.

Described in few words, the current situation in FOM is as follows. The mainstream FOM is a relatively isolated and very specialized area of today's mathematical research. The majority of working mathematicians and mathematical educators know very little about FOM and cannot see its relevance to their works. This is certainly not how FOM, traditionally conceived, was expected to function. This unusual situation produces a range of different reactions in the mathematical community.

Some mathematicians including many FOM researchers explain and justify the gap between FOM and the rest of mathematics by a natural division of labor. They assume (i) that an ordinary working mathematician does not need to master details of the foundations of her discipline and (ii) that the research in FOM just like research in any other special area of mathematics requires a long professional training that cannot possibly be provided for all working mathematicians. A version of this view may go along with the conviction that FOM is of little or no significance for other mathematical disciplines. This view, however, is also compatible with the belief that all mathematical disciplines crucially depend on FOM whether or not working mathematicians are aware of it.

A number of mathematicians working outside the mainstream FOM research believe that mathematics needs foundations in a more traditional sense of the term, according to which FOM should represent some core mathematical contents and be known to and used by all mathematicians. On this basis Lawvere and Rosebrugh boldly disqualify the received FOM as a valid foundation:

> A foundation makes explicit the essential general features, ingredients, and operations of a science, as well as its origins and general laws of development. The purpose of making these explicit is to provide a guide to the learning, use, and further development of the science. A "pure" foundation that forgets this purpose and pursues a speculative "foundations" for its own sake is clearly a nonfoundation. (Lawvere and Rosebrugh 2003, p. 235)

Some other mathematicians try to make a peaceful agreement between the two concepts of FOM. They reserve the name of *practical foundations* for the traditional notion without trying to challenge the received FOM explicitly (Taylor 1999). On a parallel – albeit chronologically more recent – development in the philosophical camp a group of philosophers constituted the *philosophy of mathematical practice* as a subfield of philosophy of mathematics outside the mainstream FOM-oriented philosophy of mathematics (Mancosu et al. 2008). Since pure mathematics is a theoretical discipline *par excellence*, the grounds of the relevant distinction between mathematical theory and mathematical practice are far from clear, moreover so that philosophers of mathematical practice in their work systematically refer to mathematical theories and other mathematical content, but not only to practical issues related to mathematics research and education. The popular wisdom according to which "in theory there is no difference between theory and practice, while in practice, there is" perfectly applies in this case. Practically speaking, it is indeed the case that philosophers who associate themselves with the mainstream FOM research and philosophers of mathematical practice are doing different research and form different communities. But from a theoretical point of view it is not clear to me why these lines of philosophical inquiry into mathematics should be so different.

In order to clarify the situation I will not go deeply into philosophical generalities about theory and practice. Instead, I will analyze the nature and the genesis of the aforementioned gap between the received FOM and the rest of mathematics. I will use the above concise nonorthodox description of FOM coined by Lawvere and Rosenburgh as my working definition of this concept.

2 The Received FOM and Metamathematics

Today's received concept of FOM stems from Hilbert's seminal works in axiomatic geometry (David Hilbert 1899) and his later works on what is known today under the name of *Hilbert's Program*, which includes a modern form of proof theory (Hilbert and Bernays 1934, vol. 2). A special feature of this conception of FOM, which distinguishes it from more traditional conceptions, is its *metamathematical* character. The idea of metamathematics, as Hilbert and Bernays explain it in (Hilbert and Bernays 1934, Chap. 2, Sect. 5), is to provide *mathematical* answers to certain general mathematically related questions, which have been earlier seen as purely logical and philosophical (Ferreiros 2005). (Such as Hilbert's *Entscheidungsproblem*.)

The idea of metamathematics can be traced back to Descartes and Leibniz but it is not constitutive in the traditional FOMs. In particular, Euclid's *Elements* (which

qualify as FOM in our sense) has no metamathematical capacity. Let me use this classical example for explaining where the idea of empowering FOM with metamathematics comes from.

Euclid's *Elements* comprise a number of impossibility results such as a proof of impossibility to find a common measure for a pair of arbitrary straight segments. (See the *Elements*, Book 10, Problem 10.) Such proofs show that certain geometrical constructions can be specified in Euclid's theoretical language but, on pain of contradiction, cannot be performed within Euclid's theory. Such impossibility proofs solve certain mathematical problems in the *negative* way by showing that certain desired constructions are impossible.

However, there are also well-known mathematical problems that are are well posed in Euclid's mathematics but cannot be solved using only Euclid's principles either positively (by performing the required construction) or negatively (by showing that the required construction is impossible). The angle trisection problem is an example. A trisected angle is not an impossible geometrical construction. One can easily perform an instance of such construction by tripling a given angle (as usual by ruler and compass). Yet, as we know it today thanks to Galois' theory, the trisecting of arbitrary given angle by ruler and compass is not possible. This latter result is metamathematical (relative to Euclid's mathematics) because it belongs to a different theory, to wit Galois' theory, built on different principles. In what follows I call a mathematical theory M_E *meta*mathematical with respect to mathematical theory E just in case theorems of M_E describe relevant general features of E such as its consistency, limits of its methods, etc. (This informal description of the concept of metamathematics is broader and less exact than formal conceptions found in standard textbooks (Kleene 2009) but it better elucidates the epistemic role of metamathematics than more technical definitions.)

Let us call a theory *epistemically complete* when it allows one to solve – positively or negatively – any well-posed problem within this very theory (see (Pastin 1979) for a formal treatment). The concept of epistemic completeness raises a bunch of questions such as: Are epistemically *in*complete theories (epistemically) acceptable?; Is the epistemic completeness epistemically valuable?; How does epistemic completeness relate to the semantic completeness and other forms of theoretical completeness? and, last but not least, Are epistemically complete theories possible? David Hilbert was occupied with issues of epistemic completeness during all of his long-term work in FOM. His view on this matter was formed in the context of the so-called *Ignoramibusstreit* (*ignoramibus* debate; the debate about unknowable) that was started back in 1872 by Emil du Bois-Reymond who claimed that certain scientific questions and problems are unsolvable in principle. Responding to du Bois-Reymond Hilbert developed an opposite view according to which every well-established theory (and every mathematical theory at the first place) must be epistemically complete. Hilbert's belief remained remarkably stable during his long academic career. Hilbert expressed it publicly on many occasions, most famously in his 1900 address delivered in the Sorbonne at the International Congress of Mathematicians where he pronounced his famous "no ignoramibus" (in mathematics),

and also in his last major public lecture delivered in 1930 in Königsberg, which Hilbert concluded with the words "We must know. We will know" (McCarty 2005).

Hilbert believed that the epistemic completeness of mathematics (appropriately reformed) can, and should, be irrefutably proved by rigorous mathematical means, and not only be supported by general philosophical arguments. Whence the idea to identify FOM with a metatheory of all mathematics that could rigorously prove the epistemic validity of every mathematical theory deserving the name. Hilbert's metamathematical conception of FOM was based on the assumption that the wanted foundational theory could be kept minimal and form a reliable, trusted core of contemporary mathematics without imposing restrictions onto its conceptual contents. In 1927 Hilbert speculated that since "a formalised proof, like a numeral, is a concrete and surveyable object" proving the formal consistency of a given formalized theory "is a task that fundamentally lies within the province of intuition just as much as does in contentual number theory the task, say, of proving the irrationality of $\sqrt{2}$" (Hilbert 1967, p. 471). Retrospectively, it is clear that at this point Hilbert seriously underestimated the complexity of metamathematical tasks related to his foundational goals.

The question of how much (if any) of Hilbert's aspiration remains today sound in view of later FOM-related metamathematical and logical research has been widely discussed since 1930s (Zach 2003; Detlefsen 1990; Artemov 2020). Leaving aside this and other special questions about the Hilbert-style FOM I would like to stress once again that the very idea Hilbert had of providing FOM with a metamathematical capacity is highly original, and should not be simply taken for granted. From the traditional perspective on FOM, which has been outlined above, a metamathematical capacity of FOM appears as useful additional feature. It goes without saying that this new feature of FOM cannot serve its intended epistemic purpose unless the given FOM also performs its more basic functions, which Lawvere and Rosenburgh describe as "making explicit the essential general features, ingredients, and operations" of mathematics. Unless a given FOM performs these basic functions satisfactorily, its metamathematical power remains useless and irrelevant.

3 Is the Received FOM Adequate?

Any FOM has two sides. One is normative, logical, and epistemological. It deals with questions like: What is a correct mathematical proof? and provides tools for building sound mathematical theories and means for ruling out erroneous theories. The other side is "practical" and descriptive. It has to do with applications of the given FOM in mathematical practice including mathematics education and research, and, in particular, with the practical enforcement of epistemic norms associated with this given FOM.

An epistemological analysis of FOM needs to take both these sides into account. On the one hand, stripping away the normative dimension would reduce the epistemological analysis to historical, sociological, and psychological accounts and thus

destroy its specific character and purpose. On the other hand, ignoring the past and present mathematical practice deprives the epistemological analysis of mathematics of its subject matter. This concerns FOM just as much as any other part of mathematics. A normative epistemological judgement, which is grounded solely on general philosophical principles and does not accurately take into account what falls under its scope (in our case this is FOM as they are practiced), can hardly be justified.

The adequacy of the received Hilbert-style FOM is questionable on both these accounts. The most obvious problem concerns its *feasibility*: it turns out that attempts to represent standard mathematical contents in symbolic languages reserved by this FOM for this purpose require manipulations with chains of symbols, which cannot be represented in printed form and surveyed by a human. A notorious example is Bourbaki's definition of cardinal number 1 that comprises about 10^{15} symbols (Grimm 2010). At first glance the unfeasibility problem appears to be merely "practical," and can be successfully dealt with by using symbolic shortcuts such as "1." What is problematic here from an epistemological point of view is the relationships between mathematical theories represented "informally" or "semi-formally" with colloquial means and their formal counterparts represented with formal languages that make part of Hilbert-style axiomatic FOMs. The situation when theory T is represented formally as $\lfloor T \rfloor$ and the situation when T is represented by different means but can *in principle* be translated into form $\lfloor T \rfloor$ are very different from an epistemological point of view. In the latter case the given FOM have only a weak and indirect control over T, which works counter-positively. If T is shown to be *not* representable in the form $\lfloor T \rfloor$ then one concludes that the given FOM does *not* justify T. But the mere fact that T *is* representable in the form $\lfloor T \rfloor$ does not, by itself, allow one to judge whether T is valid by the given FOM's standards or not. Such a judgement is possible only when the formal representation $\lfloor T \rfloor$ is built effectively. Since $\lfloor T \rfloor$ is usually unfeasible, such a judgement is usually not available. This feature of the received Hilbert-style axiomatic FOM is at odds with the traditional expectation that mathematical theories can be justified by the very fact of being "based on" an appropriate FOM. Justification of a given mathematical theory is a basic FOM-related task, which is, generally, not performed via metamathematical considerations concerning the epistemic (in-)completeness of the given theory. Thus the feasibility problem has an epistemological dimension, which does not allow one to call this problem "merely practical."

Another problem concerns basic epistemological assumptions about mathematics that underpin the received axiomatic conception of FOM. Hilbert assumes that (ready-made) mathematical knowledge is representable in the form of axiomatic theories, and that such theories are systems of sentences, where each sentence is deducible from a set of distinguished sentences called axioms. This conception assumes that all established mathematical knowledge has a propositional character. This strong epistemic assumption about the mathematical knowledge typically extends to all scientific knowledge and is not specific for Hilbert's axiomatic approach to FOM. As Bertrand Russell remarked in 1900 "That all sound

philosophy should begin with an analysis of propositions, is a truth too evident, perhaps, to demand a proof" (for references and further discussion see (Gaskin 2009, p. v)).

However the assumption according to which all mathematical knowledge deserving the name has a propositional character does not square well with the existing mathematical practice. This can be clearly seen with the historical example of Euclid's theory of elementary geometry presented in Books 1–4 of his *Elements*. The first principles of Euclid's theory are of two types: geometrical *postulates* and *common notions* aka "axioms," which apply in the geometrical and in the arithmetical Books of the *Elements*. Euclid's postulates 1–3 are not propositions but schemes of elementary geometrical operations that intake some geometrical objects and output some other objects. (I assume here that a proposition, generally, admits for a truth-value. Euclid's postulates 1–3 are not propositions because they do not admit for truth-values.) For example, Postulate 1 is a scheme of operation that intakes two different points A, B and outputs a straight segment AB. Unlike the postulates the common notions 1–3 do operate with propositions, namely with propositions of the form $A = B$ (equalities). However, as Lewis Carrol rightly stressed back in 1895, these common notions should be read, on the pain of infinite regress, not as propositions but rather as schematic rules of inference, i.e., schemes of operations that allow one to obtain new equalities from some given equalities (Carroll 1895). Under this reading Common Notion 1 intakes two equalities of the form $A = C$ and $B = C$ and outputs equality of the form $A = B$.

Accordingly, the main body of Euclid's geometrical theory comprises items called *problems* along with theorems. Euclid's problems are recipes for making geometrical constructions provided with proofs that these constructions have their desired properties; these recipes are not expressed in a propositional form. For example, Problem 1 that opens Book 1 of the *Elements* tells us how to construct an equilateral triangle given its side; it provides a construction using Postulates 1,3, and a proof (using Common Notion 1) that the output of this construction qualifies as an equilateral triangle. Most of Euclid's geometrical theorems also involve constructions, which in this case are colloquially called "auxiliary." So problems and theorems in Euclid's *Elements* are intertwined and form a single deductive order, where earlier solved problems and earlier established theorems are used for solving further problems and establishing further theorems. Prima facie there is no reason for thinking that the operational *knowledge-how* expressed in Euclid's *Elements* in the form of problems is epistemically less significant than the propositional *knowledge-that* expressed in Euclid's geometrical theorems. (Logical reconstruction of Euclid-style geometrical reasoning remains problematic and cannot be more systematically explored here. For a more detailed analysis of Euclid's geometrical reasoning see [55, Ch. 1.2]. Back in 1974 Ian Müller claimed that no contemporary system of modern logic could adequately account for Euclid's form of geometrical reasoning (Müller 1974), see also (Müller 1969). In my opinion this situation did not significantly change during the following decades.)

Hilbert's work in the axiomatic foundations of Euclidean geometry (David Hilbert 1899) demonstrated that a rigorous propositional rendering of Euclid-style

traditional geometry is possible. However, it also showed that such a rendering is not innocent from a logical point of view, and requires a fundamental revision of Euclid's style of reasoning. In the introductory part of their *Foundations of Mathematics* published in 1934 Hilbert and Bernays stress the difference between their propositional axiomatic approach in theory building and Euclid's "genetic" aka "constructive" approach, which involves nonpropositional operations such as construction of new geometrical objects from given objects. The authors do not dismiss the genetic approach as an outdated version of their axiomatic approach but recognize its specific character, and conceive of a possibility to combine the two approaches (Hilbert and Bernays 1934, v. 1, Introduction).

The traditional Euclidean pattern of geometrical reasoning presented above remains very much alive in today's mathematics; various patterns of "genetic" reasoning coexist in today's mathematics with the axiomatic reasoning (Rodin 2014, p. 35 ff). As we shall shortly see (Sect. 4.3 below), the univalent foundations of mathematics proposed in the mid-2000s provides a formal framework where the two patterns of mathematical reasoning work jointly. Thus the assumption according to which all ready-made mathematical knowledge is essentially propositional is at odds with the current mathematical practice where various forms of knowing-how continue to play a major role.

Let us now consider the normative dimension of this assumption. A theoretical epistemological objection to this assumption can be formulated as follows. *Models* are at least as important constituents of mathematical theories as the sentences that these models make true, and arguably are even more important (as will be explained shortly). Today's mathematics is model based with very little exception. Mathematical models (but not only mathematical theories construed as systems of sentences) play a key role in today's science. The thesis that mathematical knowledge reduces to propositional knowledge does not do justice to the epistemic role of mathematics in science and technology.

Back in the 1950s Patrick Suppes put forward an influential epistemological thesis according to which scientific theories should be identified with classes of models rather than with certain syntactic structures (like $\lfloor T \rfloor$) that are interpreted as systems of sentences. Since one and the same class of models can, generally, be determined by different theories identified syntactically, theories in Suppes' sense are invariant or "robust" with respect to a range of possible syntactic choices used for axiomatic presentation of these theories (Suppes 2002). Suppes' view of theories is known in the literature under the name of *semantic* aka *nonstatement* view (Halvorson 2016). Suppes and his followers developed this view of theories attempting to apply Bourbaki-style axiomatic techniques in formal presentations of physical and other scientific theories. In spite of the fact that they referred to Bourbaki's project explicitly (Suppes, 2002, p. 33), (Stegmüller 1979) the discussion of the concept of theory for some reason remained limited to philosophy of science and never extended to philosophical logic and philosophy of mathematics. Similar views in philosophy of mathematics, however, were in different words expressed by proponents of *mathematical structuralism* who were equally motivated by Bourbaki's project but preferred to use Bourbaki's term "structure" instead of the

term "model" avoiding in this way a terminological interference with model theorists (Hellman 2006).

The standard semantic approach in FOM does not do full justice to the model-based character of mathematical reasoning because it offers a new way of thinking about existing formal techniques (to wit, about the Hilbert-style axiomatic method empowered with Tarkski-style formal semantics) without developing new techniques appropriate for the purpose. True, building models (structures) and experimenting with them is a key element of today's mathematics. But the Hilbert-style axiomatic FOMs provide no means for the formal encoding such operations and giving them a stable theoretical form. This is because such FOMs comprise only formal rules, which are logical rules including rules of truth-preserving logical inferences. FOMs of this type do not include rules similar to Euclid's postulates that regulate manipulations with nonpropositional objects. Hilbert-style FOM may justify the *existence* of a given mathematical structure with certain properties but is indifferent as to how this structure is obtained or "found." The idea that one may stipulate an object or structure with certain desired properties by fiat without asking how to build such an object from some familiar elements makes the axiomatic method in mathematics very useful and powerful. But the constructive aka *genetic* reasoning that does take such issues into account is at least equally important in mathematics (Term "constructive" in logic and foundations of mathematics is highly overloaded. Following Hilbert and Bernays, I call here a mathematical reasoning constructive when it involves nonpropositional operations such as building complex mathematical objects (aka constructions) from some given simple constituents, see (Rodin 2018) for further discussion.). This constructive aspect of mathematics is particularly important in the applied mathematics where mathematical methods (applied outside of pure mathematics) have a major epistemic role. As we shall see in Sect. 4.3 below, the univalent FOM provides a technique for encoding mathematical knowledge-how and implementing this knowledge computationally.

4 Foundations at Work

In this section I provide a very brief overview of three different "practical" FOMs that emerged in the twentieth and early twenty-first centuries: Nicolas Bourbaki's *Elements of Mathematics*, the category-theoretic foundations first proposed by William Lawvere and the univalent foundations more recently proposed by Vladimir Voevodsky. This list is not supposed to be complete: there is a number of other interesting FOM-related developments in the twentieth-century mathematical practice that I do not consider here. (This concerns, in particular, early attempts to adopt the Hilbert-style axiomatic presentation of elementary geometry in school education (Halsted 1904) and current attempts to introduce computer-assisted proofs into mathematical practice, which are independent of univalent foundations (Avigad 2018).) It is essential to keep in mind that we talk here not about some accomplished foundational theories per se but about continuing efforts to organize some large fragments of mathematics in a particular way with certain open-ended foundational

theories: Set theory in the case of Bourbaki, Category theory in case of categorical foundations, and Homotopy Type theory (HoTT) in case of univalent foundations. The three projects started at different times: Bourbaki in the mid-1930s, category-theoretic foundations in early 1960s, and univalent foundations in the mid-2000s. (More exact dates are, of course, conventional. Bourbaki group has been created in 1934 (Baulieu 1994). The idea of category-theoretic FOM has been first put forward by Lawvere in 1963 in his Ph.D. thesis (Lawvere 1963). The idea of univalent foundations (at this point without the name) has been first publicly presented by Voevodsky during his talk in the Institute of Advanced Studies (Princeton) on March 22, 2006 (Voevodsky 2006).)

Since the development of each later project involves a critique of earlier foundational projects and purports to fix their shortcomings, it is not unreasonable to regard these three projects as consecutive stages of the same overall process. However, the real history of these projects does not fit into such a linear Hegelian scheme. Bourbaki-style set-theoretic FOM, category-theoretic FOM, and univalent foundations (UF) all play roles in current mathematical practice – typically not in their "pure" forms but combined with some older foundational schemes and patterns. These roles are very different in the three cases. The set-theoretic FOM still maintain their "official" status (at least in eyes of the majority of logicians) and elements of Bourbaki-style presentation of mathematical reasoning are still widely used in practice (including mathematics education) in spite of the general skepticism about Bourbaki's foundational project shared by the majority of working mathematicians. Category theory is presently widely used as a convenient abstract theoretical language that extends and in some cases wholly replaces the Bourbaki-style set-theoretic language in many areas of mathematics. Situations when the category theory has a role of *foundation* are rarer and more specific; some such examples are referred to below. Finally, UF is a relatively new project (work in progress) aiming, in Voevodsky's words, at "a computerized version of Bourbaki."

4.1 Bourbaki

The continuing multivolumed *Elements of Mathematics* produced by a group of (mainly French) mathematicians of several generations that uses the pseudo-name of *Nicolas Bourbaki* is a unique long-lasted attempt to build Hilbert-style axiomatic foundations of mathematics and implement them into a broad mathematical practice in research and education. (The first volume of Bourbaki's *Elements* was (first) published in 1939 (Bourbaki 1939). The latest original volume appeared in 2016 (Bourbaki 2016); in 2019 appeared a new edition of an earlier published volume. Further references and updates concerning the work of Bourbaki's seminar and recent publications of the group can be found on the group's webpage https://www.bourbaki.fr) The title "Elements of Mathematics" refers to Euclid's *Elements*; following Euclid's example Bourbaki aims at providing a self-contained introduction into the contemporary mathematics, which systematically presents not only its principles but also its basic contents. The original French title is *Eléments de*

mathématique, which uses the unusual singular form "mathématique" that expresses Bourbaki's goal to unify mathematics. A concise general description of this project, which makes explicit some grounding ideas behind it, has been published in 1950 as a separate programmatic article titled the "Architecture of Mathematics" (Bourbaki 1950). (The article has been written by Jean Dieudonné and signed by the name of Nicolas Bourbaki, see [Corry 2004, Chap. 7].)

After a recognition of the unifying power of the Hilbert-style axiomatic method Bourbaki makes an interesting move by distinguishing between the *logical* aspect of the axiomatic method from another aspect, which can be called *structural*; in Bourbaki's view this is the latter rather than former aspect that makes the axiomatic method a powerful instrument of the unification:

> [E]very mathematical theory is a concatenation of propositions, each one derived from the preceding ones in conformity with the rules of a logical system [...] It is therefore a meaningless truism to say that this "deductive reasoning" is a unifying principle for mathematics. [...] [I]t is the external form which the mathematician gives to his thought, the vehicle which makes it accessible to others, in short, the language suited to mathematicians; this is all, no further significance should be attached to it. What the axiomatic method sets as its essential aim, is exactly that which logical formalism by itself cannot supply, namely the profound intelligibility of mathematics. (Bourbaki, 1950, p. 223)

In order to understand Bourbaki's misgivings about the "logical formalism" it is essential to take into account how Bourbaki's axiomatic method differs from Hilbert's. Using the term borrowed from the philosophy of science I have characterized in the last section Bourbaki's method as *semantic*. Bourbaki's "axiomatic" theories are not Hilbert-style theories provided with some default interpretations but theories of set-theoretic models of such Hilbert-style theories. For example, each particular group (identified either up to set-theoretic equality or up to isomorphism) qualifies as a model of Bourbaki's axioms for group theory (nowadays standard). But group theory does not reduce to proving general theorems that follow from these axioms alone and thus apply to all groups indiscriminately. For example, the elementary Lagrange theorem does not belong to this kind because it involves two different groups, i.e., two models of the axioms. Since all such models are set theoretic, Lagrange theorem as well as any other group-theoretic theorem proved by Bourbaki is deducible from axioms of set theory. This is how Bourbaki's semantic approach makes set theory into a core of their FOM.

Interestingly enough Bourbaki expresses some misgivings about set theory along with the aforementioned misgivings about the "logical formalism":

> [T]he axiomatic studies of the nineteenth and twentieth centuries have gradually replaced the initial pluralism of the mental [mathematical] representation [...] first to the concept of the natural number and then, in a second stage, to the notion of set. This latter concept, considered for a long time as "primitive" and "undefinable", has been the object of endless polemics [...]; the difficulties did not disappear until the notion of set itself disappeared [...] in the light of the recent work on logical formalism. From this new point of view, *mathematical structures* [my emphasis - A.R.] become, properly speaking, the only "objects" of mathematics. (Bourbaki 1950, pp. 225–226)

The provided references do not allow one to identify the precise sense in which Bourbaki talks here about the "disappearance of sets." But the above quotation makes it clear that already at an early stage of their project Bourbaki were motivated by the idea to represent mathematical structures without using set theory. Yet, officially, all Bourbaki's structures are construed set theoretically, namely, as set-theoretical models of certain systems of Hilbert-style axioms. The intended notion of "self-standing structure" (without an underlying set) is nowhere rigorously defined in Bourbaki's *Elements*. But as a matter of practical implementation of this intended notion Bourbaki systematically disregard details of their own set theory and its associated formal logical machinery.

A reason why Bourbaki feel so uneasy about their set-theoretic representation of mathematical structures concerns the idea (that historically dates back at least to Hilbert) that *isomorphic* structures should count as identical (MacLane 1996). The problem is that no (Hilbert-style) axiomatic set theory that comes with its internal identity relation provides a rigorous sense in which isomorphic structures can be said to be identical. We shall shortly see how this problem drives the category-theoretic approach in FOM and how it is settled in the univalent FOM (Ahrens and North 2019). In Bourbaki's *Elements* the notion of self-standing mathematical structure independent of any set-theoretic background remains a wishful thinking or, on a more charitable interpretation, a *regulative idea* in the Kantian sense of the word.

Outside a narrow group of enthusiasts who continue today to push further forward Bourbaki's project there are very few research mathematicians and mathematical educators who are ready to use Bourbaki's volumes in their teaching and build their research on them. Nevertheless it is clear that Bourbaki's *Elements* indeed "make explicit the essential general features, ingredients, and operations" of certain style and pattern of mathematical thinking that has played a major role in twentieth-century mathematics. Even if a number of important achievements of twentieth-century mathematics have been wholly unrelated to Bourbaki's edifice, Bourbaki provided a certain vision of mathematics as a whole and contributed to its unification and connectedness by developing the semi-formal "set-theoretic language" that is still routinely used in various fields and areas of mathematical research and helps their cross-fertilization. Even if there are serious reasons today to regard Bourbaki's set-theoretical FOM as outdated it still serves mathematicians and students of mathematics for many everyday purposes.

The story of the rise and fall of the Bourbaki-based approach in the elementary mathematics education, which took place worldwide in the course of twentieth century, deserves special attention. It starts with an attempt at reforming school mathematical education on the national level according to the new standards known as the *New Math* in the USA at the end of 1950s as a key element of the American response to the Soviet launch of the first Sputnik in 1957 (Phillips 2015). This educational reform aimed at the reinforcement of national technological and intellectual power and promoted the Bourbaki-style approach at the elementary school level. It was led by a number of prominent American mathematicians including Marshall Stone and was predictably opposed by the majority of school teachers and pupils' parents. More remarkably, this reform was also severely criticized by some

leading mathematicians and scientists, including such a prominent figure of the time as Richard Feynman (Feynman 1965). The opinion that the *New Math* was a pedagogical error prevailed already in the early 1970s (Kline 1973), and this controversial reform was soon largely abandoned.

Ironically or not, in the Soviet Union a similar radical reform of mathematical education was started almost simultaneously with the American *New Math*. In 1959 Boltyansky, Vilenkin, and Yaglom published a programmatic paper (Vilenkin NYa et al. 1959) where they urged for renewal of standard school mathematical curriculum. In the late 1960s the reform of mathematical education was supported by Soviet authorities and soon developed into a project of national scale; a Bourbaki-style version of school mathematical curriculum was chosen for implementation in school textbooks, developed by a group of leading mathematicians and mathematical educators under the general supervision of Andrey N. Kolmogorov. The fate of this Soviet reform was similar to that of the American *New Math*: in the late 1970s under the pressure of complaining school teachers, pupils' parents, and harsh critique of some mathematicians, this reform was abandoned and the new mathematical textbooks were again replaced by more traditional ones.

Similar reforms were undertaken in France and some other countries, and their fate was also similar. These national reforms of school mathematics did not proceed in isolation; they were parts of an international trend in mathematics education where the leading role belonged to French mathematicians including André Lichnerowitcz and some other members of the Bourbaki group.

The failure of Bourbaki-style approach in the elementary mathematics education cannot be fully analyzed here. Let me only mention that proponents and critics of the Bourbaki-style approach in mathematics and mathematics education agreed that this approach was not helpful for pointing to, illuminating, and supporting applications of mathematics in science and technology (Stone 1961; Feynman 1965; Arnold 1998). However they evaluated this fact differently: while the opponents argued that linking mathematics with science and technology was essential, the proponents of Bourbaki's approach argued that it was not.

4.2 Category Theory as a Foundation

Explaining the legacy of set theory in the twentieth-century mathematics, Yuri Manin remarks that in the second half of this century "sets gave way to categories" (Manin 2002, p. 7). The mathematical concept of *category* emerged in 1940s, its official birth is marked by 1945 paper by S. Eilenberg and S. MacLane (Eilenberg and MacLane 1945). Category theory (CT) soon proved to be a useful mathematical language that helped to organize a number of emerging concepts and new results into a stable theoretical form. Among early examples that justified the usefulness of CT in eyes of many mathematicians were (Eilenberg and Steenrod 1952; Eilenberg and Cartan 1956; Quillen 1967). Some new mathematical concepts and mathematical theories developed during the same period would not even emerge without CT. A number of today's mathematical disciplines including algebraic geometry,

homological algebra, and functional analysis use CT as their basic language (Kromer 2007; Marquis 2009).

The success of CT as an alternative language that allowed for effective theoretical accounting for mathematical structures in terms of their maps bypassing the redundant set-theoretic details appeared to many mathematicians, among them some Bourbaki members (including H. Cartan, S. Eilenberg, and A. Grothendieck) as a way to realize Bourbaki's dream about the "disappearance of sets" in their role of universal foundational background. Remarkably, Samuel Eilenberg and Norman Steenrod in the *Preface* to their (Eilenberg and Steenrod 1952) as well as Daniel Quillen in (Quillen 1967) boldly claim that using the language of CT they build "axiomatic" theories. Their approach was indeed axiomatic in its spirit in the sense that these authors stipulated the existence of categories with some special properties and on this basis developed abstract theories, which generalized upon many earlier known examples. However, these theories did not meet standards of formal and logical rigor used by mathematicians working in FOM, and in fact did not pursue this goal.

The idea to develop CT into a genuine FOM is due to William Lawvere. In his 1963 Ph.D. thesis (Lawvere 1963) he proposed Hilbert-style axioms for CT that are sometimes referred to in the current literature as Eilenberg–MacLane axioms and the corresponding theory is called EM; in the same thesis Lawvere built the elementary theory of category of sets (ETCS), where the word "elementary" refers to the first-order character of this theory, see also (Lawvere 2005) for a more detailed exposition of this work. Unlike the aforementioned theories of homological algebra and homotopy (Eilenberg and Steenrod 1952; Quillen 1967) that also use the language of categories and are called by their authors "axiomatic," ETCS is an axiomatic first-order theory in the standard sense of the term familiar to logicians and philosophers. Later Lawvere developed a more general project of category-theoretic FOM, namely, an axiomatic theory of category of categories (category of categories as a foundation or CCAF for short) (Lawvere 1966). In these early works Lawvere challenged the notion according to which set theory in some form should be a core part of modern FOM. In particular, he showed the possibility to develop an axiomatic set theory on the basis of axiomatic CT rather than the other way round. However at least at this stage of his career he did not challenge the notion according to which a modern FOM should involve the Hilbert-style axiomatic approach in some form.

The most remarkable of Lawvere's achievement in the category-theoretic axiomatization of mathematics is his work in topos theory. The concept of *topos* emerged in the circle of Alexandre Grothendieck in the early 1960s as a far-reaching generalization of the concept of topological space. Grothendieck's concept of topos had no special relevance to logic; the discovery of logical structure of topos is wholly due to Lawvere and his foundational approach. In the beginning of his 1970 paper (Lawvere 1970) Lawvere provides his definition of topos usually called today the definition of *elementary* topos; the title "elementary" reflects the fact that Lawvere's definition unlike Grothendieck's original construction almost straightforwardly translates into the standard first-order formal language (McLarty 1992).

A necessary and sufficient condition under which a given elementary topos is a Grothendieck topos was found in 1972 by Grothendieck's student Jean Giraud (Giraud 1972).

Even if Lawvere's theory of elementary topos qualifies as a Hilbert-style axiomatic theory it has a feature, which makes it quite unlike ZFC and other similar theories. The standard approach applied by Hilbert and later described and justified by Tarski from a metodological viewpoint assumes that an axiomatic theory is based on a certain symbolic calculus with fixed logical semantics, which allows one to formulate some specific axioms and then interpret nonlogical terms of this syntactic structure in certain intended models. The logical part of such theories, i.e., their "underlying logic," is supposed here to be rigidly fixed in advance (Tarski 1941). Lawvere's approach is different in this respect. His insight behind the axiomatization of topos theory is that every topos has an internal logical structure, which is analogous to that present in the category of sets. As Lawvere puts it "logic is a special case of geometry" (Lawvere 1970, p. 329). This understanding of relationships between logic and geometry is very unlike Hilbert's and Tarski's.

Studies in the category-theoretic FOM not only provided a new grounding for CT independent of set theory but also helped to simplify many category-theoretic concepts and apply them in various areas of mathematics as well as outside of pure mathematics, in particular, in computer science. Lawvere's axioms for elementary topos made topos theory more accessible and helped many people outside the community of experts in algebraic geometry to enter this field and conduct fruitful research in it. Although the category-theoretic FOM so far did not have a general impact on mathematics comparable with Bourbaki's impact it also had a significant effect on mathematics education (at the university level) and research.

4.3 Univalent Foundations

The univalent foundations (UF) is a novel foundation of mathematics first proposed by Vladimir Voevodsky in 2006 (Voevodsky 2006); UF uses homotopy type theory (HoTT) as a language and purports to express in this language various mathematical contents. HoTT in its original form is an interpretation of Martin-Löf's type theory (MLTT) in terms of homotopy theory where types are interpreted as homotopy spaces and terms of these types are interpreted as points of those spaces. This interpretation was discovered by Vladimir Voevodsky and, independently, by Steven Awodey and Michael Warren in the mid-2000s (Univalent Foundations Group 2013).

For Voevodsky a major motivation for developing UF was pragmatic and concerned the possibility of computer-assisted formal verification of long mathematical proofs. As we have already stressed, the received FOM does not support a formal checking and verification of mathematical proofs beyond trivial cases. However the practical need for such a reliable verification becomes more and more pressing. Even if the use of computer-assisted proofs remains today uncommon in the mainstream mathematical research, there is a growing corpus of

mathematical results proved with computer; in many such cases nonassisted "purely human" proofs are not known and there are indications that such proofs may not exist. A recent overview of existing proof assistants and presentation of the state of the art in the interactive computer-assisted theorem proving – which however does not cover the *UniMath* and other UF-motivated projects – is found in (Avigad 2018) and references therein.

It is remarkable that no existing proof assistants straightforwardly implement Hilbert-style formal representations of mathematical theories but use instead some form of type theory in their theoretical background. Per Martin-Löf designed and developed his constructive type theory with dependent types (MLTT) back in 1980s already in view of its possible implementation on computer; its fragments were effectively implemented in Coq and some other proof assistants. He provided this formal system with a *proof-theoretic* logical semantics, which essentially differs from Tarskian model-theoretic logical semantics used in the received Hilbert-style FOM (Piecha and Shroeder-Heister 2015); syntactically, MLTT is a Gentzen-style (rule-based) but not Hilbert-style (axiom-based) formal system. The discovery of homotopical interpretation of MLTT in the mid-2000s, which gave rise to HoTT, convinced Voevodsky that this theory can serve as a basis for a new FOM that supports an automated proof checking. Voevodsky called this FOM *univalent* because of the *univalence axiom* (UA) explained in what follows. The origin of term "univalence" is somewhat arbitrary: it comes from the expression "faithful functor" translated into Russian on some occasion as (in the backward translation due to Voevodsky) "univalent functor" (Grayson 2018, footnote 4). See (Grayson 2018) for a concise introduction into UF, and (Univalent Foundations Group 2013) for a more systematic exposition.

The homotopical semantics of MLTT allows one to distinguish between types of different *homotopy levels* and interpret types of different levels differently: types of level (-1) are interpreted as propositions, types of zero level are interpreted as sets, and types of level 1 are interpreted as groupoids (namely, fundamental groupoids of homotopy spaces) and so on up to higher homotopy groupoids. Formal rules of the underlying type theory are interpreted, at the propositional level, as rules regulating logical inferences; at higher homotopy levels the same formal rules regulate geometrical (to wit homotopical) constructions, which make certain propositions true. Thus HoTT justifies the aforementioned view of Lawvere on logic as "a special case of geometry." This feature of HoTT makes the UF-based mathematical reasoning in some respects similar to the traditional Euclid-style geometrical reasoning where geometrical constructions help to prove theorems. Since homotopy-theoretic concepts are spatial and intuitive in low dimensions, UF helps to visualize and understand many abstract mathematical concepts and proofs. In particular, it helps to have an intuitive grasp of formal proofs represented with a computer code and ready for an automated verification. This feature of UF addresses the issue of "opaqueness" (i.e., lack of surveyability) of computer-assisted proofs widely discussed in the literature (Bradley Bassler 2006).

Like in case of the traditional geometrical reasoning the epistemic role of UF-based constructions does not, generally, reduce to witnessing certain

mathematical sentences but have other important epistemic roles. Notice that by constructions I mean here rule-based mathematical procedures but not only their outcomes. Such constructions represent mathematical know-how in an explicit form. For a historical example think of Euclid's construction of five regular polyhedra aka platonic solids in Problems 13.13-17 of *Elements*, Book 13. This is the crowing achievement of Euclid's edifice; when one traces these constructions back to their first principles, i.e., to postulates and common notions of Book 1, then one can see that the necessary theoretical background of these five problems comprises a significant portion of the mathematical knowledge presented in the *Elements*. This large bulk of mathematical knowledge is packed in the five aforementioned problems in the operational but not propositional form. For another important historical example think of algebra in its early form presented by al-Khwarizmi in the book, which gave the discipline its current name (Rashed 2010). Al-Khwarizmi's algebra is a systematized collection of recipes (provided with an Euclide-style geometrical background) for solving problems of a certain sort. The current mathematical practice does not give one any indication that the role of the operational knowledge-how in mathematics is less significant today than it used to be in the past. The fact that UF unlike the standard Hilbert-style axiomatic FOMs allow for a formal and meticulous representation of operational knowledge in the form of UF-based homotopical constructions is one more reason in favor of the claim that UF are more adequate.

The significance of knowing-how is particularly evident in the applied mathematics where mathematics is seen as an epistemic tool rather than an independent discipline. Mathematical models of natural phenomena and technological artifacts always verify certain mathematical sentences; to put it colloquially, such models have certain mathematical properties. However, the main epistemic role of such models is not to instantiate and witness these mathematical properties but to account for empirical data. In such contexts knowing *how* to build an appropriate mathematical model is a key issue.

Let me briefly illustrate this point with two examples: the historical example of Ptolemean astronomy and the up-to-date example of topological data analysis (TDA). Ptolemean astronomy involves the traditional Euclid-style geometry as its mathematical foundation (but goes beyond the geometrical content of Euclid's *Elements* since it applies spherical geometry). Visible motions of celestial bodies are reconstructed as superpositions of circular motions. In case of planets this requires using a number of supplementary circular motions, which are not observable. The trajectories of such motions Ptolemy calls *epicycles*. The resulting geometrical model, by Ptolemy's famous word, "saves the phenomena," i.e., is empirically adequate (with a certain degree of approximation). Importantly, Ptolemy's geometrical models of astronomical phenomena are built step by step and thus adjusted to observational data; such genetic procedures are based on constructive geometrical principles closely related to Euclid's postulates (think of epicycles). Such a systematic way of model building is made possible by the constructive (genetic) character of Euclid-style geometry explained in Sect. 3 above.

In TDA, which is a rapidly developing area of today's applied mathematical research (Patania et al. 2017), large datasets of various nature are accounted for in

terms of topological spaces and their invariants. This allows one to extract from the given data some essential information, which turns out to be relevant and useful in many cases. All relevant characteristics of those topological spaces – and, in a sense, also these very spaces – are computed on the basis of the given data. Even if such a procedure can, in principle, be fully specified in terms of truth conditions within an appropriate external theoretical framework, UF offers a possibility to interpret such computations internally (and yet formally and rigorously) as genetic topological constructions. Such a direct internal interpretation better squares with the colloquial language and intuition of working mathematicians and computer scientists working in the field. This specific feature of UF has a potential to narrow the existing gap between today's abstract pure mathematics and applied mathematics (Rodin 2021).

Let us now turn to the univalence axiom (UA), which gives the univalent foundations its name. Let A, B be types, in symbols $A, B\ TYPE$. Consider the identity type $A =_{TYPE} B$ and the type of *equivalences* $A \simeq_{TYPE} B$ where by equivalence one understands a function $f : A \to B$, which is in an appropriate sense invertible; under the homotopical interpretation such equivalences are homotopy equivalences. The rules of MLTT/HoTT allow one to construct a canonical map of the form

$$e\,(A = B) \to (A \simeq B)$$

which witnesses the fact that identity is a special case of equivalence. The *univalence axiom* states that this map e has an inverse and thus is itself an equivalence. In other words, UA says that the type

$$(A = B) \simeq (A \simeq B)$$

is inhabited. More recent versions of UF based on cubical type theory (CTT) do not use UA as an axiom but prove it as a theorem. The aforementioned inverse map, which is not constructible by using the rules of MLTT, is constructible by using the rules of CTT. Thus in CTT-based UF there is no need to postulate univalence with a special axiom. This fact supports the claim that CTT is a better formal carrier for UF than MLTT (Bezem et al. 2019).

Univalence is important for a variety of reasons. A reason which has a particularly strong philosophical appeal is that the univalence property apparently justifies the structuralist idea of mathematical reasoning "up to isomorphism" (or up to another type of equivalence), which reflects the existing practice in the Bourbaki-style set-based mathematics and in the more recent category-theoretic mathematics but lacks a firm logical grounding in these foundational frameworks. A detailed analysis of this claim, which includes further qualifications and certain reservations, is found in (Ahrens and North 2019).

It should be born in mind that the homotopical semantics of MLTT is an extension (not fully conservative) of its intended logical semantics but is not a model of this theory in homotopy theory. *Models* of HoTT are further interpretations of its syntactic structures, which respect the homotopical semantics in an appropriate sense. When formal rules of HoTT are interpreted in external structures they can

be understood as rules for building such structures from their elements. This feature of UF has no analogue in the standard Bourbaki-style semantic approach to theory building where all structures are supposed to be "static." From a historical perspective this aspect of UF can be described as a synthesis of axiomatic and *genetic* approach, which has been considered by Hilbert and Bernays back in 1934 as a theoretical possibility (Rodin 2018).

Since UF is still a work in progress it is too early to evaluate its success and practical impact on mathematics against the impacts of earlier FOMs. However, already today one can see that UF is designed as a practical tool for learning and doing mathematics, which unlike the received Hilbert-style axiomatic FOMs does not suffer from the "meta-mathematical bias" (see Sect. 2 above). Thus UF presently appears as a strong candidate for bridging the existing wide gap between FOM and the rest of mathematics, between mathematical foundational theories and mathematical practices.

5 Renewing Foundations and Progress in Mathematics

In the remaining part of this chapter I would like to describe my general views about mathematics and its foundations in terms proposed by Michele Friend (Friend 2014). First of all, my position is *foundationalist* insofar as I believe that FOM is an important part of mathematics both practically and theoretically; I also believe that FOM is an important (albeit not unique) point of contact between mathematics and its philosophy. Second of all, I am a *pluralist* about FOMs. This should be clear from the earlier sections where I described several different FOMs without saying which is the right one, and which are wrong.

Since my working general concept of FOM borrowed from Lawvere and Rosenburgh is broader than the one used by Friend, my position is foundationalist in a weaker sense of this term than in Friend's sense. Friend defines FOM as "an axiomatically presented mathematical theory to which all or most of successful existing mathematics can be reduced" (Friend 2014, p. 8). I assume that Friend uses here the term "axiomatic" in its usual Hilbertian sense, and I qualify an axiomatic presentation of mathematics in *this* sense as a special feature of the received Hilbert-style FOMs rather than as an essential feature of FOM in general. Univalent foundation is an example of FOM that is not axiomatic in this usual sense because the UF applies a Gentzen-style (i.e., rule-based) but not a Hilbert-style formal architecture. (It makes sense to broaden the received notion of being axiomatic, so it may include also Gentzen-style formal systems. This terminological convention, however, creates a high risk of confusion since systems like MLTT that comprise no axiom in the received sense of this term would also qualify as axiomatic. For this reason I stick in this chapter to the received meaning of "axiomatic." For discussion of a broader conception of being axiomatic see my (Rodin 2018).)

Further, I do not assume together with Friend that mathematics can be "reduced" to its foundations in any epistemically relevant sense of this term. When such a

reduction is understood in a strong epistemic sense, so the reducibility condition reads:

In order to learn all existing mathematical knowledge it is sufficient to learn FOM.

this condition is obviously too strong and even absurd. When the reduction is understood as formal provability or in some other sense that has no definite epistemic content, the same condition is too week or irrelevant. The fact that all texts written in English can be encoded into 0-1 sequences does not make 0 and 1 into building blocks of all English literature. Similarly, the fact that a lot of mathematics can be encoded into fragments of ZFC does not, by itself, make ZFC into a foundation of mathematics. (I am not trying here to dismiss the set-theoretic FOM in one stroke and realize that set-theoretic FOMs involve more than formal provability. I would like to stress, however, that formal provability of theorem *T* in ZFC in the usual sense of existence of truth-preserving inference from the axioms of ZFC to *T* does not, by itself, shed a light on how *T* is (or is not) *known*, see (Prawitz 1986) for a discussion.) Instead of looking further for an appropriate notion of reduction I shall describe the relationships between mathematics and its foundations by looking at it from the opposite end. The following epistemological condition on FOM is, in my view, appropriate:

In order to acquire any fragment of the existing mathematical knowledge it is necessary to learn (a relevant fragment of) FOM.

The latter condition implies that FOM or their relevant fragment are necessary in justification of every mathematical result but it does not imply that FOM are sufficient for that purpose.

In spite of these differences between my working concept of FOM and Friend's concept, they share many essential features in common, in particular, a normative character, a capacity to unify mathematics, and a justificatory function. So my notion of being a foundationalist is not wholly at odds with Friend's, after all.

Let me now explain how I think about multiple FOMs. My first point is historical. I believe that the development of FOM is an important part of the overall historical development of mathematics. I assume that this overall development is progressive, and understand this progress as a growth of accumulated mathematical knowledge (Bird 2007).This notion of progress is compatible with a picture of mathematics that develops on some fixed foundations (say, Euclid's), so the growth of mathematical knowledge amounts to proving more and more geometrical theorems and solving more and more geometrical problems by ruler and compass. This process is potentially infinite, at least if we abstract away from issues of feasibility. However mathematics as we know it is more interesting, it simply does not develop in this simplistic way, at least not in the long term. Our real mathematics involves a permanent *revision* of foundations, which contributes to the overall mathematical progress.

Recall that the trisection of angle and some other geometrical problems are unsolvable on Euclid's foundations. These old geometrical problems were successfully solved (in the negative way) in the nineteenth century using the then new algebraic foundations of geometry laid out during the course of seventeenth to eighteenth centuries by Descartes and others. These new foundations (Arnauld 1683) were not a conservative extension of Euclid's foundations with certain additional principles but involved a very deep conceptual revision of these old foundations. However, this revision did not disqualify Euclid's foundations as being wholly erroneous either. Euclid is still with us, and we see nothing fundamentally wrong about his geometrical constructions by ruler and compass (except for some fixable logical gaps). This situation can be compared with the foundational change in physics that was brought about with the development of quantum mechanics: this foundational theory did not wholly disqualify the earlier accepted foundational theory (classical mechanics) but explained the success of this older theory while showing the limits of its applicability. The principles according to which new foundational theories in physics should relate to older foundational theories in this way is known as Bohr's *correspondence principle*. The same principle applies to foundational changes in mathematics.

In order to use the new foundations for solving geometrical problems formulated in a different foundational framework these problems had to be reformulated in a new way. What we learn today under the name of Pythagorean theorem is not quite the same statement that we typically identify as this same theorem in Euclid's *Elements* (Book 2, Theorem 47); the corresponding proofs of these statements are moreover very different. How and in which exact sense mathematical contents preserve their identities through such foundational changes is a tricky and little explored question, which I should leave aside. However the very fact that the acquired mathematical knowledge is capable to survive through foundational changes is remarkable.

The above example of foundational change in geometry is typical rather than exceptional. Sometimes new foundations help to identify old errors, but I do not know about examples of foundational revisions that have invalidated large bodies of mathematical knowledge established earlier on different foundations. Thus I observe that a revision of FOM typically has these three effects: (i) it preserves earlier acquired mathematical knowledge but expresses it in a new form, (ii) it helps to solve open problems, and (iii) it triggers new developments that were not possible with only the resources of the old foundations. So the continuing revision of FOM contributes to the overall progress of mathematics.

The above historical point does not commit me to a historical relativism about epistemic norms provided by different FOMs used in different historical times. It is quite justified to judge older FOMs by epistemic standards of more recent FOMs. One should bear in mind, however, that different FOMs often have very different designs, so some such judgements can be easily ill-formed. To repeat, new FOM, generally, does not disqualify the older FOM that they replace but put them in a new perspective. I can see no reason for thinking that such a renewal of FOM should ultimately converge to a certain "true" FOM. The continuing revision of FOMs has a

character of expansion (in its depths and scope) rather than convergence. I believe that this specific form of progress is worth encouraging rather than being stopped by choosing the current FOM as ultimate.

6 Tolerance and Pluralism

My final point concerns what Friend calls the principle of *tolerance* to conflicting philosophical views on mathematics associated with different FOMs (Friend 2014). What has been said above about the continuing revision of FOMs during the historical development of mathematics should not be understood in the sense that at any given moment of historical time mathematics relies or should rely on a unique FOM. In practice, mathematicians of the same generation often use different foundations, including more traditional and more "progressive" ones. The failure of the *New Math* and akin reforms in mathematics education in the 1960–1970s suggests that such a diversity is justified at least in education. I have described above how new foundations replace and "absorb" older foundations without disqualifying these older foundations completely. A similar scheme applies to contemporary FOMs. There exists a large body of mathematical knowledge that can be reconstructed on different alternative FOMs, say, on the set-theoretic and the category-theoretic FOMs. Let us consider a more problematic case when certain mathematical proof (construction) P is justified by one FOM (F) and not justified by another FOM (G). It appears that such cases make a tolerant attitude to conflicting FOMs impossible: in order to judge whether or not P is valid one needs to take a side and reject either F or G. This contradiction, however, can be avoided. There is a powerful mechanism that allows one to avoid the choice between F and G without becoming an epistemological relativist or a skeptic.

A more precise description of the above conflict between F and G involves two different versions of P, namely, P_F that construes and justifies P according to standards of F, and P_G which construes P according to standards of G and invalidates it. Now suppose that G admits an interpretation g of F that extends to P_F and provides an explanation in terms of G of how and why proof P_F is valid by the standards of F. Reciprocally, F admits interpretation f of G that extends to P_G and explains in terms of F why P_G is invalid by the standards of G. When such interpretations f, g exist, F, G are called *bi-interpretable*. These mutual interpretations can be pictured with the following diagram:

$$F/P_F \underset{f}{\overset{g}{\rightleftarrows}} G/P_G$$

So a user of G gets another reconstruction of P in terms of G, namely, $P'_G = g(P_F)$ which unlike P_G is valid by the standards of G. Reciprocally, a user of F gets another reconstruction of P, namely, $P'_F = f(P_G)$ which unlike P_F is invalid by the standards of F. The users of F and G now share a mutual understanding of principles needed for justifying or rejecting P. The user of F and the user G will think about P in

different ways and disagree about the epistemic status of *P*. But at this point their disagreements belong to the philosophy of mathematics rather than mathematics itself.

The above scheme does not apply universally but it applies to bi-interpretable FOMs, which include many cases of interest. For a trivial example consider the case when *F*, *G* are two different Hilbert-style axiomatic theories which share some axioms in common. One can use ZF as a foundation and use the axiom of choice (AC) in certain proofs as a separate hypothesis. Alternatively, one can take ZFC as a foundation, and this time view the AC as an axiom. From an epistemological and foundational point of view the two approaches differ. There is, however, a large body of mathematical knowledge that is wholly neutral with respect to choice between accepting AC as an axiom and using it as a hypothesis. In this case the interpretations $ZF \rightarrow ZFC$ and $ZF \leftarrow ZFC$ are trivial and amount to changing the epistemic status of AC from hypothesis to axiom and back. In cases when different FOMs use different formal architectures (as in the case of ZF and UF) and differ conceptually, such mutual interpretations can be very involved and nontrivial. The long-lasted continuing history of rebuilding Euclidean geometry on different foundations provides a lot of suggestive examples of this sort.

Some conditions stronger than the mere bi-interpretability can also be considered. Let *f*, *g* be composable in a associative way. If $g \circ f = 1_F$ and $g \circ f = 1_G$, i.e., the image of image of *F* in *G* is *F* itself and, reciprocally, the image of image of *G* in *F* is *G* itself, the two FOMs are equivalent – in a way which is specified by the character of these interpretations. The elementary category theory, this time in its role of a metatheoretical tool, suggests many other possible configurations between different FOMs, which I leave for another study.

The possibility of the coexistence of different FOMs in mathematical practice does not undermine the significance of philosophical arguments in favor of certain FOMs and against certain other FOMs. Such philosophical discussions have multiple impacts on mathematics including shaping its new trends. The tolerant attitude to multiple FOMs and their philosophical underpinnings, which I defend here, does not imply a neutrality and lack of interest to FOM-related philosophical matters. I understand tolerance as a methodological principle according to which a foundational debate in mathematics needs an environment, which is both concurrent and cooperative. As far as one accepts that conflicting philosophical ideas about mathematics deserve a common stage where they are systematically presented, criticized, and further developed, one should also accept the notion that a part of this stage belongs to mathematics and accommodates multiple FOMs. As I have explained above, the multiplicity of FOMs does not break mathematics down into disconnected pieces. Different FOMs may serve different special purposes and be useful in different ways. We showed that the received set-theoretic axiomatic FOM was designed for metatheoretical purposes and that this FOM cannot be effectively used for the purpose of formal proof verification. Using UF for this latter purpose does not exclude a possibility to use the received set-theoretic FOM for metamathematical purposes. I do not believe that these different epistemic tasks – to verify proofs and to provide a metatheoretical view on a given theory – can be adequately

distinguished as being practical and being theoretical. Both tasks have theoretical aspects that are analyzed in normative logical and epistemological terms and practical aspects that are described in terms of past experiences and recommendations for novices.

As many authors have earlier remarked, the traditional architectural metaphor behind the concept of theoretical foundation can be not only useful and suggestive but also very misleading. Unlike traditional buildings mathematical theories do not rise and fall with their foundations but have a capacity to survive through foundational changes. Martin Krieger compared mathematics of the nineteenth century with an industrial city (Krieger 2015, Chap. 6). In line of Krieger's metaphor FOM should be thought of as a city infrastructure, which uses elements inherited from earlier historical times. We may extend Krieger's metaphor and think about today's FOMs as even larger, more flexible, and more robust infrastructures, which are more suitable for our diverse postindustrial economies. Pluralism in Friend's sense is a sine qua non of FOM so conceived. My short answer to the question asked in the title of this chapter is this: one mathematic(s) and multiple foundations.

only way to model society is a pluralist one. Along the way to this conclusion, we argue why mathematical logic is a good part of mathematics to use in modeling and, in particular, explain the use of set theory in this context.

Pluralism · Set theory · Society

1 Introduction

Mathematicians of the eighteenth century, starting with the celebrated Carl Friedrich Gauss, were the first in the Western world to question the uniqueness of mathematical interpretation. Thinking of geometry on the surface of the globe, Gauss realized that it exhibits a non-Euclidean geometry, consistent with all but the fifth postulate of Euclid. Due to its departure from the then established view that the whole of mathematics is based on the axioms of Euclid, the core of mathematics, this discovery was quite shocking to Gauss. So shocking that he did not publish it.[1] Yet, there is no way to stop history and the fact was re-discovered independently by János Bolyai in 1832 (Bolyai 1832) and Nikolaï Lobatchewsky in 1837 (Lobatschewsky 1837). Speaking of this and the similarly dramatic discovery of non-commutative algebra, Paul Dirac has said in (Dirac 1931) "Non-euclidean geometry and non-commutative algebra, which were at one time considered to be purely fictions of the mind and pastimes for logical thinkers, have now been found to be very necessary for the description of the general facts of the physical world."

Following this line of reasoning, this chapter demonstrates the usefulness as a modeling tool of mathematical logic, a part of mathematics that some contemporaries may consider as "purely fictions of mind and pastimes for logical thinkers," while in fact it has "often been found to be very necessary for the description of the general facts of the physical world." We concentrate on an aspect of mathematical logic that is considered even more abstract than the others, set theory, and on its application as a model of what is even more physical than the physical world studied by Dirac: the society. Set theory is considered so abstract for reasons similar to the non-Euclidean geometry being considered too abstract in its own time: it shakes the conviction that there is only one universe of mathematics, as much as geometry shook the conviction in the universality of the Euclidean thought. Both geometry and set theory are examples of the phenomenon of mathematical pluralism, where mathematicians have to find ways to grasp the situation in which absolute truths are a rarity, rather than a norm that they were once thought to be. The reader is probably ready to accept that plurality, given that mathematicians have been

[1] In fact, Gauss was not the only one. In 1733, Giovanni Girolamo Saccheri (1733) and in 1766 Jean-Henri Lambert, separately found counter-examples to the parallel postulate (see Kagan 1974). Saccheri's also did not quite know how to treat this discovery and it only appears implicitly in his final work, while Lambert discretely added it to the second edition of his book (Lambert 1759).

studying it for several centuries. We would like to use that good will of the reader to explain a logical consequence: if we accept that mathematics is a basis for sciences, including social sciences, and if there is a pluralism in mathematics, then this implies that the only way to model the society is a pluralist one.

The chapter will lead to accept that pluralist model of the society on the scientific basis, while using set theory as foundations. It will not add any knowledge to set theory, nor to the discussion of the place of set theory within science. It will rather try to use our experience in set theory and the multitude of its universes to understand something about the order of the human society.[2]

History and heuristics seem to show that the only chance for a society to stand united in the moments of crisis is the acceptance of the plurality of opinion. We shall defend the view that this conclusion follows from a very fundamental logical model. That conclusion feeds into our philosophical position which is that the acceptance of the plurality of opinion is crucial both in mathematics and in the society.

2 Notation and Assumptions

In this chapter, we understand the standard Zermelo-Fraenkel axiomatization of set theory given in the first-order classical logic. This is known as ZF. The Axiom of Choice could be added to this to obtain ZFC, as it is known since Kurt Gödel's work in (Gödel 1938) that if ZF is consistent, so is ZFC. However, we have no use of the Axiom of Choice in what are interested in here and hence we shall skip it.

There are several other worthy formulations of set theory that have been studied for philosophical or mathematical reasons (see (Fraenkel et al. 1973) for more on this matter), but ZF(C) is the mainstream one and the one to which all the results cited in the paper refer to. It is part of the standard toolbox of a mathematical logician to know that nothing essential would change in the philosophical conclusion of this material by either changing the axioms or even by changing the foundations from set theory to some other ones. This is because a trace of Gödel's Incompleteness (Gödel 1931) would catch up with us one way or another (see, e.g., Fraenkel et al. 1973).

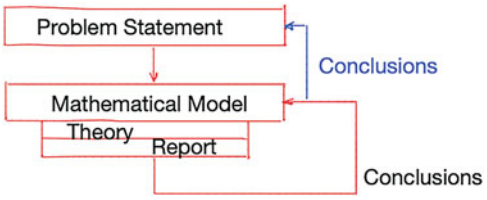
The reader not familiar with mathematical logic may simply think of ZF(C) as a significant representative of the method that mathematicians use to obtain mathematical foundations. The reader not familiar with the concept of mathematical foundations may simplify further and remember that any theory in human experience is based on some foundational truths, some unquestionable statements that are a base for all reasoning within the theory. Mathematical foundations are what mathematicians would like to declare their foundational truths. The question of what exactly mathematical foundations are is not a simple one, and no simple answer is possible; taking set theory as foundations is a very good and very common partial answer.

[2] In this text the noun *human* is used for members of any gender identity and the pronoun *he* is used as a generic human pronoun as well as the masculine pronoun.

3 On the Methodology of Mathematical Modeling

As stated, we wish to develop a model of the human society based on our knowledge of mathematical logic and then use the conclusions about the model to make some conclusions about the society. In other words, we develop a mathematical model. At this point, it is worthwhile to discuss what this means exactly, addressing both the advantages and the limitations of this process.

The steps involved in mathematical modeling are rather standard, let us, for example, use the description from Neumaier (2004). We start with a Problem Statement and provide a mathematical model, including elements of Theory and their report with the problem. We draw conclusions about the mathematical model and hope that the fit with the problem is sufficient to be able to carry the conclusions back to the Problem Statement. Then, we make conclusions about the Problem Statement.



While some parts of this diagram are purely logical, we point out that the fit of the model with the problem is a leap of faith. This in some cases can be defended by heuristic information and experiments, for example, in biology, and in others, as is the case here, by a philosophical position. In all honesty, the art of mathematical modeling is a bit of a mixture of experiments, and the philosophy and believing a model is never more than that: believing a model.[3]

3.1 Set Theory as a Modeling Tool

There are many examples where mathematical logic has made considerable advances in modeling social situations. Perhaps, the most striking recent example is Jouko Väänänen's Dependence Logic (Väänänen 2007). This logic, although of great independent interest in pure abstract logic, for its original treatment of dependence, independence, and teams, has also found numerous applications including some in social sciences, such as an analysis of Arrow's theorem (Arrow 1950) (of which more will be said in Sect. 6) done by Eric Pacuit and Fan Yang (2016). Game theory, which is in close connection with logic through game-theoretic

[3] Those who claim otherwise, waging equations and statistics in their own defense, need only to consider the remarkable lack of success that such a dogmatic approach has had in various concrete contemporary situations. Modelling is hard and nobody has a monopoly.

definitions of semantics, was in part developed as a theory of social organization in the tumult of the Second World War, as is documented in the book (Leonard 2010) by the well-known historian of economic thought, Robert Leonard. In fact, much earlier in mathematics, we can mention Condorcet's Jury Theorem and Condorcet's Paradox by Nicolas de Condorcet in (de Condorcet 1785), as one of the first attempts to model democratic processes by mathematics.

We shall stay within the area of mathematical logic, specifically set theory. Set theory has proved its worth as a modeler in many mathematical contexts, making contributions to a diversity of fields, within logic, such as model theory, and in a broader way in mathematics, such as in topology, measure theory, analysis, algebra, and combinatorics, and further in computer sciences. There are whole fields of mathematics whose name starts with the words "set-theoretic," such as the set-theoretic topology, and there are innumerable books on various aspects of mathematics whose title is "Set-Theoretic Methods in . . .," for example (Blanchini and Miani 2015), in control theory, (Michał Skrzypczak. Descriptive set theoretic methods in automata theory, volume 9802 of Lecture Notes in Computer Science. Springer-Verlag, Berlin 2016) in the theory of automata, and (Eklof and Mekler 2002) in algebra, to cite just a few. Moreover, set theory has played a major foundational role in mathematics, in that it is understood by many mathematicians as *the* foundations of mathematics and by all as *a* possible foundation of mathematics. This success speaks to the modeling power of set theory. Simply, a great variety of mathematical concepts are sets, with some additional properties. This is indeed what made the reputation of set theory in the foundations of mathematics and incited David Hilbert to say, perhaps somewhat too optimistically, that "nobody will take us out of the paradise created by Cantor" (Hilbert 1926).

We shall test the modeling power of set theory by going one step further, to social sciences. Set theory has famously entered into humanities through the work of Alain Badiou, including the book (Badiou 1988) which gives a mathematical ontology through set theory and uses the axioms of ZFC to identify the relationship of a being to the Nature, to the God, to the State. As the name of the book suggests, Badiou discusses the greatest philosophical questions using set theory, which he continues to do in further volumes of work (Badiou 2006, 2019). Of course, the four pillars of Badiou's work being Art, Love, Politics, and Science, he certainly uses his set-theoretical ontology to a great variety of social ideas. Our ambition is more modest and rather concrete: it will evolve around the idea of membership as a founding concept in set theory, but also in the society. Therefore, if we accept to define the society using the idea of membership as a defining feature, as we argue in the following, then it is reasonable to model that same society as a model of some sort of set theory. As mentioned above, we shall work with the axioms of ZF. We shall show, firstly, that the axioms of ZF(C) set theory have a natural interpretation in a model of the society and that, hence, the society can be modeled using the ideas we have about the universes of set theory. We shall call the resulting model of the society *the societal interpretation*.

4 Formulating the Societal Interpretation

The basic object in set theory is, evidently, a set. It is not a concept that we define, rather we take it as given and we build set theory by studying the relation of membership between sets. This relation is guided by the axioms of ZF(C) and deductions from the axioms, which are done using the rules of deduction in first-order logic. The resulting theory is a rich domain of mathematics, and it is made even richer by the fact that many objects in mathematics can be modeled using sets and the membership relation: the set of natural numbers, the set of real numbers, the set of all lines in a plane, and so on. As much as many mathematical concepts are sets, even more *social* concepts are sets: the set of members of a family, the set of students in a class, the set of members of a political party, followers of a religion, or the set of citizens of a country. Indeed, when introducing the concept of a set to a new audience, one would usually first go through this type of example, before even entering into the examples coming from mathematics. Furthermore, the basic relation of set theory is that of belonging to a set and we support the idea that this is also a basic relation in the society. While we might find that the idea proposed by Robert Park (1921) that "the individual is a product of group life," that is, the identity of a member of a society is determined by which sets he belongs to, is somewhat extreme, it would be difficult to disagree with the converse, that is *the identity of any society is determined by its members*.

This is exactly one of the basic axioms of set theory, the *Axiom of Extensionality*. Next, in Sect. 4.1 we explain how the rest of the axioms of ZF can be interpreted in the society. The reader not familiar with the axioms of ZF can find them listed in the Appendix. We shall not attempt to duplicate the work already done by Badiou (Badiou 1988) in interpreting ZF(C) set-theoretic axioms as ontology. Rather, we shall give a self-contained and very concrete interpretation of the axioms in the context that interests us.

4.1 ZF in the Societal Interpretation

To interpret a list of axioms in a logical context, we need to understand the domain where the variables appearing in the axioms are allowed to range. This domain for us will be the society. Therefore, the societal interpretation will have one society, the society of all humans on the planet and many societies, which represent smaller groups of humans. Humans individually, in families, in their work place, in their street, in their city, in their political party, on their Facebook page. All of these examples of societies will be represented as sets.

In the introduction to this section, we have already discussed the Axiom of Extensionality in the societal interpretation. Several following axioms in the list of ZF have a very natural interpretation in the model, as we now discuss.

The *Axiom of Pairing* says that for every two sets, there is a set which contains exactly the two of them. This would simply mean that for any two societies, one can form a third which consists of exactly the two we started with, which conforms with

observation. The *Union Set Axiom* says that if we have a set Z of sets, there is one set which contains exactly the elements that belong to some element of Z. Therefore, if we have a society of societies, say the Russell group of universities in the UK, each university consisting of students in that university, then we can form the union of all students of all Russell group universities. The *Power Set Axiom* says that if we have a set A, then we can form a set which contains exactly the subsets of A. For example, we can form a set which consists of all possible social subgroups of the students of all Russell group universities. The *Foundation Axiom*, which is given a very prominent role in (Badiou 1988), has a rather natural interpretation, saying that in any society, one can go back to the root to break the society into its constituent members which have no societies as members.

4.2 The Axiom of Infinity and Relativization

Now we arrive to the Axiom of Infinity, which might pose a problem. Namely, if we put ourselves at the external point of view, clearly the number of all inhabitants of the planet is finite, and so the number of all societies is finite. The *Axiom of Infinity* states that there is an infinite set. Do we have a contradiction?

No, we do not have a contradiction, and this is the main point. To understand this, we need to introduce the idea of the relativization, an idea which plays a major role in set theory since the work of Gödel on the constructible universe, in (Gödel 1938), but which, stated in different terms has already played a role in the work of Bolyai (1832) and Lobatchewsky (1837), on the models of geometry. Let us explain that idea abstractly.

Suppose that we have two sets M_0 and M_1 in which we have interpreted some mathematical language $\mathcal{L}$. An important observation to make is that the sentences of $\mathcal{L}$ might have different truth values in M_0 and M_1. For concreteness, let us consider as M_0 the set of $\mathbb{N}$ of natural numbers, as M_1 the set of $\mathbb{R}$ of the real numbers and, for the language in question, the language $\mathcal{L} = \{\leq\}$, which we interpret as the usual orderings on the sets $\mathbb{N}$ and $\mathbb{R}$. Then to every abstractly formed sentence in $\mathcal{L}$, say

$$(\exists x)(\forall y)\, x \leq y$$

we may associate the truth value that this sentence has in the models M_0 and M_1, and this truth value will not only depend on the sentence but also on the model in which the sentence is interpreted. For example, if we interpret the above formula in $(\mathbb{N}, \leq)$, then it is true, and if we interpret it in $(\mathbb{R}, \leq)$, then it is false. This is so because $(\mathbb{N}, \leq)$ has the least element and $(\mathbb{R}, \leq)$ does not. To formalize this idea, we shall introduce some notation and a formal definition, following the presentation in our book (Džamonja 2020), where the reader may find more details on the topic.

Let us recall how formulas of first-order logic are constructed, concentrating simply on the language $\mathcal{L} = \{\in\}$ of set theory. The basic, *atomic*, formulas, are of the form "$x = y$" or '$x \in y$'. The short definition of the set of first-order formulas in this language is that this is the collection of well-formed formulas that we obtain

from the atomic formulas by applying negation $\neg$, the conjunction $\wedge$, and the existential quantifier $\exists$ any finite number of times and in any order desired.[4] Well-formed formulas are those strings of symbols that obey the grammar rules for the formation of formulas, for example, $(\exists x)\varphi(x)$ is well formed, but $(\exists x)$ is not. Sentences are those formulas in which all variables are bound by some quantifier. For example, $(\exists x)(\forall y)\ x \leq y$ is a sentence, but $(\exists x)\ x \leq y$ is not.

We need the following notation:

Notation 4.1 *We write* $(\exists x \in M)\varphi(x)$ *as a shorthand for* $(\exists x)(\varphi(x) \wedge x \in M)$, *and similarly, we use the shorthand* $(\forall x \in M)\varphi(x)$.

Definition 4.2 *Suppose that* $(M, \in)$ *is a model of the language* $\mathcal{L}$ *of set theory and* φ *a formula of* $\mathcal{L}$. *We define the* relativization φ^M *of* φ *to* M *by induction on the complexity of* φ:

- *If* φ *is* $x = y$ *or* $x \in y$, *then* $\varphi^M = \varphi$.
- $(\varphi \wedge \psi)^M = (\varphi^M \wedge \psi^M)$, *and similarly for* $\vee$ *and* $\neg$.
- *If* φ *is* $(\exists x)\psi(x)$, *then* φ^M *is* $(\exists x \in M)\psi^M(x)$, *and similarly for* $\forall$.

For example, the relativization of the formula $(\exists x)(x^2 = -1)$ to $\mathbb{C}$ is $(\exists x \in \mathbb{C})(x^2 = -1)$, which is true, while its relativization to $\mathbb{R}$ is $(\exists x \in \mathbb{R})(x^2 = -1)$, which is not true. In general, note that the definition of $\models$ is set up so that $M \models \varphi$ iff φ^M is true.

The example above shows that there can be a large difference between a formula and its relativization. If we imagine two models of the same theory, say $M \subseteq N$ such that M is a part of N, then we can consider the formulas relativized to M and N as two different points of view on the truth in M. For a given sentence φ, we may think of the *internal* point of view of M as being represented by φ^M and of the *external* point of view, known to N and represented by φ^N. The two statements φ^M and φ^N come from the same formula, but are not the same, and they do not necessarily have the same truth value.

Let us go back to the point that we started this discussion, the Axiom of Infinity. The formalization of this axiom in ZF (see the Appendix) basically posits the existence of a non-empty set that is closed under the successor operation, defined by $S(a) = a \cup \{ a \}$. This operation is not particularly interesting in the society, and it would be rather futile to take this as a definition of what infinite means in everyday life. That is, we are not interested in that external view of an infinite society. Rather, we are interested to model the society as it appears to an internal observer, an inhabitant of the planet. In this we take a line of thought that is presented in applied mathematics, where "infinite" stands for a finite object of such large finite

[4] Note that the other connectives $\vee$, $\Rightarrow$, and $\Leftrightarrow$, as well as the quantifier 8, can be derived from the ones given above.

size that for all practical purposes this size may be infinite. For example, in modeling waves in deep water, Jean-Marc Vanden-Broeck (2014) uses the expression "infinite depth" to describe that the depth being very large, the effect of the bottom of the sea can be neglected. The well-known set-theorist Đuro Kurepa, in one of his popular presentations of his subject, used to describe his favorite object of study: a Souslin tree (an object of size $\aleph_1$), as a tree of life of a microorganism which starts dividing and at regular intervals has to face a choice of which units will be allowed to continue (the limit levels of the tree), raising the question of any unit surviving to the end (Kurepa 1987). From the point of view of the microorganism, going to the next limit level might very likely represent a life span, or even a life span of a whole generation. This microorganism cannot imagine what comes after, all the relevant information is already encapsulated in the several steps ahead. We may interpret "infinity" as being closed under a very large number of repetitions of a given operation, like measuring 1 mm of the depth of water in (Vanden-Broeck 2014) or a division of a microorganism in Kurepa's example.

Let us then try to interpret infinity in the societal interpretation. We shall do this by the notion of *distance to the influence*. To start, observe that there are some small societies, such as the nuclear family of an individual, or him and his two best friends. In both of these societies, this individual has a very direct input and engagement. Then, there are larger and larger societies he might belong to, and we might observe that the direct influence of him as an individual decreases. We could in fact model the relation of an individual a to the society or to a society, by considering the membership graph generated by the individual: a belongs to a society A, and it directly influences the decisions in A. However, A belongs to the society $\mathcal{A}$, where a also has an influence, but only an indirect one, passing by A. The membership distance of a to A is 1, while the membership distance of a to $\mathcal{A}$ is 2 and so on. We may notice that the influence that the individual as a unit has in a society decreases with the membership distance. Moreover, although from the external point of view there is no truly infinite membership distance on the planet and from the internal point of view there are membership distances which are so large that for all practical purposes, they are infinite. The distance of a typical Greek citizen λ to the Eurogroup, which in 2015 is deciding if Greece will be forced to exit the Euro or will have to increase the austerity measures which would perhaps cost the citizen his livelihood, is infinite for all practical purposes.[5]

We posit that large societies and legal entities such as countries but even smaller entities such as large cities or regions are best modeled as infinite sets. In fact, we claim that this is the point of view taken in everyday practice. For example, in what is the most popular understanding of democracy at the moment, it consists of asking a large number of citizens their opinion on a multiple choice question (which usually

[5] Of course, this example is somewhat subjective, which is why we emphasise that like in any model where large finite numbers are treated as infinite, there is an element of fine-tuning the model to the purpose. Usually, the rule followed in applied mathematics is that a quantity that is being treated as infinite is indeed infinite in some reasonably taken limit. In our case that limit would be the limit taken over the growing number of inhabitants of the planet.

only has two choices) in elections and then deciding by simple majority. Obviously, this idea is much more fruitful in elections in which there is a large number of participants-elections in which only a small number of citizens vote are usually cancelled. This point that was expressed mathematically by Condorcet in his Jury Theorem (de Condorcet 1785) and it basically says that the probability that a jury will make a decision that best represents the majority increases as the size of the jury goes to infinity. Believing in democratic elections by simple majority in large societies is basically confirming that everyday practice treats these societies as infinite, as we shall do in the societal interpretation.

4.3 The Remaining Axioms

It remains to interpret the Axiom Schemas of Comprehension and of Replacement.

Comprehension states that if we have a set y and a property φ of its elements, then the collection of all members of y that satisfy φ is also a set. In the society, this would correspond to forming subsocieties that is isolating those members of a given society that have a certain property. This, of course, conforms with the everyday practice, where we might want to address the set of all citizens of Paris that live on the left side of the river Seine, or the set of all of Mr. X's children that are older than 13. Comprehension is actually a scheme, since it gives a separate axiom for every formula φ.

Similarly, Replacement is a scheme. It says that if we have a formula φ which acts as a function, in the sense that to every argument it assigns exactly one value, then we can collect all these values in one set. In everyday life, this would correspond to the practice of choosing something from every member of a society. When every adult Estonian creates an income tax return declaring the flat income tax of 21% of their income, the resulting set of all the returns collected is guaranteed to exist by the Axiom of Replacement. So is the set of all exact moments of birth of all inhabitants of the Earth, or the set of all first books read of the citizens who have ever read a book.

5 Plurality of Models of Set Theory

A careful reader might have already noticed a curios property of the societal interpretation. It is not unique. There are many societies! This is a phenomenon well studied in set theory. There are many models. In this part we shall describe how set theorists view the models or universes of set theory, with the plan to use the knowledge of these universes in Sect. 6 to make conclusions about the societal interpretation.

The present state of knowledge in set theory has fully acknowledged that there are some simply stated statements about sets which are not decided by ZF or ZFC. A canonical such statement is the Continuum Hypothesis (CH), which posits in ZFC that every infinite subset of the real line is either bijective with the set of natural numbers or with the set of real numbers, the two being known not to admit a

bijection. If there is a model of ZF at all, then there is one in which ZFC+CH holds (Gödel 1938) and there is another one in which ZFC+¬ CH holds (Paul Cohen 1963). We say that CH is *independent* of the axioms of set theory. In fact, there are many other such independent statements, and even if we were to axiomatize a truth value to CH, so accepting that it is true or false, there still would be independent statements, concrete examples of which are well known. One such statement is the Souslin Hypothesis which is independent of ZFC+CH and of ZFC+¬CH (see books (Kunen 1980; Shelah 1998), or (Džamonja 2020) for expositions).

The state of affairs with CH is the tip of the iceberg. Modern set theory abounds with ways to produce new models of set theory from the existing ones by using forcing or large cardinals or both. This leads to rather opposing views of the structure of the part of mathematics described by the axioms of set theory. These are, roughly, the universe view and the multiverse view. The societal interpretation has elements of both and in fact is the best described by an elegant combination of them in Jouko Väänänen's view from (Väänänen 2014). Let us describe the universe and the multiverse views.

The universe view holds that there exists the true Universe of set theory, axiomatized categorically by some axioms, leading to a unique model. These axioms, evidently, are still to be found, given the situation with CH and other independent statements. Gödel's Incompleteness theorems (Gödel 1931) tell us that without a radical solution such as changing the logic, there is no way out of this conundrum. There is a solution if we change the logic to the second order logic, which does not lend itself to the arguments used in the Incompleteness Theorems. Moreover, second-order ZFC set theory enjoys what is known as quasi-categoricity. Namely, Ernst Zermelo (1930) proved that the second-order version of ZFC axioms, known as ZFC^2, has one single type of models, namely the sets V_κ for a strongly inaccessible cardinal κ. There are unfortunately many disadvantages of second-order set logic for the practical purposes in mathematics, since exactly by being abundantly expressive, it fails to satisfy any properties that make mathematical logic useful in practice. For example, the completeness or compactness theorems or Downward-Skolem theorems fail for second-order logic. In fact, a theorem of Lindström (1969) characterizes the first-order logic as the maximal satisfying both the compactness theorem and the downward to $\aleph_0$ Löwenheim-Skolem theorem. So, if we want to have a useful, rather than merely expressive, set theory out of ZF(C), we better stuck with the classical first-order version, and then the universe view needs to be defended or defeated.

This leads to the multiverse view, which defends the idea there is no canonical Universe of set theory; rather, there are many models, and it is their plurality that gives the real information on the subject. Many authors defend this view, which is well known in set theory, but got known to a wider philosophical audience through the much-cited paper (Hamkins 2012) by Joel Hamkins. This beautifully written paper centered on forcing extensions is sometimes over-simplified in applications, which do not always account very carefully for the seeming contradiction that in order to take forcing extensions of a model in the multiverse, this model already needs to be in a larger universe. To understand this, one has to distinguish the

internal and the external views. This important point is underlined in Väänänen's view from (Väänänen 2014), where the *multiverse* consists of a multitude of universes. We are going to take this view, except that for us a model of set theory will not be called a universe but simply a model, and the multiverse of Hamkins and Väänänen will be called Universe. This terminology aligns us with Shelah's view from (Shelah 2003), where he explains a fine line that differentiates a pure Platonist from the one that believes in a universe but also in undecidable problems.

6 Universe and Models in the Societal Interpretation

For the application that we are interested in here, the societal interpretation, there is an obvious Universe, namely the society as a whole. However, like in any other context where set theory appears, there are also many smaller models of set theory, sometimes in contradiction with each other, sometimes defending the opposite axioms, but it is their multitude that gives the real information of the Universe. By applying the same logic that we have used in constructing the societal interpretation, we may interpret as models of set theory the large societal units, concretely the states-countries. These countries obey the basic laws of the society, but they differ greatly in their interpretation of further laws. Some are communist, some are liberalist, some are religious, some are western-democratic, and so on. Each defines its own model. We shall interpret the set-theoretic knowledge about the societal interpretation to the society to defend the idea that it is the multitude of societies that describes the truths in the society and that is only through their multitude that the society can advance.

The strength of set theory is to recognize the fallacy of modelling an absolute truth. A set theorist can look at the Universe and see two models, M and N such that a model M sees certain statements as true, while N sees them as false. However, both M and N being models of set theory, they agree on the basics and can live in collaboration in the Universe of models. By no means, the vision of M will negate the vision of N or vice versa; there is simply a plurality of visions. This is the main point we wish to retain regarding the societal interpretation. There are many societies in the society, and various societies may have different opinions on some statements, but the plurality of their opinions is what determines the society.

6.1 The Silent Majority

The view that it is only the plurality of voices that determines the society is in contradiction with the reality of the lives of most inhabitants of the planet, whose opinion is not heard. They pass under the various qualifications, from the "silent majority" to some more negative descriptions. The fault for this silence is often put on the specific society that they inhabit, the lack of something or other in their country, and the lack of freedom or education, for example. While these are undeniably aspects that the society suffers from, we would like to point out another

aspect that passes like a taboo under the radars of most but the most outspoken critics.

What we claim is that the silent majority exists because there is a particular idea that has permeated the political life of this planet and which silences and marginalizes everybody who is not adhering to it. Under the umbrella of making the political choices more just, we have started believing in the existence of a universal system which will make everybody's voice heard. However, we have not defined what this would mean exactly. Those who think that as soon as everybody has the right to vote we will have reached the ideal society, we have still to define what is actually understood by this ideal society and then defend its existence. However, in today's society, a particular idea, these days called Democracy, pretends to being an absolute truth. Everyday experience shows that the latter is clearly not the case. What we claim here is that there is a mathematical proof that it cannot be the case. This Universal Democracy, as pushed on us as it may be by certain big powers, is not the absolute truth simply because the absolute truth does not exist.

Even the simple belief that such an absolute truth exists has stopped the society from accepting the plurality of its constituents and advancing towards a more fruitful international cooperation.

6.2 Universal Democracy Is Undefined

Universal Democracy, which has been presented as the only true way, has not ever been correctly defined. In fact, universal democracy has a lot to do with the Continuum Hypothesis. We do not seem anywhere close to having a decision on the value of the Continuum Hypothesis, and we are not anywhere close to having a good definition of what the word "democracy" might actually mean and yet less close to what "universal" might mean, apart from the simplistic and unsatisfactory answer of everybody having the right to vote. The question of how the votes are distributed, influenced, and used, and moreover, what it is that we are voting for, is very variable.

In fact, there is a theorem which states that the question is much more difficult than just giving the votes to everybody, namely a theorem that illustrates the impossibility of having an ideal voting structure.

Theorem 6.1: Arrow's Impossibility Theorem (Arrow 1950) *In all cases where preferences are ranked, it is impossible to formulate a social ordering without violating one of the following conditions:*

- *Nondictatorship: The wishes of multiple voters should be taken into consideration.*
- *Pareto Efficiency: Unanimous individual preferences must be respected: If every voter prefers candidate A over candidate B, candidate A should win.*
- *Independence of Irrelevant Alternatives: If a choice is removed, then the others' order should not change: If candidate A ranks ahead of candidate B, candidate A*

should still be ahead of candidate B, even if a third candidate, candidate C, is removed from participation.
- *Unrestricted Domain: Voting must account for all individual preferences.*
- *Social Ordering: Each individual should be able to order the choices in any way and indicate ties.*

Arrow's Impossibility Theorem forms a basis of social choice theory. There are many theorems which indicate that simple voting systems are impossible or at least very difficult to implement; for an early example, one can see Condorcet's Theorem, (de Condorcet 1785). The experience including the two world wars and the Cold War and many other wars since has taught us that universal democracy is an ideal which might not be easy to reach. Some think that universal democracy is to have the rule of the market, others think that it is to have the pure rule of the majority, yet others find themselves embracing various compromises between the visions of democracy. Democracy seems to live on a spectrum. At the moment of writing, there are at least two big powers in the world who are located on the two opposite parts of that spectrum, both entirely convinced in their own model, and many others who remain unconvinced by any of the two. Therefore, due to a still rather vague and discorded understanding of what the word "democracy" actually means, searching for a universal meaning of this word might not even be an aim that one would want to reach, or at least not an aim that seems to be anywhere in the remit of the society of today.

Like CH, the Universal Democracy is a vision which does not admit discord. Like CH, for the moment we do not know how to obtain it and moreover we have proofs that we cannot do it. So, in our opinion, the universal democracy is an Absolutely Undecidable Proposition, in the language of (Väänänen 2014).

6.3 Back to Kant

The proponents of the Universal Democracy find that their vision is so clear that it does not even have to be defined. In their minds, it goes without saying that every great philosopher has started with the Universal Democracy as given. For example, Kant is reputed to have claimed that perpetual peace could be secured by universal democracy and international cooperation in (Kant 1795). However, closer inspection of (Kant 1795) shows that there is no discussion of universal democracy, not even of what today is a given, a vote for everybody. Instead, there is a lot of discussion of international cooperation and very concrete suggestions of how such a collaboration could be achieved. Our view is completely in line with Kant, in believing that international cooperation is a definable and achievable goal.

As for the democracy, we still can have a measure of understanding it, by observing how it behaves in various models. In our paper with Marco Panza, (Džamonja and Panza 2018), we have argued that concentrating on resolving or not resolving CH and hitting their head on the wall has made set theorists blind to what they actually can resolve. It has made them, for a long time, neglect the parts of the cardinal hierarchy where their methods are very powerful. In (Džamonja and Panza 2018), we have discussed the situation of singular cardinals as an example of where ZFC has much to

say, in spite of it not having anything to say on CH. It is the same with the universal democracy. Once we accept that for the moment we do not really have the means to give a just definition of this concept, then, rather than burning the planet in yet another war of ideological supremacy to show that one or another possible definition of the concept is correct, we should concentrate on what we *can* do.

International cooperation has received much less attention than the universal democracy, and when it did, it has often been overwhelmed by the latter. Many wars repeatedly came to the point of destroying the planet, run by ideologies. Bringing "democracy" or "liberating" was always somewhere in the background, and it almost always went wrong. This is because even when genuine, those messengers of the universal democracy have acted in a biased way that has been based on their belief that they have all the answers. It is painfully clear that this is not a way to proceed. Moreover, we feel that the moment is propitious to point out that no society is more worth than another, as the crisis we live in has brought up nationalist and selfish behavior on the parts of many governments who feel that the "natural supremacy" of their system gives them the right to make decisions and choices that badly influence livelihoods and even lives of those living in other systems. Yet, if we unite in an international effort to resolve the crisis, we might succeed.

To conclude, we suggest that the ideal of international cooperation is possible even without the fuzzy notion of universal democracy. International cooperation is exactly the lesson we can learn from believing that the society is a multiverse. Nobody has all the answers.

7 Conclusion

As much as science and mathematics can explain certain societal questions, societal questions do influence science. This point of view complements what is done in this chapter and is material for another article. However, we can openly admit that our views are not divorced from the society in which we live. Mathematicians and logicians are engaged in the society even when they believe not to be. Their research is in phase with that society. This is an honor and a responsibility, and it does not apply only to the ones who do an obviously applied research. We have advanced one way in which research in mathematical logic can be engaged in this process. To put it in context, many mathematical competences have been used in modeling possible consequences of economic and political decisions. Sometimes they obtained surprising results which show that ill-defined moves may have consequences which are completely opposed to what the superficial definition might indicate. The inherent error in the theory leads to disastrous consequences (see, for example, the book (Varoufakis et al. 2009) by Yanis Varoufakis, Joseph Halevi and Nicholas J. Theorcarakis who, among other competences, use game theory, to make the above conclusion in the concrete example of the economic reflexivity). Game theory is a staple of economic reflection and the inherent study of the society. In this chapter, we suggest a complementary competence coming from set theory to make the same conclusion, which we study on the concrete examples of universal democracy and international cooperation.

In simple words, the conclusion of this chapter is short. Unify in respect of each other or perish while searching for dominance, which is nothing but an elusive and ill defined concept.

8 Appendix: Axioms of ZF

The following is the standard axiomatization of the ZF system, as found, for example, in our book (Džamonja 2020). We express our axioms in first-order logic, where the variables are taken to range over sets. It is common to assume that the domain of discourse is non-empty, so we do not need Axiom 0 from (Kunen 1980). We shall use the following notation.

Notation 8.1

(1) *For any choice of* $y, x_1, \ldots, x_n$ *the notation*

$$(\exists! x)\ \varphi(x, y, x_1, \ldots, x_n)$$

is a replacement for

$$(\exists x)(\varphi(x, y, x_1, \ldots, x_n) \wedge (\forall z)(\varphi(z, y, x_1, \ldots, x_n) \Rightarrow z = x)).$$

(2) *When writing* $\varphi(x, y, x_1, \ldots, x_n)$*, we mean that the free variables of* φ *are among* $\{x, y, x_1, \ldots, x_n\}$*, but do not necessarily include them all.*
(3) *For any set* x*, the operation* $S(x)$ *is defined as* $x \cup \{x\}$.[6]

Axiom of Extensionality Two sets have exactly the same elements if and only if they are the same set or

$$\forall x \forall y\ \ (\forall z(z \in x \Leftrightarrow z \in y) \Rightarrow x = y).$$

Axiom of Pairing For every two sets x, y there is a set whose elements are exactly x, y or

$$\forall x \forall y \exists z(x \in z \wedge y \in z \wedge \forall w(w \in z \Rightarrow w = x \vee w = y)).$$

Union Set Axiom

$$(\forall A)(\exists Z)(\forall b)(b \in Z \Leftrightarrow (\exists a \in A)(b \in a)).$$

[6] One needs the axioms of Union and Pairing to verify that for any set x, the resulting set $S(x)$ is a set.

Replacement Axiom Scheme For each formula $\varphi(x, y, x_1, \ldots, x_n)$ we have

$$(\forall x_1, \ldots, x_n, I)((\forall x \in I)(\exists! y\, \varphi(x, y, x_1, \ldots, x_n) \Rightarrow (\exists A)(\forall z)(z \in A \Leftrightarrow (\exists x \in I)\varphi(x, z, x_1, \ldots, x_n))).$$

Comprehension Axiom Scheme For each formula $\varphi(x, y, x_1, \ldots, x_n)$ we have

$$(\forall x_1, \ldots, x_n, y)(\exists z)(\forall x)(x \in z \Leftrightarrow x \in y \wedge \varphi(x, y, x_1, \ldots, xn)).$$

Axiom of Infinity There exists an infinite set, which we formalise as.[7]

$$(\exists x)(\emptyset \in x \wedge (\forall y \in x)\, S(y) \in x).$$

Power Set Axiom For every x there is y whose elements are exactly those z which are a subset of x or

$$(\forall x)(\exists y)(\forall z)\ (z \subseteq x \Leftrightarrow z \in y).$$

Axiom of Foundation Any non-empty set is disjoint from at least one of its members or

$$\forall x(\neg(x = \emptyset) \Leftrightarrow \exists y(y \in x \wedge y \cap x = \emptyset)).$$

Abstract

This chapter expounds the view that mathematical implicit definitions, i.e., systems of axioms as well as abstraction principles, underpin some aspects of pluralism in mathematics. Firstly, it takes in account Horwich's "uniqueness problem" concerning implicit definitions and examines it particularly in the case of mathematical systems of axioms as well as abstraction principles. Meanings accrued to the *definienda* are not uniquely determined, and multiple systems of objects may satisfy the system of axioms or the abstraction principle in question. Multiplicity in ontology is one of the aspects of pluralism which characterize the ways in which we implicitly define mathematical terms. Systems of axioms as well as abstraction principles are taken to play a foundational role in building up mathematical theories. However, the chapter turns the focus of interest to a structural view of mathematical implicit definitions. A structural account of mathematical implicit definitions supports a view of modest pluralism.

A structuralist is not interested in foundations. In this view, systems of axioms as well as abstraction principles implicitly define structures. Shapiro's *ante rem structuralism* involves implicit definitions in procedures of *disclosure* of certain mathematical structures. Structures have an ontological status independent of their exemplary cases. In the penultimate section, the chapter takes into account the case of *satisfiable* abstraction principles. Such principles are taken to implicitly define certain structures independently of the "virtues" or "defects" that characterize the principles themselves. In particular, satisfiable abstraction principles that preclude each other, e.g., *Hume's Principle* and *Nuisance Principle*, describe alternative structures with different exemplary systems of objects.

1 Introduction

This chapter presents the way that implicitly defining mathematical terms implies some connections with certain versions of pluralism in mathematics. Systems of axioms as well as abstraction principles are regarded as implicit definitions of mathematical concepts. In Sect. 2, the chapter describes how implicit definitions work and discusses Horwich's "existence" and "uniqueness problem." Then it takes under consideration those problems particularly in case of mathematical implicit definitions. In regard to the "uniqueness problem," meanings which are accrued to the *definienda (: the mathematical terms)* are not uniquely determined, so multiple systems of objects may satisfy the postulates (Sect. 3). After a short outline of some obvious instances of pluralism in foundations, the chapter describes the way some philosophers (M. Balaguer, Ø. Linnebø) endorse *pluriverse* accounts in order to rescue realistic positions by reconciliating them with pluralism (Sect. 4). In the sequel, the chapter turns the focus of interest to a structural view of mathematical implicit definitions (Sect. 5). Structuralism is not interested in foundations, but it appeals to model theory. Shapiro's account of *ante rem structuralism* takes implicit definitions to be involved in procedures of disclosure and description of certain structures. According to it, structures have an ontological status independent of their exemplary cases, since they are one level of generality up. The structures provide the place for certain examples. A basic presupposition for a mathematical implicit definition (either a system of axioms or an abstraction principle) to work successfully is satisfiability. Besides, truth is dependent on structure. In particular, the chapter takes in account satisfiable abstraction principles which preclude each other, and it maintains that they describe alternative structures. This account presupposes a notion of truth in a structure (or according to the structure). The chapter describes a connection between the structural account of mathematical implicit definitions and some modest version of mathematical pluralism.

2 Implicit Definitions and Availability of Meanings

An explicit definition regularly substitutes the *definiendum* (e.g., a scientific term) by some already known expressions. In contrast, an implicit definition does not work in that way. It settles certain conditions under which scientific terms can acquire meanings. If L is a language and "t" a new term, then we take the extension of the initial language L+{t}. An implicit definition is a sentence (or a set of sentences) in the extension L+{t} that includes (include) the *definiendum* and accrues (accrue) meaning(s) to it. There may be more than one terms (*definienda*) which are assigned meanings on the basis of their mutual relations stated by a system of postulates. According to a commonly held view about implicit definitions, a sentence that contains the *definiendum* is *stipulated* as *true*. B. Hale and C. Wright (2001, p. 117) describe this (traditional) view as the following: "Implicit definition, taken as the complement of explicit, embraces a variety of subtypes. What all have in common is the idea that we may fix the meaning of an expression by imposing some form of *constraint* on the use of longer expressions -typically, whole sentences containing it. On one traditionally influential conception, this constraint is imposed by the free *stipulation of the truth* of a certain sentence, or range of sentences, embedding the *definiendum* and composed of otherwise previously understood vocabulary." On this account, we take a sentence (or a range of sentences) that contains (contain) the *definiendum* (*definienda*) and some already well understood expressions, and we stipulate that sentence (those sentences) *as true*. In similar words, "the meaning accrued to an expression *F* (or expressions *G, H* etc.) is such that the postulate(s) in which it (they) occur(s) is (are) true" (Psillos and Christopoulou 2009). Accordingly, the *definiendum* should have *the meaning it needs to have* for the sentence in question (the vehicle of the implicit definition) to express a truth. The "traditional" (as being characterized in the above passage) model of implicitly defining theoretical terms in science is discussed by philosophers like P. Horwich (1998) and the advocates of Neofregeanism Hale and Wright (2001). The view in question expects that appropriate meanings for the *definienda* should be *available* in order that the outcome of the stipulation in question is an a priori true proposition. A priori true propositions are independent of sensory experience. Rationalists standardly regard basic mathematical truths, e.g., axioms, as a priori. Implicit definitions are connected with the issue of non-inferential a priori knowledge. In the case of mathematics, discussion about implicit definitions includes mainly systems of axioms and Fregean abstraction principles as indicated below.

Horwich (1998, pp. 134–138) has exposed some serious difficulties the above account faces. When one assumes that the term "*f*" should have *the meaning it needs to have* for the stipulated sentence to express a true proposition, she presupposes that (a) *there is* a meaning such that if "*f*" has that meaning then the sentence which works as an implicit definition *is* true and (b) there is at most one such meaning. Those points made by Horwich have produced a discussion about the "existence problem" and the "uniqueness problem," respectively. Let us make use of the symbol "#*f*" to present an implicit definition of the expression "*f*." The sentence bearing the implicit definition says that *f* satisfies *such* and *such* conditions (: #). Hence, if an appropriate

meaning is available for "*f*," then the stipulation of the sentence "#*f*" gives a *true proposition*. However, there may be no such meaning for "*f*" or there may be more than one. Horwich argued that it is possible, for example, for a physical theory to be falsified (1998, pp. 136–138). In those cases, the sentences that bear implicit definitions are questioned. So Horwich preferred to say that a meaning is accrued to the *definiendum* "*f*" so that the sentence in question "#f" *is held to be true* or it is *accepted as true*. Furthermore, he defended an account according to which "a meaning is accrued to a term" means that a certain "pattern of use" is established for that term. In other words, Horwich maintained that a *use theoretic account of meaning* is more appropriate than an account requiring the preexistence and availability of meanings. A pattern of use of the theoretical term "*f*" is regularly established by the postulation of a sentence as true which contains this term.

Horwich's suggestions appear to concern implicit definitions of physical terms rather than implicit definitions of mathematical terms. His proposal aims to provide a solution for a difficulty that emerges in case of scientific terms like "phlogiston," "ether," etc. Such terms occurred in scientific theories which eventually were falsified and thereby abandoned. Those facts have raised certain questions concerning the truth of the postulate, i.e., the sentence "#*f*" which bears the implicit definition of a theoretical term like "f" = "phlogiston." This is because that term is denotationless as D. Lewis (1970, p. 429) remarks. In general, worries arise if we endorse certain semantics according to which if there is no object of reference of a term "f" then the sentence "f is *so* and *so*" cannot be true. Nevertheless, there are differences between implicit definitions of physical terms and implicit definitions of mathematical terms since mathematical propositions are not falsifiable for empirical reasons. Philosophical discussion concerning implicit definitions takes systems of axioms to be implicit definitions of mathematical terms (e.g., in case of arithmetic: the terms "*number*," "*zero*," "*successor*"). Meanings are obtained collectively on the basis of mutual relations they are taken to satisfy by means of a series of postulates. D. Hilbert elaborated the idea of treating systems of axioms as implicitly defining mathematical terms (Resnik 1974, pp. 390–391). An example of such implicit definition is the system of Euclidean axioms, let be "#(*f*, *g*, *h*)." That system is taken to define collectively the geometrical terms "*f*," "*g*," "*h*" (: "*point*," "*line*," "*plane*") by laying down certain mutual relations ("#") that points, lines, and planes should satisfy. Hilbert stated that his total system of axioms defined his primitive terms; however, his axioms did not uniquely determine any single concept. He thought that every theory is a schema of concepts together with their necessary relationships with each other (Resnik 1974, p. 390). So, the first question that arises is whether the *existence problem* pointed out by Horwich emerges also in the case of systems of mathematical axioms working as implicit definitions. The second question concerns Horwich's *uniqueness problem*.

Perhaps, the case of definitions of mathematical terms is clearer and more tractable than the case of physical terms. In mathematics, a "phlogiston case" cannot appear, and the stipulations in question do not bear empirically falsifiable propositions. Mathematical implicit definitions are expected to work successfully as the vehicles of true propositions in which the *definienda* appear. Horwich's *existence*

problem can be dealt with in the mathematical case if only certain conditions are met. A condition that should be required is *satisfiability*. If a system of axioms is satisfiable, then the system has models, and certain meanings can be accrued to the mathematical terms under definition.

There is a second kind of implicit definitions in mathematics, i.e., abstraction principles. An abstraction principle coming from the philosophical work of G. Frege (1884/1953) is formulated as a universally quantified biconditional which includes an identity statement on the left-hand side and an equivalence relation on the right-hand side. The general form is as the following:

$$(\forall a)(\forall b)\ [(\Sigma(a) = \Sigma(b)) \leftrightarrow (a \approx b)],$$

($\approx$: an equivalence relation between a, b, Σ : an operator that forms new singular terms, "Σ(a)": a singular term that is purported to refer to an object).

A famous example of Frege, presented in *Grundlagen* §63, §69, is a second-order quantified abstraction principle called "Hume's principle" which introduces the concept of natural number. The name is due to a comment of Frege (in *Grundlagen* §63) that his inspiration concerning 1-1 correspondence had come from D. Hume.

$$(\mathrm{HP})\ (\forall F)(\forall G)\ [(Nx : Fx = Nx : Gx) \leftrightarrow (F\ 1-1\ G)]$$

(HP) says that for every two concepts F and G, the number of Fs is identical to the number of Gs if and only if there is a 1-1 correspondence between the instances of F and the instances of G.

Abstraction principles have been characterized as implicit definitions in recent philosophical discussion (Hale and Wright 2001, pp. 117–150; MacBride 2003, pp. 103–163). They assign certain meanings to the singular terms appearing on the left-hand side, e.g., "Nx:Fx," "Nx:Gx" in the above principle. Abstraction principles settle the truth conditions of identity statements in which the *definienda* appear. For example, in the case of (HP), the *definienda* "the number of the concept F," "the number of the concept G" appear in the identity statement on the left-hand side ("the number of the concept F = the number of the concept G"). The truth conditions of that identity statement are settled by the abstraction principle so that if "F 1-1 G" is true, then "the number of the concept F = the number of the concept G" is true and vice versa. An abstraction principle is a kind of implicit definition with a *conditional* form as B. Hale and C. Wright (2001, pp. 142–145) note. Moreover, the advocates of Neofregeanism have suggested that a requirement that implicit definition should fulfill is to be conditional in form (Hale and Wright 2001, pp. 129–131).

In fact, abstraction principles are universally quantified formulas. (HP) introduces a pattern of *use* for the operator N so that anyone who understands that there is a 1-1 correlation between the instances of the concept F and the instances of the concept G acquires the ability to grasp a meaning for the expression "the number of the concept F" and ascertain that "the number of the concept F = the number of the concept G" is true. As F. Macbride (2003, p. 110) remarks, in the general case of an abstraction

principle, a pattern of *use* for the operator Σ is introduced so that anyone who is familiar with the equivalence relation ≈ becomes also familiar with identity statements of the form "Σ(a) = Σ(b)" and gets acquainted with the meanings of the terms of the form "Σ(a)." Hence, an abstraction principle like (HP) implicitly defines mathematical terms.

Since abstraction principles work as implicit definitions, the *existence* problem pointed out by Horwich arises here too. The suggestion made above in the case of systems of axioms will be stated here, that is, the least requirement is satisfiability (Christopoulou 2013). An abstraction principle which is satisfiable has models. Then certain meanings are accrued to the *definienda*. For example, Hume's principle presented above is satisfiable. By contrast, there is another abstraction principle, Frege's Basic Law V, which is not satisfiable so it fails.

$$(\text{Law V})\forall F\forall G\,[(\{x : Fx\} = \{x : Gx\}) \leftrightarrow \forall x(Fx \leftrightarrow Gx)]$$

Nevertheless, although in mathematics there is no empirical test, there is a consistency test of implicit definitions' operation.

3 The Uniqueness Problem in Case of Mathematical Implicit Definitions

With regard to the second problem, that is, the *uniqueness* problem stated by Horwich, both kinds of mathematical implicit definitions are affected. According to Horwich's "uniqueness problem," meanings assigned to implicitly defined terms are not uniquely determined. Systems of axioms as implicit definitions suffer from this disease, and it appears that Hilbert was aware of that semantic characteristic of axioms. His system of axioms did not uniquely determine any single geometrical term. The axioms determine many systems of concepts "each of which will satisfy the axioms so they fail to determine a unique model" (Resnik 1974, p. 393). Hence, Hilbert claimed that *whatever* entities satisfy the interconnections and mutual relations settled by the Euclidean axioms can stand for a *point*, a *line,* and a *plane*. *Whatever* entities satisfy the postulates (provided that the system is consistent) are such that the implicitly defined concepts can apply appropriately to them.

Similarly, in case of Peano arithmetic, it may be remarked that *whatever* entities satisfy the postulates in question can stand for the natural numbers. For example, the set theoretical surrogates of natural numbers according to Zermelo and Von Neumann:

$$\emptyset, \{\emptyset\}, \{\{\emptyset\}\}, \{\{\{\emptyset\}\}\}, \ldots$$

$$\emptyset, \{\emptyset\}, \{\emptyset, \{\emptyset\}\}, \{\emptyset, \{\emptyset\}, \{\emptyset, \{\emptyset\}\}\}, \ldots$$

Of course, those models are isomorphic; however, they provide different ontologies. In the first model, every set contains just the previous set in the hierarchy,

whereas in the second model, every set contains all the sets that precede it. The dilemma "which of the two sets {{Ø}} or {Ø, {Ø}} is the number 2 ?" was raised by P. Benacerraf (1965), and it is often called a "semantical" dilemma. A similar question concerns the reference of the singular term "2": which of the two sets is the object of reference of the term "2"?

M. Balaguer's (1998) answer to the issue was that arithmetical terms might possess multiple reference, for example, both {{Ø}} and {Ø, {Ø}} can be taken to be objects of reference of the term "2" in regard to different mathematical universes (: models). In fact, a *pluriverse* account can deal with such problems. Models are associated with domains (universes) of mathematical objects which bear certain properties and satisfy relations. Nevertheless, standard models of first-order arithmetic grasp the intended interpretation of the axioms of the theory. Since those models are isomorphic, one can think of just *one* model *up to isomorphism*. However, this is an extensional approach to the issue. From an intensional point of view, meanings of the defined terms may differ, as indicated in the above example concerning two different hierarchies of sets which stand for natural numbers. Moreover, first-order arithmetic allows for nonstandard models which have quite different characteristics. Intensional differences cannot been seen from an extensional point of view which punctuates uniqueness up to isomorphism. Nonetheless, mathematicians usually appeal to extensionality.

Does Horwich's *uniqueness* problem impinge on abstraction principles too, working as implicit definitions? The answer to that question is positive. For example, *Hume's principle* (HP) is the abstraction principle that implicitly defines natural numbers. The operator of it is N: "the number of the concept ( )" which applies to concepts and thereby forms singular terms of the form "Nx:Fx": "the number of the concept F.. Hence, every singular term of the form "Nx:Fx" arises from the completion of the functional expression "the number of the concept ( )" by an expression of a concept (e.g., "F").

An interesting remark which settles the issue of *plural meanings* here comes from H. Hodes (1984, pp. 134–135). Hodes claims that the operator N in question is not uniquely fixed. In general, it is a function expression (an *enumerator*) which correlates concepts to objects of reference of arithmetical singular terms. Particularly, it correlates the concept F to the object of reference of the singular term "Nx:Fx" ("the number of the concept F"). Hodes believes that the enumerator N may receive various semantic interpretations. Hodes's view is important since (HP) itself working as an implicit definition cannot fix the interpretation of the operator N as unique. Yet one of the interpretations N can receive implies the *standard enumerator* n. This works in accordance with the *intended* interpretation concerning familiar natural numbers. According to the *intended* interpretation, the following biconditional holds: "nx:Fx $=$ n $\leftrightarrow$ $\exists$nx Fx," that is, the number of the concept F is the number n if and only if there are exactly n objects which fall under the concept F. In detail, the *standard enumerator* correlates the concept "x$\neq$x" to the number *zero* (i.e., the object of reference of the singular term "nx:[x$\neq$x]"). It also correlates the concept "x=0" to the number *one* (i.e., the object of reference of the singular term "nx:[x=0]"). It correlates the concept "x=0 $\vee$ x=1" to the number *two* (i.e., the

object of reference of the singular term "nx: [x=0 ∨ x=1]") and so on. The *standard enumerator* produces an interpretation of numbers in accordance with *familiar* arithmetic. However, the very possibility of more than one interpretation of the operator N shows that multiple meanings can be accrued to the terms of the form "Nx:Fx," i.e., the *definienda* of (HP). Nevertheless, the standard enumerator is quite privileged since it draws the intended meanings of the arithmetical terms "Nx:Fx."

In fact, Horwich's *uniqueness problem* applies to both kinds of mathematical implicit definition. Many alternative kinds of mathematical "things" satisfy systems of axioms. The case of abstraction principles is similar. This situation shows that some signs of pluralism come up in the procedure of implicitly defining mathematical terms. Implicit definitions appear to be associated to pluralism in mathematical ontology.

4 Pluralism in Foundations

Although systems of axioms working as implicit definitions of mathematical concepts play a foundational role, it appears that they do not safeguard uniqueness of foundations beyond isomorphism. This chapter will present some clear cases of the position called "pluralism" in foundations. According to M. Friend (2014, p. 24), "the pluralist holds that there is insufficient evidence to think that there is a unique foundation for mathematics." Further, she argues, for example, that "the word 'set' is not fully determined by ZF" (2014, p. 22) and that the implicit definition of "set" is different in alternative theories. She also sets out alternative theories like Aczel's non well-founded set theory, Vopênka's set theory, and Hrbacek's set theory. Those theories include different axioms and describe different characteristics of the notion of set; however, they use ZF as a starting point. Nevertheless, ZF set theory is "a standard of measure" for mathematicians, while various mathematical theories are reduced to it. However, it does not constitute a unique foundation for mathematics. A position of a pluralist is that there is no guarantee that ZF is "an absolute guide" to mathematical ontology or epistemology, yet it can be taken to be "a point of reference" for mathematical practice (Friend 2014, p. 23).

In the case of arithmetic, one could mention alternative theories, for example, Robinson arithmetic which is Peano arithmetic without the axiomatic schema of mathematical induction. Instead, it includes an axiom which holds that every (natural) number has a successor (Boolos and Jeffrey 1980). Another alternative theory is Presburger arithmetic that proves every proposition which concerns only the addition of natural numbers. Yet although there are alternative arithmetics, Peano arithmetic is still taken to be the point of reference for mathematicians.

Besides, in case of analysis, aside from standard Analysis, there is Robinson's nonstandard analysis which endorses infinitesimals. Nonstandard analysis is an alternative theory with a different ontology of numbers. Apart from real numbers, it includes infinitesimals as well as infinitely great numbers. The axiom of Archimedes-Eudoxos does not hold in that theory.

To return to mathematical implicit definitions, systems of axioms are supposed to play a foundational role in mathematical theories. Whole theories are based on them. However, the advocates of Neofregeanism Hale and Wright have defended the view that at least in case of Peano arithmetic, an abstraction principle has a prior epistemological status than the axioms themselves. In fact, *Hume's principle* + second-order logic is a consistent system that provides foundation for arithmetic since Peano axioms are derived by that system. Wright (1983, pp. 158–169) proved that Peano axioms are deduced by *Hume's principle* in second-order logic. So Hume's principle plays the role of foundation of arithmetic. The question whether other abstraction principles can play similar roles for other mathematical theories has not been answered yet, and such expectations do not seem to have been fulfilled.

In most cases, mathematical axioms are regularly supposed to have a special epistemological priority and formulate basic mathematical beliefs which are regarded as self-evident and not reducible to other primitive beliefs. This is due to a kind of intrinsic persuasiveness they hold themselves. Further, certain inferential correlations (deductive relations) connect axioms with theorems. Foundationalists insist on the supposed evidence of axioms, and some of them appeal to mathematical intuition. Gödel's platonistic inclinations are widespread. He regarded sets as abstract entities, and he thought that the elementary axioms of set theory are "forced upon human mind" (Benacerraf and Putnam 1983, p. 484). Much discussion has taken place either in favor or against the notion of intuition. For example, J. Brown (1990) and J. Katz (1995) defended the case of intuition, whereas Benacerraf (1973) and Ch. Chihara (1982) criticized it. Recently, J. Bengson (2015) made an attempt to clarify the function of intuition as a representational skill about which an adequate epistemic account was never given. A presentational mental state not only represents world, but moreover, it brings and makes the objects and states of the world present to human mind. Furthermore, he holds that mental states that originate from mathematical intuition, e.g., the intuitive grasp of the case that every natural number has a successor, *make* this fact *present* to our mind. So, intuition is a process of epistemic access to basic mathematical beliefs. Axiomatization of set theory makes those beliefs clear and strict, whereas it corrects any various ill-formed primitive principles. Besides, in concern to the *intuitive* approach to axioms, M. Potter (2004, p. 36) asserts that it invites us to clarify our conceptions of sets to such an extent as to determine the axioms those conceptions satisfy. The notion of mathematical intuition is always a tempting issue in philosophy of mathematics as far as it concerns our access to *basic* mathematical beliefs like axiomatic principles. Further, if one works inside a certain mathematical theory, she gets familiar with the intellectual environment of this theory, so her familiarity might count as intuition too.

However, another interesting point is that there are axioms without self-obviousness for the acceptance of which other criteria are necessary. Decisions concerning the choice of those axioms which lack self-evidence are not based on any intuition skill. Instead, we have to consider their fruitfulness, the way they shed light on certain areas of the theory, etc. The choice of such axioms in mathematical practice is usually based on certain pragmatic criteria according to a set of research targets and theoretical perspectives. So, Potter (2004, p. 35) has taken into account an alternative

strategy of justification of axioms which he calls "regressive" that is not foundational. The *regressive strategy* regards the axiomatic base as successful in case it can produce theorems whose results are accepted on other mathematical grounds. The justification of axioms is not based on any intrinsic evidence or intuitive force, but it comes from their participation in a consistent theoretical context. The "regressive" approach described by Potter is pragmatic in principle and connected to a kind of justificatory coherentism.

Further, a more interesting fact is that different systems of axioms prove to support alternative theories. Moreover, extensions of certain theories imply different directions of building up alternative ontologies. In cases of controversial axioms like the axiom of choice, a set theorist has two paths to follow: either to (a) accept the axiom of choice and make an extension of ZF theory by adding this axiom (taking ZFC theory) or (b) reject the axiom of choice and make an extension of ZF theory adding the denial of the axiom (ZF + ¬AC). Both theories are consistent if ZF is consistent. The decision in favor of one of the two options or the other is made on more or less pragmatic grounds. Many mathematicians accepted the axiom of choice on the basis of its fruitfulness inside set theory and its interconnections with other mathematical areas (Maddy 1997, pp. 54–55). However, a difficulty arises particularly for the proponents of set theoretical realism since they should be able to offer an account of *which* of the two universes is *the real* one. Yet they have no such option since both "universes" are acceptable on different grounds, and none is a clear winner. Just one solution is available for the mathematical realist: to accept a kind of pluralistic account, endorsing alternative mathematical universes.

A similar case is that of CH (the *continuum hypothesis*), the hypothesis that $2^{\aleph_0} = \aleph_1$ (the first infinite cardinal which follows $\aleph_0$ is the cardinal number of the continuum). CH is undecidable. Undecidable propositions are not provable, while their opposites are not provable either. In this case, one can extend ZFC toward two alternative directions: either to (a) add CH to ZFC and form ZFC + CH or (b) add the denial of CH to ZFC and form ZFC + ¬ CH. Both extensions of the original theory ZFC are consistent if ZFC is consistent. Then one might make up one's mind and make use of that theory which is more fruitful than the other. Yet, again, realists are not able to answer the dilemma of *which* of the two universes described by the two alternative theories is *the* real one. Gödel believed that an independent mathematical reality exists, and the question about the truth or falsity of the continuum hypothesis should have a definite answer. Further, he thought that the axiomatic system of Zermelo-Fraenkel set theory perhaps does not provide an adequate picture of the set theoretical realm. Nonetheless, CH remains today an *undecidable proposition* in the context of ZFC theory. The different extensions of ZFC (plus CH or plus ¬CH) are incompatible with each other. Again, Friend maintains: "The pluralist is exactly someone who will at least in principle entertain the possibility that there are several extensions of ZF. The extensions are not equivalent to each other, and some pairs of extensions preclude each other – because if added together they would make set theory trivial" (2014, p. 21).

Since one might choose ZFC+CH and another might choose ZFC+¬CH for various reasons, a pluralistic account can be endorsed here. In a first view, it gives

the impression that it works against mathematical realism. However, this appears to be just an incorrect impression since one can go on by accepting a kind of mathematical realism that endorses more than one mathematical universe. For example, M. Balaguer (1998), the proponent of *full-blooded platonism*, has defended the existence of a plenitudinous mathematical reality. Besides, Balaguer (2017) argues that platonism and mathematical pluralism are perfectly compatible with one another. In that paper, he defends the view that mathematical reality is plenitudinous; hence, he calls his version of platonism "plenitudinous platonism." It seems that a contemporary mathematical realist should accept more than one set theoretical universe with different ontologies of sets in order to retain her realistic inclinations. Additionally, Linnebø (2017, p. 177) notes: "Today, set-theoretic pluralism often takes the form of a "pluriverse" view, which holds that there are many universes of sets, each compatible with our full conception of sets. CH is true in some of these universes and false in others. On this view, CH has a truth-value only relative to some particular universe, ..." The trick is to be a Platonist one level of generality up. They are Platonist about ontologies of "all" legitimate theories. The quantifier is over ontologies of theories, not ontologies within a theory. It's a higher-order quantifier.

In regard to *undecidability* (like the case of CH), D. Anapolitanos (2016, p. 208) writes: "There are models of the theory that make the sentence in question (i.e. CH) true and models that make it false. . .The truth of mathematical sentences *depends* on the specific universe of a certain model of the theory. The true sentence *in regard to* a model describes the characteristics of the relative universe and the characteristics of all universes of the models of the theory in which the sentence is true." In the above passages, the notion of truth is taken to be *relative* to certain semantical interpretations of the language of the theory in question. A standard *semantical interpretation* includes a universe (domain) of objects, whereas certain symbols (constants) are purported to refer to such objects, and others (predicate symbols) denote properties or relations ascribed to those objects. Models can exactly be regarded as those semantical interpretations which make the axioms of a theory true. So, this account takes truth to be *relative* to models. Such an account allows for multiple systems of mathematical objects. Of course, undecidable sentences allow for alternative extensions of the initial theory.

Again, Linnebø ascertains that also in case of geometry, we come across a pluralistic situation, since "it makes no sense to ask, without further qualification, whether the parallel postulate is true or false: it is true of some spaces and false of others" (2017, p. 176). For example, Euclidean geometry and Hyperbolic geometry make a pair of mutually contradictory mathematical systems. They differ over the parallel postulate so a number of true propositions of Euclidean geometry are not accepted in the context of Hyperbolic geometry. In similar words, Euclidean geometry and non-Euclidean geometries describe different possible spaces, and they are each acceptable.

In conclusion, it appears that there are alternative consistent systems of axioms in each one of the most well-known mathematical areas. Those systems of axioms support alternative mathematical theories. Besides, the existence of independent mathematical sentences like CH shows that we possess different options of building

up different extensions of certain theories. The very notion of truth appears to be *relative* to certain semantical universes associated with the axiomatic systems. Besides, an abstraction principle, that is, (HP) plays a foundational role in arithmetic; however, it allows for multiple systems of arithmetical objects. Pluralism in foundations amounts to accepting this.

5 Structuralism, Implicit Definitions, and Pluralism

Both kinds of mathematical implicit definitions (systems of axioms and abstraction principles) can also be considered in the light of some version of structuralism. According to Friend, "Structuralism consists in the view that within the discipline of mathematics, we find a number of theories. Theories can be thought of as structures or as a set of formulas closed under some operations. . .. Objects are only ever objects in a structure. The truth of a theory can only be judged from a meta-perspective: a meta-theory or meta-structure. The standard meta-perspective is provided by model theory. . ." (2014, p. 52). Structuralism is not purported to be foundational. In particular, Friend holds that S. Shapiro's structuralism expresses a kind of anti-foundationalism "which is inspiring for the pluralist" (2014, p. 51). Shapiro (2000) examines how implicit definitions work in the context of *ante rem* structuralism. A successful implicit definition is taken to characterize a structure, that is, a system of mutual relations among certain elements.

A structuralist focuses her attention especially on the relations, not the objects. If certain objects fill in the positions of a structure, then the system of objects in question satisfies the structure and constitutes an exemplary case of it. For example, the axioms of Peano arithmetic determine a structure. The system of natural numbers is regarded as an exemplary case of the structure in question. What concerns a structuralist is not the numbers themselves as objects but their positions in the structure and the mutual relations among them. Such relations might be, for example, the relation between a natural number and its successor, the relation of a as greater than b, the relation between a and b in case a divides b (without remainder), etc. S. Hedman notes: "Structures naturally arise in many branches of mathematics. For example, a vector space is a structure. The groups, rings, and fields of abstract algebra also provide examples of structures. . .. The real numbers provide examples of structures that should be familiar to all readers" (Hedman 2004, p. 58).

Shapiro is an advocate of "ante rem structuralism" according to which structures have an existence independent of all their exemplary cases. Structures are ontologically prior to the systems of objects which satisfy them. Appropriate singular terms are purported to refer to positions in a structure. As Friend (2014, p. 69) remarks, Shapiro develops his structuralism in accordance with model theory.

Besides, Shapiro holds that an implicit definition might define a structure even though no exemplary case of it is known. The Euclidean system of axioms defines a structure (the Euclidean structure of space). As noted earlier, Hilbert believed that *whatever* entities satisfy the relations in question can stand for a *point*, a *line*, and a

plane. Though not a structuralist, Hilbert focused his attention on the system of relations laid down by the axioms. He did not focus on the objects playing the role of a *point*, a *line*, and a *plane*. Additionally, he showed that there is a model for the system of axioms in question.

Shapiro (2000) states two conditions for successful implicit definitions. The first requires that at least one structure is characterized by an implicit definition. According to the second condition, at most, one structure is described by the implicit definition up to isomorphism. What the second condition means is that all systems of objects that satisfy the implicit definition in question share a common structure. Further, Shapiro has chosen second-order logic as the underlying logic of his structures, so he guarantees a unique characterization of those structures up to isomorphism. For example, in the case of arithmetic, the logical background of second-order logic makes possible avoiding all structures which are related to the Löwenheim-Skolem theorems. Unique characterization could not be achieved if the logical background were that of first-order logic. Nonstandard models would appear which satisfy alternative structures. As Shapiro (2000, p. 285) states, in first-order logic, the Löwenheim-Skolem theorems are developed so "no theory that is true of an infinite system characterizes a unique structure."

Another crucial point in Shapiro's account is that an implicit definition needs to be consistent with the rest of the theory in order that it determines a structure. Particularly, Shapiro makes use of the notion of *satisfiability* instead of the notion of (deductive) consistency. Yet, he explains that his choice is quite appropriate: "In the second order logic that I favour there are sentences that are deductively consistent but have no models" (2000, p. 287). As stated above, second-order logic has different characteristics from first-order logic. For example, in second-order logic, the downward Löwenheim-Skolem theorem is not true. Besides, second-order logic is not complete; hence, it does not guarantee that every universally valid second-order formula, under standard semantics, is provable (Hedman 2004, p. 391). Further, what Shapiro stresses in the above passage is that in second-order logic, deductive consistency and satisfiability are not equivalent notions. So, he has chosen satisfiability which implies consistency. In this setting, both kinds of mathematical implicit definitions should be satisfiable: a satisfiable system of axioms defines a structure, and similarly, a satisfiable abstraction principle defines a structure.

The abstraction principle (HP) is satisfiable. In the context of ante rem structuralism, that principle is regarded as an implicit definition that characterizes an arithmetical structure:

$$(\forall F)(\forall G)\,[(Nx : Fx = Nx : Gx) \leftrightarrow (F\ 1-1\ G)]$$

Of course, this would be a structural view of (HP), not the Fregean view (which is foundational). Frege's arithmetic might be regarded just as an exemplary case of that structure. In fact, more than one nonequivalent exemplary case of that structure is possible (see Hodes' considerations in Sect. 3).

An interesting characteristic of implicit definitions is called "non-eliminability" of the *definienda* (Shapiro and Weir 1999). If L is the original language and S is a set of new terms (the *definienda*), then the implicit definition is formulated in the extension of the original language L, i.e., L+S. The expression "non-elimination of the *definienda*" means that there is at least one formula Φ lying in the extension of the original language for which there is no formula Φ′ in the original language L, so that Φ can be translated in terms of Φ′. That is, the *definienda* cannot be translated in terms of the original vocabulary. Moreover, a consequence of that characteristic is no *unique extendability*, i.e., if M is a model of the original language, then there is more than one way to extend that model to a model of the extension of the original language. Hence, this account can explain why the meanings which are accrued to the terms introduced by an implicit definition are not uniquely determined up to isomorphism. This situation holds equally for systems of axioms as well as abstraction principles functioning as implicit definitions.

In general, multiple *meanings* are accrued to the *definienda* of an implicit definition (as Horwich's *uniqueness* problem indicates). Yet, the issue is now addressed by means of a structural perspective: implicit definitions describe structures with *various* exemplary systems of objects. As Hilbert pointed out, *whatever* objects satisfy the supposed system of mutual relations might be regarded as objects falling under the defined notions.

Apart from the pluralistic aspects of structuralism which were just discussed, there are more options to take into account. In fact, different satisfiable abstraction principles characterize alternative structures. For example, the *Nuisance principle* (NP) describes a structure quite different from that of *Hume's principle* (HP). The Nuisance principle is formulated as the following:

$$(\mathrm{NP})\ (\forall F)(\forall G)\ [\upsilon(F) = \upsilon(G) \leftrightarrow F \approx G]$$

$F \approx G$: *a finite number of objects fall under F but not G or under G but not F*

The *Nuisance principle* has only finite models. It is true only in finite domains.

The two abstraction principles (HP) and (NP) are incompatible, that is, they preclude one another. The exemplary cases of the former exclude the exemplary cases of the latter. However, both can be accepted from a pluralistic point of view.

The advocates of *Neofregeanism* Hale and Wright maintain that the Nuisance principle (NP) is a *nonconservative* abstraction principle so it has a serious defect. A principle is *conservative* in case, if when it is added to a theory T, it does not provide new consequences concerning the preexisting ontology of the initial theory T. In fact, (NP) is nonconservative, since it imposes restrictions on the size of the extensions of the concepts F, G, etc. Besides it is usually taken to be a threat for (HP) since the two abstraction principles cannot be together true. Yet, the fact that (NP) has a serious defect entitles the *Neofregeans* to dismiss it.

However, if one is not interested in the motivations of the *Neofregeans*' account (which works as a foundational program), one is not obliged to endorse certain virtues or defects *Neofregeanism* often ascribes to abstraction principles in order to vindicate or dismiss them. Moreover, a pluralist does not need to dismiss any

nonconservative abstraction principle. After all, the above abstraction principles are both satisfiable and describe alternative structures with different kinds of exemplary cases. None of them might be a threat for the truth of the other, because the truth of every such principle should be regarded as relative just to the structure it defines and its own models. Nonetheless, the situation concerning the abstraction principles (HP) and (NP) gives rise to a pluralistic option. All *satisfiable* abstraction principles can be accepted. They define various structures with possible exemplary systems of objects. Of course, unsatisfiable abstraction principles should be rejected as unsuccessful (unless one is interested in exploring an inconsistent situation). This is the case of Frege's Basic Law V which was presented earlier in Sect. 2 and defines the extensions of concepts:

$$\forall F \forall G\, [(\{x : Fx\} = \{x : Gx\}) \leftrightarrow \forall x(Fx \leftrightarrow Gx)].$$

Shapiro's structuralism is not interested in providing mathematical foundations; it appeals just to models. As Friend (2014, p. 156) puts it, model theory is used in order to compare structures. Accordingly, implicit definitions do not play a foundational role in the context of structuralism, but they are supposed to define structures. Theories are about structures, and truth is not independent of structure. Particularly, truth of the bearers of implicit definitions is relative only to the models of the structures so defined. For example, a satisfiable abstraction principle describes a structure, and it is regarded as *true* in respect to the structure. So, there is no purely *mathematical* reason to favor one structure. There are, of course, other reasons: logicality, aesthetics, simplicity, and fruitfulness. In fact, no satisfiable implicit definition (axiomatic system or abstraction principle) describing a structure is favored over other satisfiable implicit definitions on purely mathematical grounds. Especially, in Shapiro's view, model theory individuates mathematical structures. Isomorphic mathematical structures count as *one* structure, i.e., structures are individuated up to isomorphism.

6 Conclusion

Mathematical systems of axioms as well as abstraction principles work as implicit definitions of mathematical terms. If they are satisfiable, then certain meanings are accrued to the *definienda* (: mathematical singular terms or predicates). However, Horwich's *uniqueness* problem indicates that multiple systems of meanings are assigned to the *definienda*. This situation reminds us of Hilbert's remark that *whatever* objects satisfy the Euclidean system of axioms can stand for a *point*, a *line,* and a *plane*. Nonetheless, in Sect. 3, a similar situation was presented for abstraction principles working as implicit definitions. Horwich's *uniqueness* problem affects (HP) too. Except for pluralism in mathematical ontology, there are other aspects of pluralism which are also detected in regard to the issue of implicit definitions. Systems of axioms and abstraction principles are regularly taken to play a foundational role. Systems of axioms support mathematical theories, and, as

Sect. 4 reminds us, the abstraction principle (HP) has been taken to play a foundational role for arithmetic in terms of Wright (1983). However, in various mathematical areas, there are alternative mathematical theories and alternative systems of axioms which support them. Moreover, the case of independent axioms (like the axiom of choice in regard to ZF set theory) shows alternative directions of development of mathematical theories. The case of undecidable sentences indicates similar situations. So *pluralism* in foundations appears to characterize mathematical implicit definitions, particularly systems of axioms as foundations of certain theories. From a different point of view, structuralism offers an interesting account of both kinds of mathematical implicit definitions (systems of axioms and abstraction principles). That account is not foundational. Systems of axioms and abstraction principles are regarded as implicitly defining mathematical structures. In the case of ante rem structuralism, they are taken to *disclose* structures. Satisfiability is a necessary condition for implicit definitions to successfully define structures. From a structuralist view, both kinds of mathematical implicit definitions describe structures with multiple exemplary systems of objects. Besides, Sect. 5 of this chapter deals with satisfiable abstraction principles which preclude each other. Those principles describe alternative structures with different exemplary systems of objects. This is again a situation supporting pluralism to the extent that incompatible but satisfiable abstraction principles describe alternative structures which are equally accepted.

In the context of a structural view of mathematical implicit definitions, it appears that a *modest* form of *pluralism* is brought out. This is a kind of pluralism with some limitations or "a very conservative form of pluralism" as Friend (2014, p. 69) notes. Limitations come from the fact that structuralism appeals to models and model theory. It is also wedded to set theory and classical logic so it gives account of those mathematics which are recognized by model theory. By contrast, a version of *maximal mathematical pluralism* might take in account also cases of intensional logics, paraconsistency, mathematics which are in the stage of development, etc. However, in this chapter, mathematical implicit definitions were discussed in connection with a modest version of pluralism that has been detected both in case (a) implicit definitions are taken to have a *foundational* role and (b) they are considered in the context of *ante rem structuralism*.

Abstract

In mathematics, the deductive method reigns. Without proof, a claim remains unsolved, a mere conjecture, not something that can be simply assumed; when a proof is found, the problem is solved, it turns into a "result," something that can be relied on. So mathematicians think. But is there more to mathematical justification than proof?

The answer is an emphatic yes, as I explain in this chapter. I argue that non-deductive justification is in fact pervasive in mathematics, and that it is in good epistemic standing.

Keywords

Proof · Justification · Mathematical knowledge · Mathematical justification · Non-deductive evidence · Empiricism · Non-deductive knowledge · Deductive knowledge · Induction · Foundationalism · Euclidean program

I am grateful to Michèle Friend for the invitation to contribute to this handbook and to Jim Franklin for helpful comments on a previous draft.

1 Introduction

The focus of this survey article is on non-deductive justification in mathematics, by which I mean any kind of justification for p other than a proof of p. (Unless otherwise stated, p will be a mathematical proposition.) I shall argue that this sort of justification is pervasive, and that it is in good epistemic standing. My chapter is complementary to that by James Franklin in the present handbook (Franklin 2021a). His is more focused on the practice side of things, mine more on the philosophical side. The two articles may profitably be read side by side. (It is worth noting, however, that the present chapter is not committed to an objective Bayesian analysis in the way Franklin's is. For all I say here, justificatory relationships between mathematical beliefs or truths may or may not be cashed out in Bayesian terms, objective or otherwise.)

We begin in Sect. 2 with a case study: the non-deductive evidence behind Goldbach's conjecture (GC). A famous conjecture in number theory, it was first put forward by Christian Goldbach in a 1742 letter to Euler. Although GC has much non-deductive evidence behind it, it remains unsolved. Section 3 briefly looks at skepticism about the value of enumerative inductive evidence in arithmetic. What is the justificatory value of, say, verifying the first trillion instances of GC, all of which are in some sense small? Section 4 ties the rise of non-deductive methods to the decline of the Euclidean ideal in mathematical epistemology. Section 5 considers how one might justify the consistency of mathematics as a whole. The natural, and perhaps only, way to do so is by means of non-deductive evidence. We conclude in Sect. 6 by examining a radical suggestion: perhaps non-deductive evidence is enough for *knowledge* of a mathematical proposition. We expound one of the arguments for this suggestion.

Right at the outset, we need to be clear that most mathematical justification, even knowledge, is testimonial, because it is acquired from other sources (people, books, journals, websites, social media, etc.). For example, I am justified in believing that Fermat's Last theorem is true because I have heard of its proof from various reliable sources. (Or at least from a preponderance of reliable sources. Fermat's Last Theorem states that if $a^n + b^n = c^n$, where a, b, c and n are all positive integers, then $n = 1$ or 2.) Testimonial justification is non-deductive because it is not based on a mathematical proof of your source's reliability. Any evidence that Andrew Wiles is a reliable mathematician is partly but not strictly mathematical: it compares his mathematical pronouncements (an empirical matter) to the mathematical facts. And evidence that the media and personal channels through which I have heard of Wiles's proof of Fermat Last Theorem's are accurate is not strictly mathematical either. (Calling it 'Wiles's proof' is a simplification; as is well-known, Wiles's original 1993 proof of Fermat's Last Theorem contained a flaw. The 1995 patch-up is owed to Wiles and Richard Taylor.) So most justification of a mathematical proposition p is non-deductive, even if the justification chain ends in a proof. That much is agreed on all hands. A more contested question concerns the extent and significance of justification that does *not* end in a proof because there is currently no proof to be had. It is this sort of justification that is our topic here.

2 A Case Study: Goldbach's Conjecture

Franklin (2021a) illustrates the notion of non-deductive evidence in mathematics with several examples. Section 5 of his article notably presents some of the evidence for the presently unsolved Riemann hypothesis. The present section does the same for GC. (The material here draws significantly on p. 779 of my (2015). My survey of the non-deductive evidence for GC is far from exhaustive.)

Before we get to brass tacks, two notes on terminology. I prefer to talk about "the justification of mathematical statements" rather than "mathematical justification" as it might be insisted that properly mathematical justification must be deductive. As a matter of definition, one might insist, any justification for p that does not take the form of a proof of p is not *mathematical*, sensu stricto. I am not sure that's right; but in any case, it's a terminological fight not worth having, why is why I called my 2015 article on the subject "Knowledge of Mathematics Without Proof" rather than "Mathematical Knowledge Without Proof."

The second point is that the word "induction" is multiply ambiguous. It has a procedural or ceremonial meaning (e.g., "induction into the Rock and Roll Hall of Fame") and a physical meaning ("electromagnetic induction"). Even setting these aside, it can mean (at least) three more things. (1) The first is an inference from particular instances to a generalization. An induction is something of the form "A_1 is F, …, A_n is F; therefore all As are F." (Or even, in some cases, an inference to this conclusion from infinitely many instances.) I shall reserve the term *enumerative induction* for this. (2) The second is a broader sense: any non-deductive inference or any form of non-deductive evidence. Bertrand Russell consistently used the word in this way, and I followed him in my (2015). But upon reflection, confusion is avoided and clarity promoted if we simply write "non-deductive" for "inductive" in this sense. That will be my policy here. (This is the sense of induction that is relevant to Hume's problem of induction, i.e., the problem of justifying an inference from observed to unobserved cases. Some recent mathematical results are highly pertinent to this problem, as discussed in my (2011) and (2008).) (3) In its third sense, it forms part of the expression "proof by mathematical induction," i.e., a proof that all numbers have P by showing that 0 has P and that if n has P then $n + 1$ also does. I shall not be concerned with induction in this sense.

On to GC, then, which states that every even number greater than 2 is the sum of two primes. Number theorists are highly confident of GC's truth on the basis of non-deductive evidence. What form does this evidence take?

First, there is enumeratively inductive evidence for GC. Specifically, GC has been checked for every even number up to about 4×10^{18} and double-checked up to a number not much smaller. (The latest results can be found on Tomás Oliveira e Silva's website http://www.ieeta.pt/~tos/.)

Second, various slightly weaker claims than GC have been proved. An example is the ternary Goldbach conjecture, that every odd number ≥ 7 is the sum of three primes. The Soviet mathematician Ivan Vinogradov proved in the 1930s that every sufficiently large odd number is the sum of three primes; in 2013, Harald Helfgott proved the ternary conjecture outright. Two more results in the same vein are:

(a) every sufficiently large number is the sum of a prime and either a prime or the product of two primes and (b) every even number is the sum of no more than six primes. Both of these have been proved, so are bona fide theorems. The idea here is that if a slightly weaker claim than GC is proved, that makes GC more likely to be true. Note in passing that this illustrates our broad use of "non-deductive evidence for p" to include *proofs* of statements distinct from p but related to it in some interesting way.

This sort of justification exhibits the following pattern (compare Mazur (2014, p. 25); Pólya (1956, 1968) is a classic early discussion of non-deductive reasoning in mathematics):

$$\begin{gathered} A \Rightarrow B_1, B_2, \ldots, B_n \\ B_1, B_2, \ldots, B_n \text{ all hold} \\ A \text{ gains in justification} \end{gathered}$$

Of course, "$A \Rightarrow B$, B; therefore A" is a formal fallacy, known as *affirming the consequent*. (Or "modus morons," as Haack (1976, p. 115) playfully calls it.) This is another way of saying that the bare formal bones of this sort of argument are non-deductive.

The schema can be further elaborated. For example, A gains *more* in justification the more consequences B_1, B_2, …, B_n are verified (i.e., the greater n is); the more varied and independent of one another B_1, B_2, …, B_n are; the "closer" each of B_1, B_2, …, B_n is to A; the more of the B_1, B_2, …, B_n were discovered after conjecturing A and independently of that conjecture; and so on. (On closeness: the claim that every even number >2 is the sum of six primes is for instance closer to GC than the claim that every even number >2 is the sum of 10 primes. Needless to say, how to make precise sense of this notion of closeness is tricky.)

Third, let G(n), the Goldbach number of n, be the number of different ways in which n can be written as the sum of two primes. GC can then be expressed as the claim for all even n greater than 2, G(n) $\geq$ 1. As Echeverría (1996) points out, computer evidence shows that the function G(n) broadly increases for even n as n increases (with oscillation, but with an increasing trend), so that for instance for even $n \approx 10^5$, G(n) $\geq$ 500. In light of this evidence, that G(n) will suddenly drop to 0 is regarded as deeply unlikely.

This third sort of evidence combines neatly with enumerative inductive evidence, because it suggests that smaller numbers are more likely to be counterexamples to be GC than larger ones. (This example is also discussed by Baker (2007, pp. 69–70).) In the case of GC, there are therefore conjecture-specific reasons for thinking that the earliest cases are the "hardest." GC, incidentally, is by no means unique in this respect. Another example is Legendre's conjecture, also currently unproved, which states that for every positive integer N there is a prime between N^2 and $(N+1)^2$. As in the case of GC, the enumerative inductive evidence suggests that not only is Legendre's conjecture true, but also that the number of primes between N^2 and $(N+1)^2$ non-strictly increases with N. Incidentally, there are heuristic arguments for this conclusion too, of

the sort we will shortly mention for GC. The prime number theorem implies that the number of primes between N^2 and $(N+1)^2$ is asymptotic to a quantity which increases with N. So for Legendre's conjecture, as for GC, smaller numbers are "hard" cases – they are more likely to yield counterexamples than larger numbers. (There are other conjectures for which we have specific reason to believe that early cases are *easy* cases. An example is the conjecture that all perfect numbers are even; a natural number N is perfect iff its factors sum to 2 N. Since Ochem and Rao (2012), we know that the smallest odd perfect number, if it exists, must be greater than $10^{1,500}$. In this respect, such conjectures are diametrically opposed to GC and Legendre's conjecture.)

Fourth, the ratio $R_N = \frac{1}{N}$. (numbers $1 < k \leq N$ such that $G(2\ k) = 0$) has been proved to tend to 0 as N tends to infinity. In other words, the density of counterexamples to GC is zero. Of course, if GC is true then R_N is simply equal to 0 for all $N > 1$.

Fifth, Hardy and Littlewood's formula for the asymptotic number of representations of

$$N = p_1 + \ldots + p_m,$$

where $p_1 \leq \ldots \leq p_m$ are m primes, has been proved for $m \geq 3$. If true for $m = 2$, it implies GC for sufficiently large even numbers.

Sixth, a well-known heuristic probabilistic argument suggests the same conclusion. The prime number theorem states that the number of primes up to N tends to $N/\ln N$ asymptotically, i.e., the ratio of these two quantities tends to 1 as N tends to infinity (here ln N is the natural logarithm of N). Using the prime number theorem, one can estimate the number of ways in which an even number N can be written as the sum of two primes. One simple way of doing so based on the theorem estimates that N can be written as the sum of two primes in $\frac{1}{2}.N/\ln^2 N$ ways, a quantity that increases with N. (The argument seems to be mathematical folklore.)

This last argument is very rough and ready, and, to stress, heuristic rather than demonstrative. But it can be improved to yield much better estimates that point to the same conclusion: the greater N is, the greater $G(N)$ is likely to be. Such arguments remain heuristic – GC has not been proved – but they make it plausible that the first counterexample to GC, if one exists, will be a "small" number. These sorts of arguments are much more convincing than one might initially think: if the numerical facts did not follow the probabilistic expectation, the thought goes, there would be some totally unknown mathematical phenomenon that would cause the deviation – and there is no reason to expect this.

On the basis of this and other evidence – our list is illustrative rather than exhaustive – mathematicians are close to certain of GC's truth. The non-deductive evidence behind GC is justification for its truth, even in the absence of proof. One might say that the truth of GC best explains this wide range of evidence, and therefore that we should infer its truth on this basis. (Lange (2022a) discusses inference to the best explanation in mathematics.)

In illustrating some of the non-deductive evidence for GC, we have taken into account the strictly mathematical evidence for it. This is, if you like, the first-order

evidence for GC. But for any given p, such as GC, there is also higher-order evidence for p: what other mathematicians make of this first-order evidence for p. To determine how much the evidence supports p, mathematicians also take each other's judgements into account. In any real-life situation, a mathematician's judgement of how much the mathematical evidence supports p will also depend on what other mathematicians make of the same question. When you think about how likely p is to be true, your peers' judgements also matter.

This last point interestingly complicates the picture of mathematical justification, and applies to proof-based and non-proof-based justification alike. We will not dwell on it further here, but simply note that the sum total of the non-deductive evidence for p includes other experts' judgements.

3 Skepticism About Enumerative Induction

The first sort of evidence for GC mentioned in the previous section consists of the first 4×10^{18} verified instances of GC. In the absence of supporting reasons, mathematicians may mistrust such evidence for arithmetical generalizations, more so than most other forms of non-deductive evidence. Some philosophers have also expressed skepticism about the value of enumerative inductive evidence in arithmetic.

Why? The reason usually given is that known instances of an arithmetical conjecture are almost always small. (We say "almost always" because, for example, one could have an argument that all *odd* numbers satisfy some arithmetical property. That would constitute enumerative inductive evidence for the claim that *all* numbers have that property. But the evidence would consist of infinitely many cases, which could not all be said to be small.) For example, in the case of GC, the evidence is potentially biased, as it consists only of the *first* 4×10^{18} natural numbers. Since the size of a natural number significantly affects its properties, our enumerative inductive evidence seems biased with respect to size.

Following Frege (see §10 of his 1884), Alan Baker has given voice to this sort of skepticism. In an article devoted to the subject, he concludes with the following normative and descriptive point (about arithmetic): mathematicians ought not and in general do not "give weight to enumerative induction *per se* in the justification of mathematical claims" (2007, p. 72). But following other writers, Baker allows that circumstantial reasons can come to the rescue of an enumerative induction, in arithmetic as well as elsewhere in mathematics.

We limit ourselves to making three quick points against the skeptic, which a more expansive treatment would develop. The first point, already made in Sect. 2, is well appreciated by Baker and is worth stressing. In several cases, we have good reason to think that early cases are hard cases. We mentioned GC and Legendre's conjecture as examples. For these conjectures, small cases may be biased, but they are *favorably* biased: they are the cases most likely to yield a counterexample. If no such counterexample is found among them, the conjecture has passed an important test, like a climber who has got past the steepest part of the mountain face. As a result, confidence that all remaining cases fall in line can reasonably increase.

In the case of GC, the evidence for thinking that early cases are hard cases is, of course, partly based on enumerative induction. However, unless one is an out-and-out skeptic about enumerative induction, the circle here is virtuous. Enumerative inductive evidence is deployed to show that, so far as GC is concerned (say), the size bias works in favor of someone deploying enumerative inductive evidence to confirm it. In any case, as we also saw in Sect. 2, a heuristic argument also points to the same conclusion.

A second and related point, also acknowledged by Baker, was implicit in Sect. 2. The situation in which *all* we have is enumerative inductive evidence is a rare one. Almost always, this evidence is accompanied by other sorts of non-deductive evidence. Section 2 detailed some of that accompanying evidence in the case of GC.

The third point is that the viability of this sort of "size-skepticism" depends on what's motivating it. In a recent article (Paseau 2021), I distinguished three sorts of size-skeptics and pointed out that some are better motivated than others. In particular, some are better able to respond to the following *frontloading argument*.

Let E, a finite subset of the natural numbers, consist of our enumerative inductive evidence for a particular arithmetical conjecture. In other words, E is the set of known instances of a generalization over the natural numbers. Let the function v be our evidential function, with domain all finite subsets of the natural numbers. We assume only that v's codomain is the closed unit interval [0, 1] with the usual order; the higher v's value in [0, 1], the stronger the evidence. Evidential values may be thought of as measuring the subject's rational degree of confidence in the generalization in question, though without commitment to the whole panoply of probabilistic ideas.

Consider next the following, presumably uncontroversial, evidential principle:

More is Better
If n is not in E then $v(E \cup \{n\}) > v(E)$.

As its name indicates, *More is Better* simply captures the idea that more evidence is better than less; so the evidential value of more evidence is greater than that of less. Next, define $l = \lim_{n \to \infty} I_n$, where $I_n = v(\{0, 1, \cdots n\})$. By *More is Better*, if $m < n$ then $I_m < I_n$; and since 1 is an upper bound for the I_n, the limit l exists. The real number l itself, of course, may be 1 or smaller than 1, but it has to be greater than 0 (by *More is Better*). So we deduce that $0 < l \leq 1$. Now by the definition of a limit, for any $\varepsilon > 0$, however small, there is an N_ε such that for any $N^* \geq N_\varepsilon$, I_{N^*} is to within ε of l.

Here's another way of putting it: for ε much smaller than $l - \varepsilon$, almost all the evidential value stems from the first N_ε instances of the enumerative induction. The remaining instances add very little evidential value. The evidential value of any finite amount of numerical instances is therefore concentrated almost entirely in an initial segment. Whatever arithmetical conjecture you wish to test, the value of further instances beyond some finite bound (that depends on the conjecture) will be vanishingly small. An initial segment provides the lion's share of the confirmation.

The conclusion of this remarkably simple argument appears to contradict size-skepticism. Paseau (2021) discusses in detail which forms of size-skepticism are genuinely affected by it. The conclusion there is that some but not all are.

4 The Last Bastion of the Euclidean Program

What is the structure of mathematical justification? The traditional picture is foundationalist. More specifically, it is a form of foundationalism largely inspired by Euclid's geometrical method in *The Elements* (c. 300 BC). So what was Euclid's method? Starting from some definitions, postulates, and common notions, Euclid derives the geometry of his day theorem by theorem, in a cumulative manner over the course of 13 books. A concise summary of what he calls the *Euclidean program* is given by Imre Lakatos in the following passage, where he contrasts it with the *Empiricist program*:

> The Euclidean programme proposes to build up Euclidean theories with foundations in meaning and truth-value at the top, lit by the *natural light of Reason*, specifically by arithmetical, geometrical, metaphysical, moral, etc. intuition. The Empiricist programme proposes to build up Empiricist theories with foundations in meaning and truth-value at the bottom, lit by the *natural light of Experience*. Both programmes however rely on Reason (specifically on logical intuition) for the safe transmission of meaning and truth-value. (Lakatos 1962, p. 5)

The most obvious way to spell out the Euclidean program would be to base it on what Euclid himself has to say about it in *The Elements*. But that would give us very little to go on, because Euclid offers us no philosophical gloss on his method, as many commentators down the ages have noted.

Lakatos offers us more. He characterizes the Euclidean program as follows:

> I call a deductive system a 'Euclidean theory' if the propositions at the top (axioms) consist of perfectly well-known terms (primitive terms), and if there are infallible truth-value-injections at this top of the truth-value True, which flows downwards through the deductive channels of truth-transmission (proofs) and inundates the whole system. (If the truth-value at the top was False, there would of course be no current of truth-value in the system.) Since the Euclidean programme implies that all knowledge can be deduced from a finite set of trivially true propositions consisting only of terms with a trivial meaning-load, I shall call it also the Programme of Trivialization of Knowledge. Since a Euclidean theory contains only indubitably true propositions, it operates neither with conjectures nor with refutations. In a fully-fledged Euclidean theory meaning, like truth, is injected at the top and it flows down safely through meaning-preserving channels of nominal definitions from the primitive terms to the (abbreviatory and therefore theoretically superfluous) defined terms. A Euclidean theory is eo ipso consistent, for all the propositions occurring in it are true, and a set of true propositions is certainly consistent. (Lakatos 1962, pp. 4–5)

Now in this passage Lakatos speaks of truth (and meaning) injection; but this is somewhat misleading. The Euclidean program represents an epistemological conception, and the hierarchical path from axioms to theorems is a path the subject, as

opposed to reified truth, follows. The flow-of-truth metaphor is better construed as transmission of an epistemic good of some sort, such as justification say. The picture is then a foundationalist one in which one gains justification for axioms first and thence for theorems by inferring them from the axioms.

Historical proponents of mathematical epistemologies that, to one or degree or another, approximate the Euclidean conception are many and varied. The conception's high point came in the seventeenth century; see in particular Pascal's posthumously published *On the Geometric Mind* (written in the 1650s) or even Descartes' *Discourse on Method* (1637). For various reasons, the Euclidean program is no longer tenable as a mathematical epistemology for *all* mathematics. Paseau and Wrigley (2024) explains the reasons why for the case of set theory. In brief, the standard axioms of set theory are no longer generally regarded as self-evident; at least, not all of them are. And deductive rules that take us from theorems to axioms are also not thought to be certainty-preserving, or even rational-credence-preserving. On top of that, the Euclidean program's ideal of completeness is also, post Gödel, not realizable. Any reasonable axiomatic organization of set-theoretic truths in a deductive system will omit some of them.

Arithmetic much more closely approximates the Euclidean picture than set theory does. (As discussed in Sect. 5 of Franklin (2021b), for example.) The justification of its axioms seems more intrinsic than extrinsic. Extrinsic evidence for a principle consists in its instrumental value, in drawing consequences, forging connections between different areas, making for better explanations, and the like. This is the kind of evidence on which theoretical principles in science are mostly, if not exclusively, based. Intrinsic evidence we may take to be non-extrinsic evidence: the sheer obviousness or plausibility of a principle, as well as how it fits with the broader conception of the subject matter. And many would see the axioms of arithmetic as intrinsically evident.

One of the Euclidean program's tenets that's still very much standing is that deduction is prized as the highest form of justification available for a mathematical proposition and regarded as necessary for knowledge. In fact, in some quarters, deductive justification is thought to be the *only* available form of justification; and for many, non-deductive justification pales in comparison to the real McCoy: proof. To challenge these sorts of proof-centric ideas, or at least weaken their hold, is thus to challenge one of the last bastions of Euclideanism.

Friends of non-deductive reasoning in mathematics will find what Lakatos called the Empiricist program much more congenial than the Euclidean one. This post-Euclidean outlook was perhaps first articulated by Russell, who drew a "close analogy between the methods of pure mathematics and the methods of the sciences of observation" (1907, p. 272). On a thumbnail, the idea is this. We commonly conceive of natural-scientific propositions as being divided into two broad kinds: data and more theoretical principles, ultimately laws. On this (simplified) conception, the data are empirical propositions that we take to be the facts, and the principles/laws are propositions formulated in order to predict the facts. Indeed, the prediction of the data is the primary means of verifying these principles/laws. Whether or not the principles/laws are intrinsically plausible, to a first

approximation we take them to be true if they predict all the data and don't predict anything false.

By analogy, mathematical axioms are supposed to be verified by "predicting" mathematical propositions of some privileged kind identified as the data. Prediction here is simply deductive implication. The justification of these principles or laws would then be extrinsic. This is broadly Russell's view of the matter, which he calls the "regressive method." It plays a major role in his own foundational system; for example, in the introduction to the first edition of *Principia Mathematica*, he (with Whitehead) had this to say about the controversial so-called axiom of reducibility:

> That the axiom of reducibility is self-evident is a proposition which can hardly be maintained. But in fact, self-evidence is never more than a part of the reason for accepting an axiom, and is never indispensable. The reason for accepting an axiom, as for accepting any other proposition, is always largely inductive, namely that many propositions which are nearly indubitable can be deduced from it, and that no equally plausible way is known by which these propositions could be true if the axiom were false, and nothing which is probably false can be deduced from it. (Whitehead and Russell 1910/1962, pp. 59–60)

It is essential to the Empiricist program that certain propositions are identified as being data, and that these have a special epistemological status which explains their role in the program. Various manifestations of the Empiricist program will have different ideas about which propositions are properly classified as data, or which propositions are lit by the natural light of experience. Plainly, not just any mathematical truth can be considered a datum, otherwise any true axiom would be self-certifying in an unacceptable way. For Russell and Whitehead, notably, this moral applies to arithmetic as well: the axioms are justified because they entail propositions such as "$1 + 2 = 3$," not the other way round.

The use of non-deductive methods in mathematics therefore tallies better with the Empiricist than the Euclidean program. To put it very roughly, mathematical justification is much more like scientific justification than traditionally imagined. At the very least, it has an important extrinsic component. It is then a short step to the idea that non-deductive evidence has an important role to play in mathematical justification, just as it does in science. Coming at it from the other direction, to recognize the important role this sort of evidence plays in mathematics is to chip away at the epistemological dimension of the empirical science/mathematics divide. Mathematics is much more like science than our philosophical forebears imagined. Just as in science, non-deductive justification has an important role to play.

5 Justifying the Consistency of Mathematics as a Whole

Let's now turn to an apparently unrelated question, whose connection to our main topic will emerge shortly. Set theory is regarded by many as a foundation for mathematics – though in what sense exactly remains a source of controversy. An incontrovertible fact is that almost all mathematics can be carried out in set theory. And we can prove the consistency of virtually all mathematical theories – arithmetic,

analysis, geometry, and so on – in set theory. (The consistency of a theory may here be understood as its not implying every sentence.) If set theory were inconsistent, a proof of, say, the consistency of arithmetic in set theory would be cold comfort, since set theory would also prove that arithmetic is inconsistent – indeed, it would prove anything statable in its language. A set theoretic proof of arithmetic's consistency is thus best understood as a relative consistency proof: it establishes the consistency of one theory (arithmetic) on the assumption that another (set theory) is consistent. To interpret such a proof as telling us that arithmetic *is* consistent, we need reason to think that set theory itself is consistent.

But now a difficulty looms: we have no proof of this latter fact, that is, of set theory's consistency. And this for a principled reason: by Gödel's second incompleteness theorem, if set theory is consistent then it cannot prove its own consistency. Of course, we can take our preferred system of set theory S and extend it to S^+ and then proceed to prove the consistency of S within S^+. But that only pushes the question back one stage: how do we convince ourselves that S^+, our new ultimate theory, is consistent? By Gödel's theorem again, we cannot do so in S^+ (assuming S^+ is consistent).

So far we have assumed that set theory is the foundation of mathematics. But actually this is inessential. The question of consistency can be raised for any putative foundation for mathematics, e.g., category theory as opposed to set theory. And even if you think mathematics has no foundation, you still face the question of why we are justified in thinking mathematics as a whole is consistent. Everything said here can be easily reformulated to accommodate either of these alternative views.

The question of the foundation's consistency is particularly pressing if you take all justification in mathematics to be deductive, i.e., to be given by proof and exhausted by proof. For, on that view, how on earth are we justified in believing set theory's fundamental principles? The reply that an axiom has a zero-step proof from the axioms, though true, is hardly consoling. In any axiomatic system, the axioms are trivially provable, for systems consisting of true axioms and of false axioms alike. Any crank can put forward a hare-brained mathematical "system" and give a zero-step proof that each of its axioms is true. So how do we know that the axioms of our *not* hare-brained but trusted (we think) system are true? Or at least why are we justified in so thinking?

Indispensabilists have an answer. Indispensabilism is the philosophy of mathematics inspired by Quine and Putnam; see Paseau and Baker (2023) for a more recent account. In a succinct formulation, the idea is that we are justified in believing the axioms of mathematics as a whole – whatever exactly these are – because they are successfully and indispensably applied in science. Mathematical justification ultimately rests on scientific justification. This is the indispensabilist's broad answer to the question of how axioms are justified. Plainly, though, the answer is indirect and holistic: to justify the thought that set theory is true, or even consistent, requires no less than a detour through the whole of science, or at least large parts of it. It would be better to combine this holistic justification with more direct evidence for the consistency of mathematics. As we have seen, this evidence apparently cannot be deductive, so has to be non-deductive. In sum, we have here an important role for

non-deductive evidence to play. Such evidence, if it exists, can be used to show that set theory (and hence mathematics as a whole) is consistent.

Does such evidence exist? Most definitely. Maddy (1988) is a then state-of-the-art discussion of non-deductive evidence for the axioms of set theory and their possible extensions. As such, it offers plenty of reasons for believing in set theory's consistency. Chapter 8 of Paseau (forthcoming) is a shorter and less technical survey of some non-deductive evidence for the same.

6 An Unorthodox Claim: Non-deductive Knowledge of Mathematics

We have so far been concerned with non-deductive *justification* and *evidence* in mathematics. We end this chapter by considering a much more radical idea: that there can be non-deductive (non-testimonial) *knowledge* of mathematical propositions. This claim goes squarely against the way mathematicians speak, since mathematicians typically equate p's being known with there being a proof of p. (For mathematical p, obviously. In my (2015), I argue that gainsaying mathematicians is much less problematic when they are talking not about mathematics but about its epistemology, as in this case.) This is the quasi-universal, orthodox view. I am among the very few who dissent from it, because I believe that, in the best cases, non-deductive evidence can yield knowledge of a mathematical proposition (Paseau 2015). In this section, I shall present an argument for the unorthodox view, adapted from Sect. 5 of Paseau (2015); my article contains several other such arguments.

Epistemologists have given a good deal of general thought to knowledge. Not just mathematical, but empirical, scientific and moral knowledge, self-knowledge, knowledge of the past and the future, a priori and a posteriori knowledge, and so on. Ever since the publication of Gettier (1963), one particularly prominent concern has been to provide necessary and sufficient conditions for knowledge. Notoriously, none of the myriad proposed conditions has achieved consensus (for general reasons lucidly discussed in Zagzebski (1994)), although many have been thought to be along the right lines, or at least to cover an important range of cases. For brevity, call any analysis that has gained at least some traction in the literature a "right-track analysis." (Some examples will shortly follow.)

The argument for non-deductive knowledge of mathematics is that any right-track analysis falls into one of two categories. *Either* it allows that knowledge of mathematics may be obtained by non-deductive means; call this category *Type A*. *Or* it does not apply to knowledge of mathematics, so *a fortiori* does not privilege deductive, as opposed to non-deductive knowledge of mathematics; call this *Type B*. The underlying thought here is that if (non-testimonial) knowledge of a mathematical proposition could only be deductively acquired, at least *some* right-track analyses would have that implication, when supplemented with some generally accepted principles.

So let's take a look at a few accounts of knowledge. The first and most venerable one is that knowledge is justified true belief. As Gettier (1963) notes, Plato in the

Theaetetus and the *Meno* may have respectively considered and proposed such an account. This account is of Type A: it allows for non-deductive knowledge of mathematics, since a mathematical proposition may be justified non-deductively. For example, the evidence behind GC (some of which we encountered in Sect. 2) justifies our belief in it.

An influential revised account was offered in Goldman (1967). Goldman suggested that a subject knows that p just when her true belief that p is causally connected to the fact that p. Whatever the merits of this account for other domains, it does not apply to mathematics, since the subject matter of mathematics does not have causal powers: the number 53 itself does not causally impinge on our senses any more than a Banach space or an ordered field do. Goldman's "causal analysis" of knowledge is therefore of Type B. Goldman himself could not have been clearer on this point, declaring in the first paragraph of his famous article that "[m]y concern will be with knowledge of empirical propositions only, since I think that the traditional analysis is adequate for knowledge of nonempirical truths [including those of mathematics]" (Goldman 1967, p. 357).

Now that we have seen how this sort of argument goes, it can be extended to other post-Gettier right-track analyses more swiftly. These typically supplement the first two clauses, that p is true and S believes that p, with a third condition that aims to improve upon the justification clause. Here is a sample, along with their classification:

- The belief that p is not inferred from a false lemma (Clark 1963). Of Type A, since non-deductive evidence for p need not contain a false lemma.
- The justification that p must not essentially rest on a false assumption (Harman 1973). Similar to the previous: of Type A, since non-deductive justification for p need not, and in many usual cases will not, essentially rest on a false assumption.
- There is a law-like connection between the fact that p and the belief that p (Armstrong 1973). Armstrong intended it to cover empirical cases only, so this analysis is of Type B.
- The belief that p is produced by a reliable process not undermined by the subject's cognitive state (Goldman 1976). Of Type A, since non-deductive evidence can be the product of a reliable process.
- If it were the case that not-p then the subject wouldn't believe p (Nozick 1981). (Ignoring Nozick's other condition, which is problematic and does not affect the moral. More generally, in presenting these accounts, I have omitted qualifications, refinements, and extra clauses that do not affect the general point.) To apply this, note that mathematical propositions are usually thought of as necessary. The standard account of counternecessaries in the literature takes them to all be true, in which case Nozick's analysis is of Type A – it allows for non-deductive knowledge of mathematics. (The standard accounts are derived from Stalnaker (1968) and Lewis (1973). As Baker (2021) notes, following an observation by Ralph Wedgwood, counternecessaries are usually known as "counterpossibles." If the analogy with "counterfactual" is to be exact, however, "counterpossibles"

should be known as counternecessaries. See Baker (2021) for more on these types of conditionals, whatever they should be called.)

Even if we reject the standard account of counternecessaries, it seems that Nozick's account is of Type A. For example, we are liable to think that if the Riemann Hypothesis were false, we would lack the evidence we in fact possess for it, and consequently that we wouldn't believe it. Similarly, if the perpendicular bisectors of Euclidean triangles did not meet in a point then trying to confirm this fact empirically—by drawing the lines with the utmost care on a plane surface—would not lead us to conclude that they do. If a particular number were composite rather than prime, the primality test evidence would be different. And so on.

- The subject could not easily have falsely believed that p (this is the safety condition discussed in, e.g., Williamson 2000). This condition can easily be failed by true mathematical beliefs, e.g., if they are the product of happenstance or of an unreliable method that happens to be right in this instance. For instance, suppose I believe that $1^3 + 5^3 + 3^3 = 153$ because I recognize it as an instance of the generalization $a^3 + b^3 + c^3 = abc$, where abc is written in decimal notation, which I believe to be true. The generalization is patently false, but this instance of it happens, quite fortuitously, to be correct. The condition is of Type A: the best forms of non-deductive evidence satisfy it.

Observe in passing that the best inductive mathematical cases are quite unlike lottery cases. Say that p is the proposition that the subject won't win the prize in a large lottery, with N tickets, that she enters. In a lottery case, the subject's evidence for p is insensitive to whether p is true. She has the same evidence and belief in the scenario in which she holds the winning ticket as in the $N - 1$ nearby scenarios in which she holds a losing ticket. Not so for the best cases of non-deductive evidence in mathematics.

Evidently, this is just a sample from a vast post-Gettier literature. But it includes most of the leading candidates; and none of them was chosen with a view to confirming the "either Type A or Type B" moral. In any case, broadening the range of examples would not alter the moral. General epistemology has not brought to light any reasonably popular condition that excludes a non-deductive (non-testimonial) route to knowledge of mathematical propositions. No right-track analyses allow deductive routes to mathematics while ruling out non-deductive ones. As a prominent field of inquiry, mathematics is, and should be, a test case for general epistemology. If the only (non-testimonial) route to knowledge of a mathematical proposition were deductive, you would expect some prominent general accounts of knowledge to have this consequence. That they don't supports the idea that such knowledge can be acquired non-deductively.

Of course, this is not a knockdown argument for the conclusion that we can know a mathematical proposition without proof. (Which, to repeat, is to be understood in the strong sense that no one has a proof of it. As stressed, we often know p testimonially without being able to prove p ourselves.) It is one of many arguments and considerations supporting that idea. To further strengthen it, one ought to consider those as well. A fuller treatment would examine not just these but the conservative backlash as well, if we may call it that. Lange (2022b), for example, is

an interesting recent article that tries to support the standard view by proposing a necessary condition on knowledge that Lange believes (i) is independently motivated and (ii) rules out non-deductive knowledge of mathematics.

A closely related point worth stressing is that, at least in some cases, there is a gap between strong justification for one's true belief that *p* and knowledge that *p*. Gettier's refutation of the "JTB" analysis of knowledge showed that justification is not enough for knowledge, even when the belief is true. (Nagel (2014, p. 58) observes that discussion of so-called Gettier cases may be found in Indo-Tibetan philosophy that predates Gettier by centuries.) In fact, one can go further: one of the lessons of so-called lottery cases is that even justification for a true belief that falls short of complete certainty by a tiny but positive margin *may* not be enough for knowing it. In a fair lottery in which there are *N* tickets, my chances of winning are 1/*N*, which for large *N* is very small, and I may truly believe that I don't hold the winning ticket; but – and this is the key point – I don't know that my ticket won't win.

What do the lottery cases teach us? The fact that a mathematician's non-deductive justification for her belief in the true mathematical proposition *p* is extremely strong does not, in itself, show that she knows that *p*. Something more is needed, at least in general. Clearly, though, not all epistemic situations are similar to lottery cases, and one should not overgeneralize from them. Their moral is not that extremely strong justification can *never* transmute true belief into knowledge; only that it *sometimes* fails to do so.

Let's take stock. Suppose you think, like I do, that non-deductive justification can yield knowledge in mathematics. Then you have a job to do. It's not enough for you to simply point out that in many such cases, the evidence for *p* is overwhelmingly strong. You must produce reasons for thinking that, at least in some cases, it's strong enough for knowledge. The argument in this section that nothing in general epistemology rules it out is just one example of an argument you could give. There are many others.

7 Conclusion

The present chapter has looked at some of the more philosophical aspects of the role non-deductive evidence plays in mathematics. The role is an important one, and its contours have only started to be investigated in detail in recent decades. There is more philosophical work to be done to understand it better.

Abstract

This chapter presents an overview of the contributions to the section on Experimental Mathematics by focusing in particular on how they characterize the phenomenon of "experimental mathematics" and its origins. The second part presents two case studies illustrating how experimental mathematics is understood in contemporary analysis. The third section offers a systematic presentation of the contributions to the section.

1 Introduction

The label "experimental mathematics" is today associated with the recent trend of using computer-based methods in mathematical research. As such, it can still be understood broadly, ranging from the use of computational tools for heuristic purposes, e.g., pointing to new results or to visualize a situation for obtaining a better understanding, to a more radical interpretation where computations are regarded as evidence for results (see, for example, Zeilberger 1994). In this light, it is natural to ask how it is possible to characterize the phenomenon of "experimental mathematics." In this connection, one might wonder whether the so-called experiments done in mathematics bear any likeness to the experiments of the natural sciences. Both of these questions are addressed by the chapters in this section. Furthermore, we also find accounts of some of the recent events that led to the establishment of "experimental mathematics."

"Experimental mathematics" is interpreted in a variety of ways by the contributors to this section. A unifying theme is that the phenomenon is understood in a broad sense. For one thing, experiments are not only done by computational tools – they might include, for example, pencil and paper as well as visualizations. This is also noted in the aims of the journal *Experimental Mathematics*: "Many mathematical experiments these days are carried out on computers, but others are still the result of pencil-and-paper work, and there are other experimental techniques, like building physical models."[1]

In addition, the use of experiments in mathematics (in some interpretations of the term) is not a new phenomenon. Mathematicians have since long performed "experiments," for example, in the form of computations, trying out and rejecting ideas. Tradition, however, prescribes that mathematics is presented in the form of definitions, propositions, and proofs that hides the work that came before. To use a famous quote by Reuben Hersh: "the "front" of mathematics is mathematics in "finished" form, as it is presented to the public in classrooms, textbooks, and journals. The "back" would be mathematics as it appears among working mathematicians, in informal settings, told to another in an office behind closed door" (Hersh 1991, p. 128).

In the literature are a few attempts to characterize "experimental mathematics" inspired by how experiment is understood in science. van Bendegem (1998) assumes that "experiment" can be understood in the naïve sense of manipulating objects and "setting up processes in the 'real' world and with observing possible outcomes of these processes" (p. 172). He examines possible descriptions of what these processes could be in the context of mathematics such as "experiment is computation" or "experiment is real-world-experiments" but concludes that they fail for different reasons. The second description fails since it is only rarely used in contemporary mathematical practice. The second occurs more often (and seems to be what

[1] Taken from the webpage of *Experimental Mathematics*, see https://www.tandfonline.com/action/journalInformation?show=aimsScope&journalCode=uexm20

mathematicians are mainly referring to), but it is not "experimental" as understood in the sciences. Baker (2008) partly disagrees with this conclusion and formulates a tentative description of the genre, as he refers to it. He first notes that "experiment" can be interpreted in two distinct ways. In the first sense, one might focus on the method of formulating and testing hypotheses as experimental. As noted above, this is frequently done in mathematics and is (usually) considered as part of the context of discovery. In the second sense, we might understand "experiment" as a form of inductive evidence for a hypothesis or a claim. Based on an analysis of different cases, Baker combines these two and suggests that experimental mathematics "involves calculating instances of some general hypothesis" (Baker 2008, p. 340).

Among the contributions are both broad interpretations, as well as specific characterizations of experimental mathematics. de Villiers and Jahnke find that experimental mathematics and its aims should be understood in a variety of ways in order to demonstrate how they can fruitfully be used when teaching mathematics. For this purpose, they take inspiration from the long list of definitions of experimental mathematics found in Borwein's "Exploratory Experimentation: Digitally-Assisted Discovery and Proof" (Borwein 2012, pp. 73–74):

- Discovering new relationships and conjecturing (looking for inductive patterns, generalizations, etc.)
- Visualizing math principles (viewing graphical or other visual representations of analytically derived results)
- Verification (obtaining certainty about the truth or validity of a statement or conjecture)
- Computing replacing lengthy hand derivations (use of computer algebra, data handling, and/or graphical representations)
- Global and heuristic refutation (disproving a false statement by generating a counterexample, as well as reformulating, refining, or polishing a true statement by means of local counterexamples)
- Understanding (gaining insight/intuition, and grasping the meaning of a proposition, concept, or definition or assisting in the discovery of a proof)

In contrast, Schlimm and Gonzàlez present a simple framework that is useful for their purpose: to show how experiments using a variety of tools such as doodling and visualization have played a role in the development of a result on how to divide a line segment in equal parts. They characterize an experiment in terms of a setup, a process, and an evaluation. Although their framework is simple, it is still flexible enough to contain aspects of all items in Borwein's list. In the chapter by Ferraro, analyzing the role of examples in the mathematics of Euler, we find experiments in the sense of verification. In this case, we learn how examples can be used as evidence for both results and proofs.

A second question in Baker's (2008) paper is whether the use of experimental methods in mathematics is philosophically interesting. It appears that it is. Sørensen's contribution lists four – partially overlapping – topics that have been discussed in recent writings in the philosophy of mathematics. They include

the question whether it is possible to derive formal results from inductive evidence and the problem of opacity of computer calculations. There is also a focus on experimental methods in mathematics in connection with heuristics, using in particular computers as explorative tools.

The computer proof of the four-color theorem (4CT) by Appel and Haken in the mid-1970s is commonly mentioned as a turning point for experimental mathematics. The proof of the 4CT was followed by discussions among mathematicians whether it could really be considered a valid proof. A later debate, after the proof had been accepted in mainstream mathematics, concerns whether the proof of the 4CT changes the conception of a proof. This debate was spaked by the influential paper "The Four-Color Theorem and Its Philosophical Significance" (Tymoczko 1979). Proofs are normally considered to be a priori (or our knowledge of proof is a priori), certain, and surveyable. Tymoczko finds that the proof of the 4CT apparently is convincing, but not surveyable. Furthermore, since computers are used to check a (large) number of instances, there is an element of empirical data that is drawn upon and so the proof becomes a posteriori.

The chapter by McEvoy presents Tymoczko's claims and takes us through the main issues and line of arguments of the ensuing debate. Sørensen's contribution further informs us about some of the debates on the role of "experimental" methods among mathematicians during the 1990s: Jaffe and Quinn's proposal to distinguish between theoretical and rigorous mathematics and responses published in the Bulletin of the AMS as well as the heated discussion between Zeilberger and Andrews in the Mathematical Intelligencer. Furthermore, Sørensen writes about the formation and consolidation of the journal of the field, *Experimental Mathematics*.

The story of the use of computational tools in mathematics is, of course, much older. The first known computational device is the abacus that was used for calculations in ancient Mesopotamia. Somewhat later, we find the idea of using mechanical tools to aid our reasoning, forming what Leibniz called a *calculus ratiocinator*. Avigad (2018) traces Leibniz's ideas to the thirteenth-century Franciscan monk from Mallorca, Ramon Llull. One of his great achievements was to invent various devices that are based on the three important assumptions (Avigad 2018, p. 683):

- We can represent concepts, assertions, or objects of thought with symbolic tokens.
- Compound concepts (or assertions or thoughts) can be obtained by forming combinations of more basic ones.
- Mechanical devices, even as simple as a series of concentric wheels, can be helpful in constructing and reasoning about such combinations.

The usefulness of using representations of various types is noted in several of the contributions. Starikova and Schlimm & Gonzàlez discuss the use of visual representations, or diagrams in the process of generating new results. Discussing the case of thought-experiments, Starikova's diagrams are both in the form of external and mental representations of mathematical situations. Schlimm & Gonzàlez refer to external representations as cognitive aids and explain some of their advantages.

These advantages are not limited to the use of diagrams but hold also for other types of representations such as calculations. One mentioned advantage is that external representations "allow us to keep a durable and shareable record of the reasoning process and they can be used to determine the boundaries of accepted inferences, such as the inferential steps within a regimented language or the restriction to a set of tools, e.g., compass and straightedge. Moreover, rather than just representing a mental reasoning process, external representations can themselves be the vehicles of epistemic inferences" (p. 6). One is reminded of the logician C.S. Peirce's characterization of mathematical reasoning as constructing, observing, and *experimenting upon* mathematical representations (which he refers to as diagrams)[2]:

> The truth, however, appears to be that all deductive reasoning, even simple syllogism, involves an element of observation; namely, deduction consists in constructing an icon or diagram the relations of whose parts shall present a complete analogy with those of the parts of the object of reasoning, of *experimenting upon this image in the imagination*, and of observing the result so as to discover unnoticed and hidden relations among the parts. . . . As for algebra, the very idea of the art is that it presents formulae which can be manipulated, and that by observing the effects of such manipulation we find properties not to be otherwise discerned. (CP 3.363, italics added)

In the last part of the introduction, I present examples of experimental mathematics (as understood by the authors) illustrating different ways that computer-based methods play a role in contemporary analysis. At the end is a systematic summary of the six contributions to the section on Experimental Mathematics.

2 Experimental Methods in Contemporary Analysis

We have noted that "experimental" is understood in two distinct ways. Mathematics – as the sciences – uses a variety of methods and tools to "experiment" when to discover new relations. In the second sense, "experimental" methods, such as computations, sometimes play a justificatory role. In this section, I present results from contemporary mathematics illustrating the varied use of experiments using computational tools. The first example considers so-called graph-algebras and illustrates two different interpretations of experimental methods. The second example concerns the Thompson group and the question whether its subgroup F is amenable. The first example is a case of what McEvoy refers to as a computer-assisted proof. The considered result is verified by having a computer program compute all instances of a large number of cases. The second and third example are experimental in the sense that hypotheses are formulated and tested with the help of computational tools. The two last cases fit the characterization given by Eilers and Johansen in their *Introduction to Experimental Mathematics* (2017, p. 1):

[2] The quote is from Peirce's Collected Papers 1931–1960, volume III, paragraph 363. I refer to (Marietti 2010) and (Carter 2020) for explanations of Peirce's diagrammatic reasoning.

"the systematic investigation of concrete examples of a mathematical structure in the search for conjectures about its properties."

2.1 The Structure of Graph-Algebras

Graph-algebras are C^*-algebras generated from so-called directed graphs. The structure of graph-algebras can be investigated by studying particular maps, i.e., endo- and automorphisms, that can be defined on them. Two different experimental methods are illustrated in this case. The first constructs an algorithm that can be turned into a computer program and so performed successfully by a computer. A diagrammatic representation of an endomorphism leads to an algorithm that gives further information about the map. In simple cases, the calculations can be done by hand. If not, the algorithm can be performed by a computer. The second type of use is closer to an experiment in its original sense – as they are done in the experimental sciences: A problem concerning the automorphisms of a graph-algebra – assumed to be undecidable – is investigated by the use of computers. In the first stage, certain calculations give rise to a pattern. The pattern is further explored – and *experimentally* verified – by further calculations or by mathematical arguments.[3] I give some more details about the case below. More details can be found in "Visualizing Automorphisms of Graph-algebras" (Avery et al. 2018) and in some articles referred to there.[4]

A directed graph is formally defined as the four tuple, $E = (E^0, E^1, r, s)$ where E^0 consists of vertices, E^1 of edges, and r, s: $E^1 \rightarrow E^0$ are range and source functions of the edges. This means they tell for each edge which vertices it ends and starts at. When dealing with a particular directed graph, it is most often easier to present it as a diagram. Figure 1 shows an example.

Whenever there is given a directed graph, E, a construction can be performed so that it generates a C^*-algebra. I refer to (Avery et al. 2018) for details.

Given a particular graph, it is possible to define the length of paths between two vertices (counting the number of edges). See Fig. 1 for an example. Given two vertices u and v, one further considers the collection, $E^k_{u,v}$, of paths of a fixed length k between them. Finally, a permutation on the paths of $E^k_{u,v}$ is referred to as an end point fixing permutation. An end point fixing permutation induces an endomorphism on the generated C^*-algebra. If the permutation is named α, the endomorphism that it induces is denoted by λ_α.

Avery et al. deal only with finite graphs (i.e., finite number of vertices and edges).[5] This means that they are discrete and finite combinatorial objects. As a

[3] The fact that the result is most likely undecidable contradicts Baker's (2008) statement that mathematics need not rely on inductive methods since it is always possible that a formal, or deductive, proof can be found of a given proposition (p. 337).

[4] I thank W. Szymanski for conversations about these cases.

[5] There are further technical restrictions imposed on the graphs that are not relevant for this brief presentation.

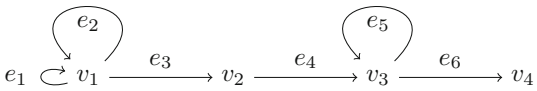

Fig. 1 A directed graph with four vertices and six edges. A path from v_1 to v_3 of length 3 is, for example, $v_1 \to v_1 \to v_2 \to v_3$.

contrast, when constructing a graph-algebra from a particular graph, one obtains an infinite, analytic object, whose study requires analysis. The idea in the study presented here is to study symmetries of the graph-algebras captured by actions of groups that can be expressed via the combinatorial properties of the directed graphs. In other words, certain "accessible and visible" symmetries of graphs are generated and studied.

The induced map, λ_α, can be shown to always be $1-1$, but it need not be onto. The considered results concern the properties of this map. The two questions that are investigated are:

1. Is λ_α onto (which would entail that it is an automorphism)?
2. If so, what is the order of λ_α?

For each particular permutation α, there exists an algorithm that will tell in finite time whether (1) holds or not. That is, thegraph-algebras solution of (1) can be found computationally.

2.2 The Order of λ_α

The answer λ_α to question (2) is likely to be undecidable, and so in this case there is no algorithmic solution. The problem has similarities to problems in automata theory that are undecidable, and it is assumed that the same holds for this problem. Therefore, an experimental approach has been taken.

The basic idea is to translate the endomorphism (which is an element of a group) into a formal language. The complexity of this language can be calculated, and this gives a particular natural number. In this way, each order of λ_α gives a natural number. If this number turns out to be zero for a particular order, k, then λ_α^k is the identity and it follows that λ_α has order k. Below is an illustration of this process when the sequence terminates quickly:

Order of λ_α	λ_α	λ_α^2	λ_α^3	...	$\lambda_\alpha^k = Id$
Corresponding number	c_1	c_1	c_3	...	0

The interesting, or challenging, part is when this process does not terminate quickly. (It should be noted that the calculations have been done by parallel computing and using Super Computers – they are huge.)

By making a number of calculations of orders of lambda for different permutations, a pattern arose. Either the sequence of natural numbers oscillated or it grew in an exponential way. Avery, Johansen, and Szymanski therefore made the following hypothesis or prediction: If the sequence oscillates, then it will eventually become zero – and so λ_α will have a finite order. If the sequence looks exponential, then the order is infinite.

These two hypotheses have been tested – and experimentally confirmed. The first case, when the sequence oscillates, has been verified by testing a number of cases – calculating even higher powers of λ_α. In each of the chosen examples, it turned out that the number eventually became zero. In the second case – where it is conjectured that the order is infinite – this procedure does not work. Instead proofs using analysis have been carried out. More precisely, a number of cases among the automorphisms that displayed an exponential pattern were selected and analyzed one by one using tools from analysis. For each of these cases, it was possible to prove that the order λ_α was infinite.

2.3 Thompson Group and Calculating the Bounds of an Expression

The Thompson group T is a famous example of a countable group that has a finite presentation. It can be generated by two elements C and D, which is reproduced in Fig. 2 below. A long-standing problem is whether one of its subgroups, the subgroup F, is amenable.[6] We consider a study by S. Haagerup, U. Haagerup, and M. Ramirez-Solano published in *Experimental Mathematics* where calculations performed by computer programs indicate that the group might not be amenable (Haagerup et al.

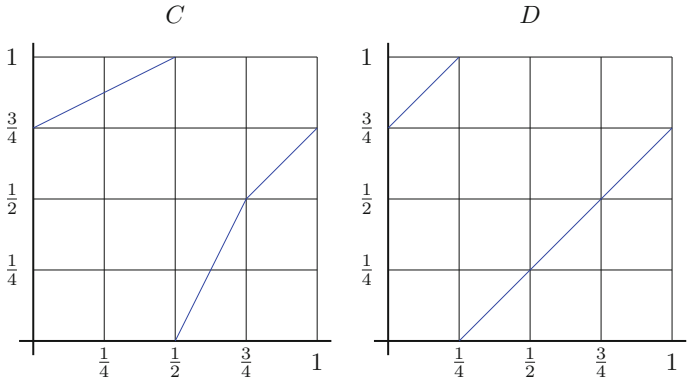

Fig. 2 Graphs of the generators C and D of the Thompson group

[6] The concept of an amenable group has been introduced by von Neumann in connection with his work on the Banach-Tarski paradox.

2021). In this case, the value of a certain expression composed by generators of the Thompson group is computed. The conclusion is based on the result of this computation as well as other indications. Before showing the expression, I present the definition of the Thompson group.

I refer to (Haagerup et al. 2021) for further details on the Thompson group and the subgroup F.

The Thompson group T is the group of cyclic order preserving homeomorphisms $f\colon \mathbb{R}/\mathbb{Z} \to \mathbb{R}/\mathbb{Z}$ for which the following hold:

1. f and f^{-1} are piecewise linear with finitely many breakpoints.
2. All breakpoints lie in $\mathbb{Z}\left[\frac{1}{2}\right]/\mathbb{Z}$.
3. All slopes of f are in the set $2^{\mathbb{N}} = \{2^n | n \in \mathbb{Z}\}$.

The group T can be generated by the elements C and D shown in Fig. 2 and the following finite collection of relations[7]:

$$\begin{aligned} T = \langle C, D \mid \quad & C^3 = D^4 = (CD)^5 = e, \\ & \left[CDC, D^2(CDC)D^2\right] = \left[D^2(CDC)D^2, C\left(D^2CDCD^2\right)C^{-1}\right] = e\rangle \end{aligned} \tag{1}$$

S. Haagerup, U. Haagerup, and M. Ramirez-Solano use numerical methods to determine an approximate value of the expression $\frac{1}{12}\left\|\left(I + C + C^2\right) \times \left(I + D + D^2 + D^3\right)\right\|$. Formal results have shown that if the value of this expression is $2 + \sqrt{2}$ then F is amenable. The value that they find is

$$\frac{1}{12}\left\|\left(I + C + C^2\right)\left(I + D + D^2 + D^3\right)\right\| \approx 3.28$$

This result is combined with formal proofs that

$$\sqrt{2} + \sqrt{3} < \frac{1}{12}\left\|\left(I + C + C^2\right)\left(I + D + D^2 + D^3\right)\right\| \leq 2 + \sqrt{2}$$

Since the numerical calculation indicates that the value is less than $2 + \sqrt{2}$, they conclude (referring also to other results) that the group F *might* not be amenable.

3 The Contributions

The contribution by Henrik Kragh Sørensen, "The role of experiments in *Experimental Mathematics,*" presents the background for contemporary experimental mathematics. It takes us through some of the debates during the 1990s and considers the formation and consolidation of the journal *Experimental Mathematics*. The second part of the chapter considers in more detail various aspects of the journal

[7] The group commutator $[g, h]$ is given by the expression $[g, h] = ghg^{-1}h^{-1}$.

obtained using data-mining techniques. It finds that the journal publishes contributions by a large number of authors in a broad range of topics. The conclusion is that experimental mathematics (whatever it means) is not of marginal interest in the mathematical community. Finally, Sørensen examines whether there is a detectable difference in how mathematicians use the methods of "observation" and "experiment" in the articles published in *Experimental Mathematics*.

Mark McEvoy's "The New Four-Color Problem Revisited" runs through the main lines of the discussions that followed Tymoczko's (1979) seminal paper formulating the "new four-colour problem." The four-color theorem states that it is possible to color any map with four different colors so that no neighboring countries have the same color. This problem was originally formulated in the middle of the nineteenth century but only solved in the 1970s by Appel and Haken partially using a computer. Whether or not to accept this as a proof is the old four-color problem. The new problem is to decide whether the proof changes our conception of the properties of a proof.

McEvoy's contribution gives us a clear presentation of the main claims and lines of argument in the discussions that followed Tymoczko's article. The main topic concerns the a priori versus a posteriori nature of the proof (also taking into account the more recent developments in computer-assisted proofs, the development of proof checkers, and formal proof assistants) in the light of the claimed unsurveyability of the proof. Despite Tymoczko's claim (and others agreeing with him), McEvoy defends the view that computer-assisted proofs such as the proof of the four-color theorem can be a priori even though they may not be surveyable.

Giovanni Ferraro's "Proofs, Arbitrary Exemplifications, and Inductive Generalizations in Euler's Mathematical Practice" offers a glimpse of Euler's use of examples in his analysis of the infinite. In contemporary usage, examples are offered as illustrations of, e.g., concepts and theorems. In contrast, Ferraro shows that Euler uses examples for verification. Ferraro illustrates that examples in this sense play two different roles in Euler's mathematical writings. One role is as verification of a result by showing that the result holds for a particular, but generic example. This type of use is referred to as arbitrary exemplification. It is further possible to find cases where Euler uses what is referred to as inductive generalization, in the sense that a number of examples are used as evidence for a general result. Euler warns of using this procedure in general, however, giving examples of sums of infinite sequences that do not generalize.

In the case of arbitrary exemplification, a result is obtained without depending on essential properties of the considered example. In such cases, it is considered safe to generalize the obtained result: The procedure can be repeated in every instance. It occurs, for example, when Euler determines the differential of polynomials: There is no main difference between determining the differential of $y = x^3$ or the general case of $y = x^n$.

In the second sense, Euler used examples to verify proofs, to demonstrate that they are indeed valid and to convince others of the correctness of the procedures they involve. Ferraro argues that this should be seen as a way to demonstrate the soundness of the new calculus which at the time did not yet rely on a solid foundation. Euler demonstrates in multiple cases that different techniques give the same results to convince of the correctness and internal coherence of the calculus.

"Mathematical experiments on paper and computer" by Dirk Schlimm and Juan Fernàndez Gonzàlez takes us to the "back" of mathematics, discussing the different processes that have led to a result obtained by Gonzàlez. We learn about the different stages, from the first vague ideas to the generation of new concepts and finally the formulation of the final theorem and proof. Their chapter further illustrates how contemporary "experiments" can be done without computers – simply by a pencil and a notebook, or even on the frozen window of a bus. The considered result is a procedure to divide a line segment in any number of equal parts (and so also by a rational number) by only bisecting line segments.[8] Schlimm and Gonzàlez understand an experiment to consist of a setup, a process with an outcome, and an interpretation. The setup is defined as a "specification of an initial mathematical situation or configuration, such as a formula or algorithm with some initial parameters." It may, but need not, include certain expectations about the outcome of the experiment formulated in the form of a hypothesis. The hypothesis is evaluated by the outcome of the experiment. The process consists of a calculation or construction that can be done on paper, by a computer, or in the mind. Schlimm and Gonzàlez illustrate how their description of an experiment applies to the development of the considered theorem focusing on the variety of tools used, ranging from the initial doodles that sparked the first ideas and the ensuing explorations giving rise to different conjectures to the later systematic use of a computer program.

Irina Starikova's "Thought experiments in mathematics: from fiction to facts" consider the particular case of thought-experiments in mathematics. Starikova notes that philosophers have argued that thought experiments cannot exist in mathematics since experiments are a form of a posteriori reasoning whereas mathematics is a priori. Others have claimed that thought experiments are just a variation of mathematical reasoning that obviously depend on thought. In contrast, Starikova maintains that thought experiments do exist in mathematics and argues that they should be considered as an independent form of mathematical reasoning.

Starikova characterizes a mathematical thought-experiment as "a method that allows epistemic progress through experimental thinking, which extends the rules prescribed by a given practice." As such, thought-experiments play a role not just in (generating) proofs but also in the formation of new ideas and conjectures. While thought-experiments may draw on both sensory and physical experience, the mathematical ideas remain a priori.

The chapter is rich in examples illustrating their varied use of thought-experiments in mathematics. They range from simple examples such as the mutilated check-board to examples of how thought-examples play a role in contemporary mathematics. The latter include how to determine the diameter of a graph using sensory experience and the "zooming out" of Cayley graphs using our imagination.

Thought-experiments are sometimes – but need not be – accompanied by visual representations. Starikova further explains that thought-experiment is not just

[8] A previous well-known method to divide a line segment in equal parts depends on the stronger assumption that it is possible to draw parallel lines.

"experimenting in the mind"; the flexibility of our imagination is an important advantage of mathematical thought experiments. In this way, they extend both our deductive and visual intuition by introducing fictional elements. She points to the example of Hilbert's hotel where physical properties no longer hold, and that it is possible to remove physical properties or combine different mathematical properties, or even mathematical with physical properties.

Finally, having noticed that experimental methods permeate mathematics, Michael de Villiers & Niels Jahnke find it natural that they should be present also when teaching mathematics. As suggested by their title "The Intimate Interplay Between Experimentation and Deduction: Some Classroom Implications," they further emphasize the dual role between experiment and proof. By including experiments in the curriculum, they argue that it is possible to stimulate the natural curiosity of children. After all, mathematics is not just about reproducing solutions to known problems, but also discovering new relations and establishing by proofs that they hold. Experiments play a role in both of these contexts.

The chapter is a great source of inspiration for teachers who wish to include experimental practices in their teaching as it contains a large number of examples that can be (and have been) used for teaching purposes. It includes different aspects of experiments in mathematics, from the simple of guessing a result or checking the outcome of a calculation to the use of both physical and mathematical models.

Abstract

This chapter is devoted to discussions about the nature of experiments in mathematics during the formative period of *experimental mathematics* and to a quantitative and qualitative analysis of the journal *Experimental Mathematics* founded in 1992. Particular attention is paid to interpret the roles of experiment and observation in the mathematical practices surrounding *Experimental Mathematics*.

Keywords

Experimental mathematics · Observation · Numerical induction · The journal *Experimental Mathematics* · Mathematical debates in 1990s · Borwein · Zeiberger · Epstein · Digital philosophy of mathematical practice

1 Introduction: Experiment, Observation, and Induction

In the early 1990s, debates over new practices arose in the mathematical research community, sparked by enthusiasm and skepticism about the role of computers in research and the potential turn toward a more *experimental* epistemology of mathematics. Indeed, the theme was not entirely new (for the history of experiments in mathematics, see, e.g., Hazewinkel 1985; Goldstein 2007; De Mol 2014), but the focus was shifting during the 1990s.

These debates roared in many of the broad mathematical journals that serve as professional discussion fora, like the *Notices of the AMS*, *the Mathematical Intelligencer*, and the *Bulletin of the AMS*; but they also had more direct consequences for publishing research mathematicians. Before the end of the century, a new mathematical journal devoted to *experimental mathematics* had been established and consolidated, a number of *schools* (or perhaps better, *cultures*) had formed which might disagree on the philosophical issues but still professed themselves to be *experimental*.

A large proportion of the philosophical interest in *experimental mathematics* has centered on the possibility of deriving formal (deductive) knowledge from inductive evidence (Baker 2008, 2007; Van Bendegem 1998), or whether the computer and the ensuing unsurveyability (opacity) of computer-assisted proofs might make mathematical knowledge dependent on non-a priori knowledge (Van Bendegem 1993; Johansen and Misfeldt 2016; McEvoy 2008, 2013). These analyses have produced important corrections to standard views of mathematical proofs, such that today demands of *formalizability* or *explanation* of proofs require consideration of the role of externalizing epistemic steps of huge proofs. These are some philosophical results derived from the debates, but when practitioners disputed the roles of computers and experiments, they often had more concrete philosophical goals in mind.

In philosophically analyzing the emergence of this experimental approach to mathematical research, practitioners and philosophers have turned to many different philosophical frameworks, from the quasi-empiricism suggested by Imre Lakatos (Lakatos 1976), over broadly generalized accounts of experiments in science (Medawar 1979), to viewing the mathematical experiment as neither heuristic nor justificatory but *exploratory* in the tradition of philosophers of science (Bailey and Borwein 2011; Franklin 2005; Sørensen 2010; Steinle 2016), or discussing whether *experimental mathematics* is a field of its own or a *culture* which can transcend the ordinary mathematical subject fields (Sørensen 2016).

As a means of mapping these debates from perspectives in the philosophy of mathematical practice, Fig. 1 provides a conceptual mapping of discussions. The

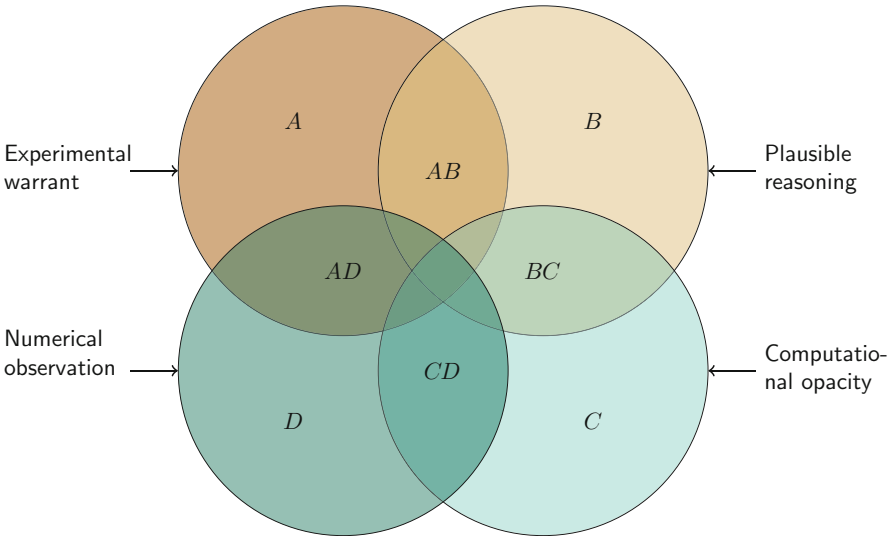

Fig. 1 Overview of the discussions neighboring *experimental mathematics* in the late twentieth century. In the following, attention will be focused on the intersection (*AD*) of *Experimental warrant* (*A*) and *Numerical observation* (*D*)

circles each signify a major topic of debate and philosophical analysis, which are introduced below. But particular attention should be paid to the overlaps between the circles, where discussions overlap and influence each other. Two of these overlaps (*AB* and *AD*) will be important in analyzing the emergence of a flagship publication of *experimental mathematics*: the journal *Experimental Mathematics* (other journals such as the *ACM Journal of Experimental Algorithms* also played important roles in shaping *experimental mathematics*, especially from a computer science perspective, but here the focus will be on *Experimental Mathematics*).

- The overlap *AD* between *Experimental warrant* and *Numerical observation* contains discussions about the extent to which experiment, observation, and induction might provide epistemic warrants in mathematics (for more on epistemic warrants of experiments, see also Lupacchini and Corsi (2008), Lolli (2008), and Sørensen et al. (2024)). One such discussion was the aptly titled paper "Strange Series and High Precision Fraud" in which Jon Borwein and his brother, Peter, show that even surprising numerical agreement for the first n instances of a complex formula studied experimentally and with the aid of computers does not guarantee the general validity of a result (Borwein and Borwein 1992): even high-precision verification is no substitute for formal proof. Consequently, the inductive support that calculating more and more digits of π or searching for bigger and bigger Mersenne primes has led mathematicians and philosophers to reaffirm that *numerical observation does not* belong in the epistemic toolbox of mathematicians.

- The overlap *AB* between *Experimental warrant* and *Plausible reasoning* points to the many examples where experimental results have been useful in the process of *conjecturing* and exploring plausible connections, often in search of counterexamples. Going back to Polya (1968, Vol. 1, Chap. 4–7), number theory had been one of the core examples of noncomputerized plausible reasoning and heuristics in mathematics. The discussion about drawing epistemic warrants from plausible reasoning is thus another recurring one, which typically is settled by pointing to a fundamental difference between heuristics and justification.
- The final circle, *C* indicating *Computational opacity*, is among the typical reasons against computers in gaining mathematical knowledge as *unsurveyable* computer-assisted proofs challenge the epistemic autonomy of the mathematician. This idea claims that mathematical knowledge depends on an autonomous epistemic agent who, alone and without external cognitive resources, comes to know a mathematical result by verifying it step by step. The view was succinctly expressed by Thomas Tymoczko as the *Simon Says Analogy* where a Martian (Simon) comes to pose a deep epistemic challenge to mathematics since he is correct in all he says, but humans have no means of inspecting his reasoning. Arguments about the necessity of epistemic autonomy is currently being challenged by work into the social epistemology of mathematics (Andersen et al. 2021a).

The relationship between induction through observation and experimentation has been a major recurring theme in the philosophy of science. In the nonformal sciences, empirical support is the sine non qua, and the distinction is often drawn from the stipulation that experimental knowledge is obtained through intervention, whereas observations leave the observed system untouched. If this distinction is transferred to mathematics, it requires expounding and interpreting the key notions:

- In mathematics, observation could be interpreted as "empirical support gained from (numerical) data" (Baker 2007, 2009, 2010).
- In mathematics, experiment could be interpreted as "in silico exploratory manipulation of mathematical objects" where the effects of changes can quickly be seen (Giardino 2022; Misfeldt et al. 2015; Sørensen 2010).

With these interpretations, the observations would connect with *D* (Numerical observation), and exploratory experimentation would influence the kinds of warrant to be drawn from experiments (*A*, *Experimental warrant*).

Therefore, the following sections are designed as follows: First, I provide some background on the scene for discussions about experiments and computers in mathematics around the turn of the century. Then I go into more detail about the different views about the experimental mathematics during that period, drawing out instances of both observations and experiments. Then I turn the focus to the founding and consolidation of *Experimental Mathematics* from its inception in 1992 to recent issues, combining quantitative analyses with short qualitative examples. Finally, before summarizing and add perspectives, I again use the combination

of quantitative and qualitative approaches to address the relations between observation and experiment in mathematical practice.

2 Background Discussions Among Practitioners in the Early 1990s

In 1992 an important step was taken in the consolidation of a new movement with mathematical research, when the journal *Experimental Mathematics* was founded. At least since the new proof of the *four-color conjecture* in the mid-1970s, mathematicians had to confront the introduction of a new epistemic tool in their arsenal: that of heavily computer-dependent practices of investigation and proof.

Although debate over the proof of *four-color theorem* – as it had then become – was initially engaging many in the community, the ensuing philosophical discussion focused mainly on one point, centered around the *unsurveyability* of large computer calculations (Tymoczko 1979). This in turn led to discussions whether mathematics was becoming a *quasi-empirical* and *a posteriori* science. Some of the concerns about quasi-empiricism went back to the controversy of Lakatos' philosophy of mathematics, indirectly drawing on Lakatos (Lakatos 1986) advancing a claim that is now a cornerstone of much philosophy of mathematical practice:

> The history of quasi-empirical theories is a history of daring speculations and dramatic refutations. (Lakatos 1986, p. 43)

However, to a large extent, these discussions shifted from the mathematical practice into the philosophical domain of epistemology.

Thus, when the discussion about the role of computers reemerged in the mathematical community in the later 1980s, it took a slightly different form. Desktop computers supplemented the mainframes which had proved to be both a bit inaccessible for the noncomputer expert mathematician and did not allow for the quick interaction that would be useful in *exploring* unknown territory.

In the first issue of *Experimental Mathematics*, the editors David Epstein and Silvio Levy published a "letter to the author," which remains on the article website in almost the same form and content. In that letter, the editors presented their "belief that theory and experiment feed on each other" (Epstein et al. 1992, p. 1). As a consequence of this belief, they explained it was deplorable that the means by which mathematicians *discovered* new results were mostly not shared.

Thereby, Epstein and Levy touched upon ideas that were also being presented in Davis and Hersh (1981), most vividly when Reuben Hersh introduced the idea that mathematics has a back and a front stage (Hersh 1991). The front stage consists of the logical exposition of proofs, but the back, he suggested, was full of the *dirty practice* that mathematicians engage with to arrive at the results to be presented – exactly the part of the practice that the mathematical community was lacking an outlet for, according to Epstein and Levy.

When Epstein and Levy introduced the new journal, they also suggested that mathematics might stand to gain from sharing their ideas at an earlier stage in the research process (Epstein et al. 1992, p. 1). This idea was, at the time, increasingly being addressed by the newly established `arxiv` (https://www.arxiv.org), where the first few mathematics papers were uploaded in 1992. And the same idea was addressed from a more skeptical point on the pages of the *Notices of the AMS* soon thereafter (Quinn 1995), expressing concern about the standards of mathematical articles if access to publication or (online) sharing became too easy.

Frank Quinn had already been debating the dual nature of mathematics – proof and exploration – in the years before, when his paper with Arthur Jaffe sparked another debate, this time in the *Bulletin of the AMS*. Jaffe, who would become president of the American Mathematical Society (AMS) later in the decade, and Quinn suggested a "synthesis of mathematics and theoretical physics" (Jaffe and Quinn 1993), in which mathematics would stand to gain from closer interaction between its "theoretical" and "experimental" sides (see Stöltzner 2005). To them, the theoretical part was responsible for exploring or conjecturing, which one could see as the backstage of Hersh. Thus, confusingly in the present context but in line with their view of physics, Jaffe and Quinn meant the "experimental" part of mathematics to be providing critical experiments and proofs. This entire suggestion was taken up by other prominent mathematicians, including Michael Atiyah who – after agreeing to much of the argument – addressed how the status of conjectures should not be diminished but recognized as a creditable part of mathematics (Atiyah et al. 1994).

Thus, around the time of the creation of the journal *Experimental Mathematics*, discussions were again running among prominent mathematicians about the relevance of conjectures and (more) open exploration and experimentation in mathematics.

3 Tasks of Computers and Experiments in Mathematical Practice

Having thus established a venue for publication, a next keystone in the consolidation of experimental mathematics can be said to be the exemplary books that came out of a group centered at Simon Fraser University in Vancouver, Canada. At Rutgers University in the USA, Doron Zeilberger was not shying away from provocation and controversy, publishing with his computer as a coauthor (e.g., Ekhad and Zeilberger 1996) – or even having Ekhad appear as the single author in papers on his webpage – and suggesting that mathematical knowledge comes with a price tag of the computational power required for it (Zeilberger 1994). Yet, the group forming around Jon Borwein and David Bailey set out another approach, showing the relevance of computers and experimentation by providing both results from their approach, as Zeilberger was doing, and philosophizing about it, as Zeilberger was also doing, but coating it in a form more amenable to their colleagues, and students and future mathematicians.

Around 1992, as the field and the journal were still finding footings, the precise meaning and expectations of *experimental mathematics* were still clouded. It seems mostly to have been a juxtaposition of words rather than a clearly defined concept. Part of this uncertainty had to do with how to classify the new content: was it a field or even a discipline of its own, were it a tool for other fields, was it comparable to parts of physics, or was it rather a community and a culture of mathematical practice such as has been suggested more recently (Sørensen 2016).

Indeed, setting out the scope of the journal in the very first issue, Epstein and Levy had given a first kind of definition of *experimental mathematics* – at least as it pertained to the journal under their editorship (and beyond). Highlighted in an introduction to the author, Epstein and Levy called attention to the following topics which might be publishable in the journal (Epstein et al. 1992):

1. Experiments
2. New theorems
3. Algorithms
4. Practical issues
5. Computer programs and software
6. Surveys
7. Essays, humor, polemic, and correspondence

Soon, however, the journal became "more professional" in the sense that the first three points came to vastly dominate its content.

About the relation between the first two points, as has already been shown, the editors saw experiments as an important part of mathematical practice, and they suggested the "essential ingredients of a paper published" in *Experimental Mathematics* are twofold: "some experimental aspect, and relevance to mathematics proper" (Epstein et al. 1992). Here the contrast between the new field and "mathematics proper" stands out. To Epstein and Levy, the role of experiments was to lead to insights that could be proved and thus be of interest to colleagues within "mathematics proper." In distinguishing experimental and applied mathematics, the editors reiterated that "focus is on work that will have a theoretical impact and contribute to the development of mathematical ideas" (Epstein et al. 1992, p. 1). Making it more concrete, Epstein and Levy suggested types of themes that would be relevant to the journal (closely adapted from Epstein et al. 1992, p. 2):

- Experiments that give rise to new theorems or new conjectures
- Experiments that lend support to existing conjectures
- Experiments that point to areas worthy of investigation
- New theorems proved with help of experimental results

In general, the letter to authors emphasized the "acceptability" of its results to the broader mathematical community: new theorems should be accompanied by "formal proofs" (which must mean rigorous proofs); computer experiments should be

reported so as to be replicable; and "results of computer experiments should be presented in such a way as to be graspable by humans" (Epstein et al. 1992, p. 2).

Epstein and Levy's conceptualization of the roles of experiments resonate with what leading experimental mathematicians Borwein and Bailey presented in (Borwein and Bailey 2004) and elaborated upon in Bailey et al. (Bailey et al. 2007), giving examples or short explanations. Borwein and Bailey presented eight roles for computation as part of their curiously named "experimental mathology" (Bailey et al. 2007, p. 11):

1. "Gaining insight and intuition – or just knowledge" from fact-gathering and aggregating data
2. "Discovering new facts, patterns, and relationships" from identifying uses of computation-intensive but well-known tools such as generating functions which might show relations even from sparse data
3. "Graphing to expose mathematical facts, structures, or principles" whenever techniques of visualization can be found, thus drawing on other perception systems
4. "Rigorously testing and especially falsifying conjectures," which draws on observations to either gain additional empirical support for a conjecture or refute it (see below)
5. "Exploring a possible result to see if it merits formal proof," which as a tool for strategic planning of proofs can focus human cognitive resources on proof sketches that pass preliminary exploration
6. "Suggesting approaches for formal proof," which complements the previous point of planning proof sketches
7. "Computing replacing lengthy hand derivations," which might have been an original point of using computers, but which can also be seen as outsourcing part of a proof sketch
8. "Confirming analytically derived results," which complements the search for refutations of conjectures, which can be settled by a single counterexample, and empirical support for conjectures, which do not (usually) provide epistemic warrant (see below) (Bailey et al. 2007, quotes from p. 13–15).

Previously, I have analyzed these eight roles as spanning heuristics (pt. 1–2), concept and result formation (pt. 3–4), and justification (pt. 5–8) (Sørensen 2016, p. 146). But in the following I will focus more on the role of experimentation and observation.

4 Experimental Mathematics Characterized by Practice

In 1994–1996, some of the early proponents of *experimental mathematics* had an exchange of views in general mathematical journals (*the Mathematical Intelligencer* and *Notices of the AMS*). Zeilberger, Borwein and Bailey, and Epstein and Levy all had something to say about the nature of *experimental mathematics*, which closely

reflect views discussed above. This debate ran at the same time as the Jaffe-Quinn debate, and they were closely related; yet, this exchange dealt more directly with the definition and nature of *experimental mathematics*.

4.1 Zeilberger and Andrews on Warrant from Unlikely Circumstances

This debate was initiated by Zeilberger's provocative opinion piece in the *Mathematical Intelligencer* entitled "Theorems for a Price" (Zeilberger 1994). In it, Zeilberger briefly presented some complicated-looking identities, which he claimed were "trivial" in *Wilf-Zeilberger theory (WZ)* (Petkovšek et al. 1996) once the use of computers had been properly accepted. Among the claims that Zeilberger made was that in the "day after tomorrow," theorems would come at a price and that "almost certainty" could be achieved for "an (epsilon) of the cost." The central step in his argument was to use Wilf-Zeilberger theory to transform identities into overdetermined systems of numerical ones, and then claim the solvability of such overdetermined systems as a "very good indication that the identity is indeed true":

> As absolute truth becomes more and more expensive, we would sooner or later come to grips with the fact that few nontrivial results could be known with old-fashioned certainty. (Zeilberger 1994, p. 14)

Zeilberger was knowingly provocative, and one of the first responses came from one of his collaborators, George Andrews. Aiming directly at the aspect of knowing *which* of the infinitely many identities are relevant, Andrews attached the autonomy of computer-discovered proofs:

> They [(Karl) Dilcher and the Borweins (Jon and Peter)] provide in the remainder of *BBD* absolute certainty about what is going on, and they provide concomitantly great insight and, dare I say it, beauty. Their paper is an almost perfect example of the computer aiding crucially in the discovery of facts but not in their proof. (Andrews 1994, p. 17)

In Zeilberger's account, Andrews not only missed the relevance of computer-discovered identities but also the more general insights usually gained from new results. To him, an identity might be a fact, but it does not (in itself) constitute mathematical knowledge – and herein lies the gist of the controversy, I think.

Zeilberger's vision of the "day after tomorrow" – with the hype and controversy so often shrouding predictions about computers and AI – was then made concrete by Andrews:

> Until Zeilberger can provide identities which are (1) discovered by his computer, (2) important to some mathematical work external to pure identity tracking, and (3) too complicated to allow an actual proof using his algorithm, then he has produced exactly no evidence that his Brave New World is on its way. (Andrews 1994, p. 17)

4.2 Epstein and Levy on Warrant from Systematic Experimentation

The next stage in the debate came when the editors of *Experimental Mathematics* tried to bring the epistemology of experimental mathematics on a firmer grounding. Calling upon Carl Friedrich Gauss, as they often have done, Epstein and Levy called for "systematic experimentation" as a way to discover new insights (David Epstein and Silvio Levy 1995, p. 670). And they advanced some of the arguments from the inauguration of *Experimental Mathematics*: Such processes should be made public, also to encourage sharing and using expertise in the community, an elaboration of the argument that tied it in with the Jaffe-Quinn debate.

> Note that we do value proofs: experimentally inspired results that can be proved are more desirable than conjectural ones. However, we do publish significant conjectures or explorations in the hope of inspiring other, perhaps better-equipped researchers to carry on the investigation. The objective of Experimental Mathematics is to play a role in the discovery of formal proofs, not to displace them. (David Epstein and Silvio Levy 1995, p. 671)

Addressing the role of computers, Epstein and Levy argued that "the introduction of the computer into mathematics has made more of a quantitative than a qualitative difference" (David Epstein and Silvio Levy 1995, p. 671). Using computers allows mathematicians to visualize and compute properties of, e.g., three-dimensional manifolds in the line of Bill Thurston, which have been published in traditional prominent journals (David Epstein and Silvio Levy 1995, p. 672).

Finally addressing the epistemic opacity of computer results, they again voiced an argument that have since become quite standard in the social epistemology of mathematics: "The danger of taking the results of a computer program on trust are not that different from taking a traditional result on trust" (David Epstein and Silvio Levy 1995, p. 672).

Thus, the editors of *Experimental Mathematics* made three points about *experimental mathematics* and their *Experimental Mathematics*:

1. Experimental mathematics is not (just) about looking for shiny objects but has a methodology of *systematic experimentation*.
2. Experimentally derived results can be formulated into traditional proofs that can be published in ordinary journals.
3. The introduction of computers is not quite the fundamental game-changer as some commentators had come to believe.

4.3 Borwein Et al. on Warrant from Crucial Experiments

The final piece of the debate to be included here is another attempt at providing philosophical grounding for *experimental mathematics*, this time coming out of the Borwein-Bailey group, whose purpose was to "[make] sense of experimental

mathematics" (Borwein et al. 1996). Framed as discussions about "discovery and verification" and "experiment and theory," they explicitly tied in with Zeilberger's piece but also, again, with the Jaffe-Quinn debate.

Some of the central points of this opinion piece were:

1. Experimentation (open ended) allows for serendipity.
2. As criticism of Zeilberger, they followed Andrews in emphasizing that mathematics "is all about insight" – not knowledge, individual facts, or computations.
3. The distinction of four different types of experiments introduced by the biologist and Nobel laureate Peter Medawar, who differentiated between
   (a) Kantian experiments which seek out the consequences of changing assumptions (or axioms)
   (b) Baconian experiments which try things out without any ulterior motive or direction
   (c) Aristotelian experiments which serve as demonstrations of already established facts
   (d) Galilean experiments which discriminate between possibilities, which provide confidence, also called *crucial experiments* (Borwein 2008; Medawar 1979).

Returning to their analyses of the roles of computers in mathematics, these points make it interesting to focus on the roles of data generation from uses of computers and experiments. On this issue, Borwein and Bailey and their coauthors also presented ideas in their books in the early 2000s, some of which are presented in a flowchart (Bailey et al. 2007, p. 7) showing the role of experiments in scientific practices as adapted to mathematical experiments. The flowchart is not thoroughly explained, but the following provides an interpretation useful in the subsequent analysis.

In their circular flowchart, four experiments are shown, each informed by "empirical knowledge": The first experiment has the form of observation and provides unstructured data. This leads to a second experiment in the form of intuition, which provides suppositions and hunches. Further, a third experiment has the form of scrutiny, resulting in questioning of the assumptions. Finally, a fourth experiment leads to results, which are also connected to formalism in the form of axioms and models through proofs and deductions. All experiments are informed by empirical knowledge and previous experiments. The results can either have the form of confirmation, giving "(almost) certainty about the validity of a conjecture" with a nod to Zeilberger, uncertainty in which no decision about a conjecture is reached, or refutation of a conjecture. However, the formation of the conjecture mentioned as the key result is nowhere included in the graph. Thus, one is led to interpret experiments 1 as connected to fact-gathering, experiment 2 as part of conjecture formation, experiment 3 as exploration of the conjecture, and experiment 4 as connecting experimental and deductive information about the conjecture.

As has been illustrated, practicing mathematicians were simultaneously engaging in advancing research in *experimental mathematics* and providing their approach

with a legitimization and a position within the mathematical community. One of the important consolidating factors for *experimental mathematics* was – as has been claimed above – the founding of the journal *Experimental Mathematics* in 1992. In the following, a combination of quantitative analyses and qualitative examples will provide a firmer grasp of what that journal intended and has achieved.

5 Empirical Studies of *Experimental Mathematics*

Over the past decades, philosophy of mathematical practice has come to establish itself on the spectrum of philosophy of science, drawing upon methods from a variety of disciplines including philosophy of mathematics, mathematics education, and sociology to answer philosophical questions about mathematical research practices (see Carter 2019; Rittberg 2019). These empirically informed studies of mathematical practices (or cultures as they are sometimes referred to) (see Löwe 2016; Kant et al. 2021) have drawn upon empirical methods such as interviews, observations, or questionnaires (see Inglis and Aberdein 2014; Misfeldt and Johansen 2015; Aberdein and Inglis 2019) and case studies (for a discussion, see Rittberg and Van Kerkhove 2019). These methods each shed important, new light on otherwise intractable aspects of mathematics as practiced by actual mathematicians. With the growth in available methods, the field is now at a stage, where the different approaches also should be capable of triangulation (see Löwe and Van Kerkhove 2019).

The present chapter uses another empirical method to study mathematical practice: that of corpus analysis. Drawing upon large corpora of mathematical texts combined with methods from statistics and machine learning, we can begin to access the vast *variety* of mathematical works, many of which are not singled out for case studies. In this vein, the digital study of mathematical practices allows us to begin to appreciate what is sometimes referred to as the *great unread*: We can begin to study dissemination of mathematical ideas, social aspects of mathematical practice, or the structure of mathematical corpora anew, this time grounded in large datasets and a new combination of quantitative and qualitative methods (for an exposition of this methodology, see Sørensen and Johansen 2024).

To get an impression and allow for analyses of the content of the journal *Experimental Mathematics*, I will use methods from this empirically grounded philosophy of mathematical practice based on large corpora of text. In the present case, I will work my way from general, summary statistics toward closer analyses. This combination of different tools then allows for some closer, but short, qualitative analyses, picked out by quantitative methods, thus giving them some empirical reasons for focus without claiming any kind of statistical representativity (Sørensen and Johansen 2024).

Thus, the method will be using bibliometric information about publications in the journal and linguistic analyses focusing on the information contained in titles and abstracts of individual papers. These methods allow us to address some of the ambitions of Epstein and Levy in founding the journal and some of the demarcations

of *experimental mathematics* that the journal has offered. Thus, I will be presenting analyses to answer questions such as:

- Who published in the journal? Which mathematical fields were represented in the journal?
- How was the experimental component of the journal framed?

Some of these questions arise from the background analyses in the previous sections, whereas others are more serendipitous in that they arose in the process of gathering and processing empirical data. For instance, it turned out that there might be something interesting to say from the data about the editors' goal of early sharing of conjectures and results.

Obviously, building quantitative analyses on short extracts such as titles and abstracts raises some methodological concerns: It is not immediately clear that abstracts reflect neither author attitudes nor philosophically interesting nuances of papers. To the first point, as argued in Hyland (2009), abstracts serve important roles in communication, in particular in framing and hedging results, so it is to be assumed that authors *and* editors will have invested in placing the right pieces of information in the very concise format of an abstract. This would also cover objections of insufficient language abilities of authors as a very large proportion of authors are native English speaking, and the editors invest effort in publishing a journal of high quality and interest to the community.

To the second point, the distinction between experiments and observations that interest me here may be an uninteresting distinction to mathematicians – if it is even recognized as a distinction to make. Practicing mathematicians may simply take the two to be synonymous, even without reflecting any ontological stances. Indeed, there are instances in the corpus where the two words occur in ways where they seem to be synonyms, but to address those, it is first required that we build a (quantitative) overview of the corpus.

The corpus from which the above questions are to be analyzed and answered consists of all research publications in the *Experimental Mathematics* between its beginning in 1992 (vol. 1, issue 1) and the last issue of 2022 (vol. 31, issue 4), a total of 124 issues containing 1175 articles with all the relevant metadata available. This corpus has an intermediate size for analyses: It is perhaps too big for human-only analysis, yet too small to draw definitive statistically significant conclusions about general representability. Thus, I am aiming for qualitative insights that can be backed by quantitative observations and visualizations.

The corpus was built by fetching the unique digital object identifiers (DOIs) of publications from the journal's webpage, and combining it with metadata such as title, authors, and abstract from the webpage of the individual article and metadata about the subject classification retrieved from the public API of *zbMATH* provided by the European Mathematical Society (EMS).

5.1 The Journal and Its Authors

The very first issue of *Experimental Mathematics* was published in 1992 and it contained eight research articles together with the information from its editors Epstein and Levy presented and discussed above. About a decade, Epstein and Levy could be proud of what might "well be the best issue" of the journal to date. Its volume had grown by almost 50% – from 420 pages to 640 pages – to make room for a large backlog (Epstein and Levy 2000). The evolution of the size of the journal is shown in Fig. 2 from which the increase in the *number* of papers during the first decade and the subsequent stabilization is clearly shown. This plateau after an early growth might indicate that the backlog has gradually been exhausted and, perhaps, that the acceptance criteria might have become higher. The papers in the very first issue stand out for three, interrelated, reasons: Some of their authors had already established great mathematical fame, the papers came from a great variety of mathematical fields, and there was little focus on the *experimental* aspects of the papers.

Among the authors in the very first issue, one finds such prominent names in contemporary mathematics as Barry Mazur and fields medalist John Milnor (Mazur 1992; Milnor 1992), whose main contributions to mathematics do not fall within

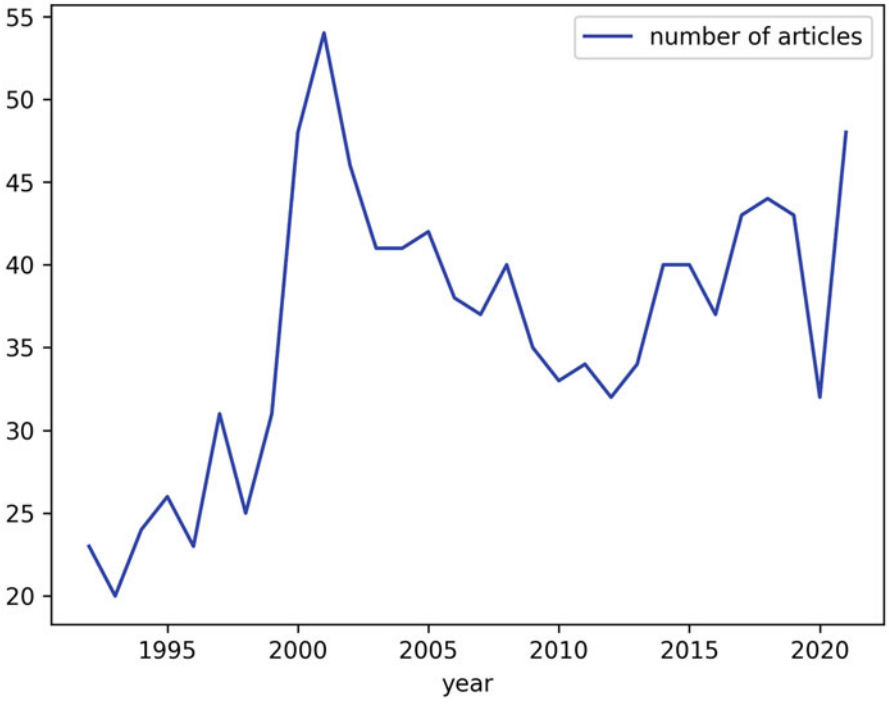

Fig. 2 Number of articles published in *Experimental Mathematics* 1992–2021. Publication metadata are extracted from the *Experimental Mathematics* journal webpage

experimental mathematics. Whereas Mazur's paper addressed conjectures and computational aspects, the paper by Milnor was more of a summary of previous research. Such contributions were no doubt partly influential in gaining immediate recognition of the journal within the broader discipline.

Other mathematicians, who became prominent in the *experimental mathematics* field, are noticeable for their absence. For instance, Zeilberger did not publish in *Experimental Mathematics* until 2006. The group around Borwein and Bailey also did not publish in *Experimental Mathematics* straight away. But when they started publishing there, they quickly rose to become the most prolific authors in the journal. As Table 1 shows, Borwein, Bailey, and their frequent collaborator Richard Crandall all published extensively, ranking top 5 as the most frequent contributors to the *Experimental Mathematics* among a total of more than 1900 distinct authors.

5.2 A Cross-Field Enterprise

The first issue also points to an interesting evolution in the distribution of fields over the first volumes. In the first issue, the mathematical subjects covered encompassed number theory and algebraic geometry which would be stable foci for the following decades. But they also included fields such as geometry (general or convex and dynamical) as well as dynamical systems and several complex variables, which would later figure less. This might suggest that the first issue included more fields where visualization was key than the later focus on fields where algebraic

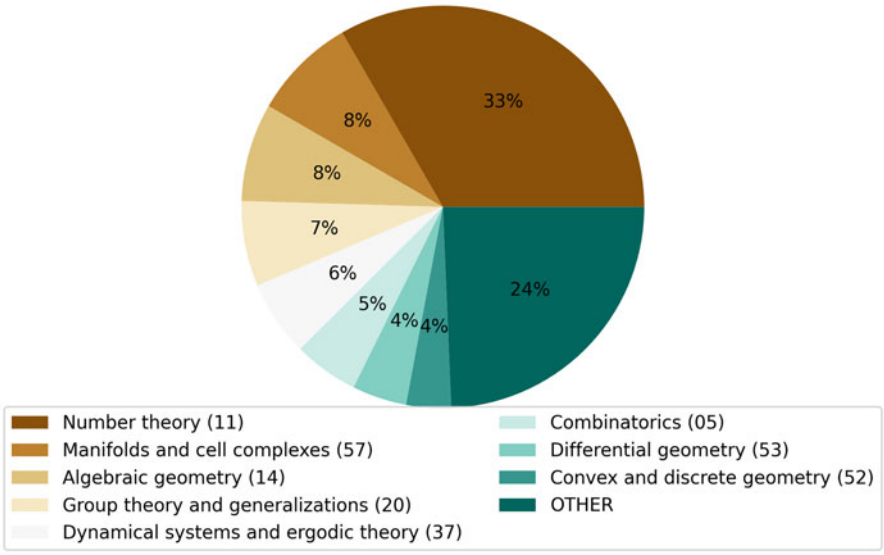

Fig. 3 Distribution of primary MSC classifications in *Experimental Mathematics*. The classification is drawn as the primary classification according to the MSC scheme as listed on zbMATH, using only the first two digits to indicate the major mathematical subject field

manipulation constituted a larger role of what computers contribute to mathematical research.

Figure 3 shows the total distribution of subjects in the *Experimental Mathematics*. Subjects are mapped by the primary classification according to the MSC scheme, and the first two digits of this primary classification are used to identify the mathematical subject field at the most general level; obviously this focus on primary classifications precludes other interesting and more fine-grained analyses of the mathematics included in the analyses. The category "OTHER" refers to classifications that each amount to 2% or less of the total corpus.

When the distribution is plotted over time, it is difficult to see general patterns, except for the dominance of number theory in the journal (see Fig. 4): If number theory – for some reason – plays a lesser role in a volume, the graph looks more erratic.

The most important information gathered from this quantitative analysis is visualization of the very broad spectrum of fields covered in the journal over the first years. Indeed, the first volume stands out as more varied, but over the entire time span, a clear dominance of number theory emerges in the journal with 33% of the articles classified as primarily belonging in that field (MSC 11) (for comparison, less than 7% of the articles on arxiv fall in the number theory classification, see more below). It is important to notice that MSC 11 is one of a number of fields to explicitly include a computational subfield: 11Yxx: "Computational number theory." Yet, a

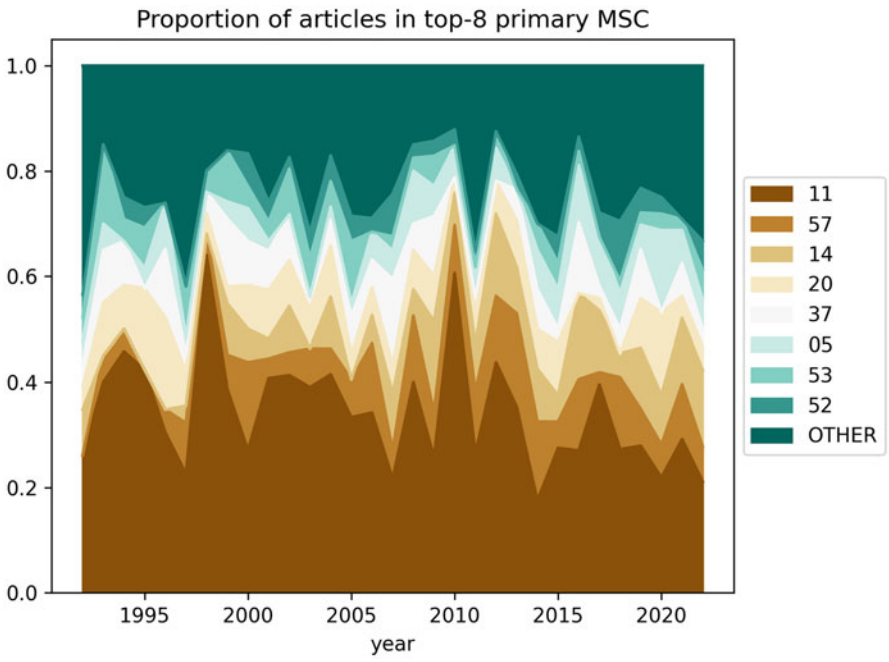

Fig. 4 Development of subject composition in *Experimental Mathematics* over time. Colors refer to primary MSC codes, see Fig. 3

Table 2 Indicators for `experiment` and `observation` written as regular expressions. All matches are case in-sensitive. Examples of matches given here are not exhaustive

Indicator	Regular expression	Example matches at start of word
Experiment	`r'\bexperiment\w*'`	`Experiment, experiments, experimental, . . .`
Observation	`r'\b(empirical\w*|data|observ\w*)`	`Empirical, empirically, data, observation, observe, . . .`

steady proportion of 25% of the articles published did not fall within the top 8 subjects which were each responsible for 4% or more of the corpus.

5.3 Experiments and Inductions: Quantitative Analyses

The primary theoretical focus of this section is the relationship between experiments and observations. To get at quantitative impression from the *Experimental Mathematics*, I chose to focus first on the framing that occurs in titles and abstracts of published papers, and I devised a set of indicators to pick out word-proxies for the topics of interest.

Two indicators were defined via regular expressions to identify experiments and observations (see Table 2). Two different approaches were then open: First to

compute and analyze the mere prevalence of these indicators, and second to use simple, but automated, linguistic analyses to see what objects and actions these indicator proxies point to.

These first quantitative forays show that the *experiment indicator* is found in 17% of the papers in the *Experimental Mathematics* corpus; in other words, almost every one in five papers explicitly refer to experiments or experimental methods or approaches in their titles or abstracts. Similar results show that fewer papers, 11%, refer to observations in their titles or abstracts, with observations being defined as in Table 2 (the frequencies should not be compared as the indicators are defined only to catch proxies).

Visualizations also show that the prevalence of the experiment indicator is slowly declining, whereas the observation indicator is slowly on the increase. The first part of this observation may be (at least partly) explained by a phenomenon like *obliteration by consolidation* when the experimental nature of the journal alone would render it superfluous to flag each paper as experimental. If this interpretation has any merit, the increase in the observation indicator becomes even more interesting.

In order to assess the extent to which these observations are specific to *Experimental Mathematics*, `arXiv` provides an easily accessible corpus of mathematical texts, albeit with the major limitation that `arXv` is *not* a journal, and papers are not refereed. Therefore this quality check is missing, and as refereeing is not only checking the validity of claims but also involves framing and narrative (Andersen 2017; Andersen et al. 2021b), this may be quite an important bias.

With this in mind, running the indicators on 450,000 mathematics papers uploaded to the `arXiv` during the period 1992–2022 can provide room for comparison. Extracting papers from these 31 years and filtering out the proxy categories for physics `(math.MP)` and computer science `(math.CS)` and the general categories math.HO and math.GM as well as the statistics category (math.ST), rather different pictures are found (for the `arXiv` categories, see https://arxiv.org/archive/math). Using the same indicators and metrics as above, one finds a proportion of 1.7% of papers having the experiment indicator and 6.2% having the observation indicator. Furthermore, the prevalence of both indicators are on a rise, steeper than seen in *Experimental Mathematics*. If anything, the first of these observations seem to lend support to the obliteration interpretation for *Experimental Mathematics* and point to this aspect of the `arXiv` as another question worthy of further study. It is *not* the case in general, that experimental (or observational) indications in titles and abstracts are on the decrease – rather the opposite.

5.4 Experiment and Observation: Linguistic Analyses

To get from the level of individual words – captured through the proxy indicators – to a higher semantic level, one might apply linguistic tools derived from natural language processing (NLP) tools. These tools are probabilistic in nature, and allow for the identification of different functions of tokens in a sentence through

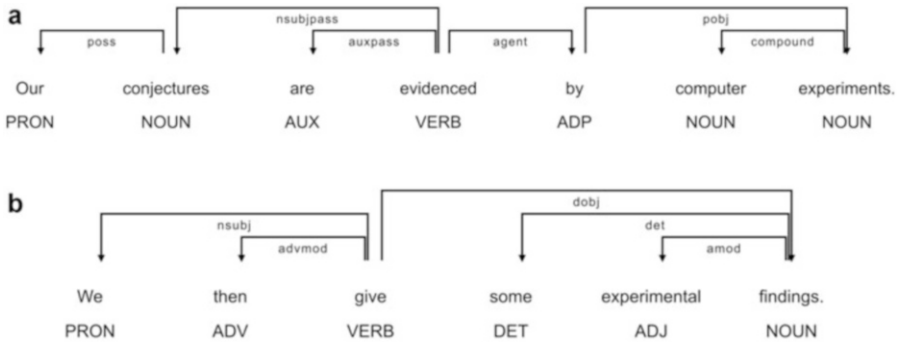

Fig. 5 Dependency graphs offer a way of analyzing linguistic relations on the level of sentences (de Marneffe and Manning 2008). In these two simple examples, a word matching the experiment indicator is shown with its dependencies. Similar graphs for verbs and adverbs can also be produced but these forms are rarer in the corpus. An arrow from *A* to *B* indicates that *A* is the *head* for *B*. (**a**) dependency graph of a noun; example from Mellit (2022) and (**b**) dependency graph of an adjective; example from Katz (2021)

Table 3 When experiments are adjoined in a noun chunk, the numerical or computational form of the experiment can be extracted. A third class contains those indescript chunks that refer to "some" or "our" experiments, etc.

Category	Extensive	Count
Experiment	4	32
Computer experiment	4	28
Numerical experiment	2	24

position-of-speech tagging (PoS) and structural-level analysis of sentences through *dependency graphs* as illustrated in Fig. 5 (spaCy 2021).

Focusing on the *experiment indicator*, it matches all nouns, verbs, adjectives, and adverbs. However, "to experiment" or "experimenting" are very rare in the corpus (total three occurrences), so the indicator is rarely a verb. The adverbial form "experimentally" is also quite rare (total 19 occurrences), referring to such experimental activities as studying, finding, confirming, discovering, exploring, or observing.

Among the 70 instances where the experiment indicator functions as a noun, we find their associated verbs which indicate the functions of experiments to include describe, suggest, study, or even lead. If there is an adjective connected to the noun, resulting in a so-called *noun chunk*, it is mostly to signify the "numerical" or "computational" nature of the experiment (see Table 3); some of these experiments were stressed to be particularly extensive.

Finally, among the 91 situations where "experimental" is an adjective, the most frequent associated noun is either evidence, data, or result, with an associated verb of

Table 4 A grounded coding led to six categories of roles of experiments as extracted from the tokens dependent on the experiment indicator. Here, the categories are shown together with their three most frequent forms

Category	Form	Total
Study	Study	14
Study	Explore	4
Study	Conduct	4
Result	Result	12
Result	Describe	9
Result	Find	8
Proof	Show	5
Proof	Confirm	4
Proof	Certify	1
Evidence	Evidence	19
Evidence	Datum	16
Evidence	Observe	6
Heuristics	Suggest	6
Heuristics	Inspire	3
Heuristics	Approach	2
OTHER	Lead	4
OTHER	Method	2
OTHER	Include	2

present, give, describe, or similar words. This may be indicating sentences describing how specific kinds of experiments (as indicated by adjectives) provide (as per the verbs) the mathematician with various items of interest.

To facilitate brief contextual and qualitative readings, a preliminary, grounded coding of the tokens dependent on the experiment indicator resulted in six categories and a miscellaneous code (see Fig. 4, Table 4).

Shifting attention to the *observation indicator*, it is similarly found that observations and empirical elements occur in the corpus. As adjectives, the token "empirical" is the most frequent match of the observation indicator (78%), and typically it is connected as "empirical evidence presents" or similar. However, the single instance of "observable" is interesting, as it encompasses many perspectives of this analysis:

> We confirm that several of the features that are predicted by the mathematical results are observable by numerical computation. (de la Llave and Petrov 2002)

From this one sentence, we see many of the indicators working together: the authors *confirm*, features can be *predicted* by *results*, and these *features* can be *observed* using computers. Thus, in what they call in their title an "experimental study," they use established results to conjecture extensions which are then shown to be in agreement with numerical observations. It might be that the authors are simply conflating different epistemic steps, and from the paper it is difficult to ascertain what constitutes the *experimental* nature of their study: The word is never explicitly used, but the paper *is* structured around the predictions, and evidence in the form of

tables and graphs is given *en masse*. Thus, the content supports the summary of the argumentative structure given here.

An even stronger claim for experimental and numerical warrants for results can be found in another abstract:

> They [certain "explicit algorithms"] are followed by numerical examples, which experimentally confirm main results of the article. (Enolski and Fedorov 2018)

This abstract is indicative of a specific type of numerical warrant that has to do with algorithms. Often, numerical experiments are undertaken to determine the efficiency or run time of algorithms (see also Sørensen et al. 2024). Here, the numerical experimentation actually confirms the *results* of the algorithms, and again the authors might simply have meant that the experiments are in agreement with the proved results. Even that would be very interesting, as one – at least from certain classical philosophical positions – might wonder what purpose an experimental verification could serve *after* the result had been formally (rigorously) proved. But the authors are not imprecise. In the paper, the experimental confirmation is given a context:

> Then we calculate [(defining) equations] by using the main Theorem 4.2 and, finally, see that the period matrices of the Jacobians and the curves share the same sets of absolute invariants. This provides an experimental confirmation of the main results of the paper. (Enolski and Fedorov 2018)

So the confirmation is not of a particular (even exemplary) case but a result of computing two defining properties and noticing that they correspond.

These two instances have shown a variation in epistemic warrants drawn from what seems to be inductive, at least numerical, examples. However, the corpus is also full of more heuristic uses of observed evidence in forming conjectures and beliefs. Here, two examples will have to suffice. In the following abstract, it is described how experimental evidence is found for certain properties that would merit proof:

> We also identify stationary solutions and periodic solutions in an associated problem, and find experimental evidence of hyperbolic behavior. (Colliander et al. 2013)

Here, the thing-to-be-proved seems rather well defined without the experiments. Another form of the heuristic use of evidence can be seen from this abstract:

> A conjectural density is derived from a single heuristic assumption, and experimental data supporting this assumption are given. (Stevenhagen 1993)

Here, the thing-to-be-proved is the result of an even vaguer form of heuristics – a single assumption – and experimental data serves to support the assumption and thus suggest the feasibility of reaching a proof.

A final example, and perhaps in a qualitative reading the most interesting, arises from the following indicator, as the verb "led" stood out and could not be given meaning from the quantitative, sentence (or abstract)-level data:

> Such experiments led to the results above. (Chas and Phillips 2010)

In the paper, it becomes more clear what roles the experiments played:

> Here is some numerical evidence, computed using the algorithm given in [Cohen and Lustig 87]; see [Chas and Krongold (09)] for a more detailed presentation (Aberdein and Inglis 2019). This evidence was in fact the motivation for the research presented here. (Chas and Phillips 2010, p. 131)

A footnote at the point (Aberdein and Inglis 2019) then points out where the Java program can be found online. The numerical evidence leads to two "Experimental Theorems," which serve as motivational theorems, called so but remaining to be proved (Chas and Phillips 2010, p. 131). The main proof is a long and complicated one, split into several partial results with proofs. At the end of the main theorem comes an entire section devoted to "experimental results and conjectures" (Chas and Phillips 2010, p. 144), containing another four "experimental theorems." The use of the term *experimental theorem* in this paper calls for some analysis, as it is – even in *Experimental Mathematics* – a rather unusual (and perhaps provocative) substitute for or adjugation to "conjecture." They stand out because they are labeled *theorems*, but *no* direct evidence is given for them. Instead, they formulate, in completely general terms, properties about the topological objects being studied. In fact, the statements could probably have been *real* theorems, if any evidence beyond induction from computational experimentation was known.

6 Conclusions and Perspectives

The first part of this chapter was devoted to present a background history of the debates and – sometimes – controversies that surrounded *experimental mathematics* in the infancy of computer-assisted experimental practices in mathematics. Particular attention was paid to outlining three different views on the possible epistemic warrants of experiments.

As analyzed, Zeilberger held that methods of checking the solvability of vastly overdetermined systems of equations provide "almost certainty," and that this would be sufficient except for *very* important mathematical results. Thereby, Zeilberger essentially drew on a very strong version of the position that "there are no true coincidences in mathematics" (see, e.g., Lange 2010), strong enough to serve as an epistemic warrant. As will be obvious, this position is a metaphysical one as much as any other position about the warrants of plausible or experimental reasoning.

From the side of *Experimental Mathematics*, another view was put out, when Epstein and Levy argued that *systematic* experimentation would be a sine non qua of

experimental mathematics and the (only) way toward drawing epistemic warrants from experiments. However, as can be extracted from Lakatos' reconstructions (e.g., Lakatos 1976), the right domain for systematic experimentation is difficult to ascertain beforehand. And the systematic approach may run into other types of bottlenecks when the domain becomes very large. To this latter point, the advent of increasingly powerful desktop computers may have alleviated some of the early challenges (Sørensen 2016), but it remains an unwinnable race between technology and mathematical ingenuity.

The third position, that of the group around Borwein, sought a middle ground by presenting what was subsequently incorporated as *exploratory experimentation*: A practice of experimentation that essentially transgressed the old divide between contexts of discovery (heuristics) and justification (proof). Initially thinking about mathematical experiments as similar to critical experiments that determine what is true and what is not, Borwein's philosophical point was limited to refuting conjectures. With the practice described as exploratory, the experiments could be guided toward forming useful concepts and proof sketches that would eventually lead to formal (i.e., rigorous) proofs. At least, this is a philosophically more coherent reading of the eight roles of computers in mathematics, that Borwein and Bailey repeatedly presented (Sørensen 2010).

Having outlined these positions in their larger historical complexity, focus shifted toward the role played by the journal *Experimental Mathematics* in shaping *experimental mathematics*, and particular importance was given to the relations between experiments and observations. But first, summary statistics allowed for answering some of the more general questions about the journal during its first 30 years of existence.

First, it was shown that on a number of parameters, set out by its initial editors, *Experimental Mathematics* has grown to be a success. Three decades into its life, it continues to publish papers of high quality from leading mathematicians – for instance, the recent fields medalist Peter Scholze has a recent paper published in the journal (Scholze 2022).

What is more, the almost 1200 papers published during these decades have a total of almost 2000 authors, indicating that the journal's body of contributors is quite large and stable. There have been some prolific authors like Borwein and Bailey, but more than anything, these numbers seem to indicate a high degree of collaborative authorship in *Experimental Mathematics*, although the average number of authors on papers in *Experimental Mathematics* is 2.07, which does not differ much from the value for all of mathematics when measured in the `arXiv`.

As a third quantitative finding, it was revealed that the broad interest from many different mathematical subjects that was part of the initial motivation has indeed been reached, and reached quite early on. Number theory has dominated the pages of the journal since the beginning, but a good number of other branches of mathematics also regularly find way into the journals, eight subject fields each accounting for more than 4% of the papers. Despite the high prevalence of number theory, this information still supports an interpretation of *experimental mathematics* not being

tied to any specific mathematical discipline, neither being a subfield of any mathematical field.

There are many more interesting phenomena around *Experimental Mathematics* that are open to quantitative analysis: For instance, the occurrence of an indicator *computer* seems to suggest a steady, but increasing reliance on computers in the journal, more so than in the `arXiv` corpus. This is not a stable finding in itself, but it does challenge the interpretation of *obliteration* invoked above, as computers surely are becoming more and more ubiquitous in mathematical research practice. And perhaps the proper way to gauge any such dependency would be to inquire about software rather than hardware, something that the corpora are also becoming more open to. Similarly, an indicator for *sharing incomplete or early results* seems to suggest that also on this point Epstein and Levy were successful. It would be interesting to know if publication of conjectures or preliminary results set *Experimental Mathematics* apart from other, otherwise comparable journals (if such even exist).

Among the many other interesting questions to pursue from this study, let me just outline one: In analyzing the subject fields covered in the very first issues of *Experimental Mathematics*, I found indications of a potential shift from some fields that mainly used computers to visualize objects toward fields where algebraic manipulation was a more important task for computers. This observation is only a hunch from the present data, but it aligns with overall historical developments at the time. So it may be worth further investigation, which, however, cannot be done from the great distance of titles and abstracts. Instead, we will need to closely analyze key papers, the identification of which is, however, prepared by the quantitative tools presented and used here.

Returning to the second research question posed above about observations and experiments, the quantitative analyses are – as expected – less productive by themselves, so they must be complemented by more qualitative aspects. This interaction between quantitative and qualitative methods is one of the strengths of an integrated approach to using digital and computational tools in studying mathematical practices. It allowed me to single out cases for closer inspection based on indicators suited to identify instances of (strong) epistemic warrants drawn from observation through induction or from (computational) experimental approach (i.e., the intersection *AD* in Fig. 1).

In studying a few cases which are not representative but still identified using general criteria, I found that indeed both experiments and observations can provide warrants in contemporary mathematical practice. Observations were often signaled by terms like “evidence” or “data,” thus highlighting the noninteractive role of the mathematician in accessing this knowledge. Rather, the computer (or other induction-producing practices) yielded data that serves its epistemic role as supporting or verifying conjectures.

Complementarily, experiments also ascribed epistemic role and warrant, both as a heuristic but also as supporting or confirming results. It is noteworthy that experimentation is here often used as a more *open* form of using computational (or other similar) practices. In general, the roles of experiments identified in these examples

closely mimic the roles which Borwein envisioned for computers in mathematical practice. And this should perhaps not come as a surprise, since Borwein and *Experimental Mathematics* were so connected.

In the end, the challenge of what can be learned from these analyses of *moderate size corpora* – larger than a human can survey in a reasonable time, yet not large enough to only be accessible statistically. The process has been to zoom in on the interesting philosophical practice from the outside, first through summary quantitative means, then through indicators leading to interesting instances, and finally to closer analyses on the level of paragraphs (abstract) or papers. One version of the challenge raised whether the phenomenon being studied is not just a mirage – an artifact brought about by accidental factors such as imprecise language or lack of philosophical finesse. As answer to such a challenge it helps to notice that mathematicians are often refined in using the terms, in particular in putting them together to bring about nuance in their argument. Thus, it is appropriate that the opening words of the abstract of Gronau and Wagenmakers (2018) function as an overall conclusion of this chapter:

> Many questions in experimental mathematics are fundamentally inductive in nature. (Gronau and Wagenmakers 2018)

1 The Traditional View of Proof and the (Old) Four Color Problem

According to what one might label the traditional view of proof in mathematics, proofs have the following characteristics. They are knowable a priori, the knowledge they provide is certain, rather than merely probable, they are surveyable, and, because of these other features, a mathematical proof is convincing to one who understands it. Opponents of this view typically drew their motivation not from the study of mathematics, but rather from a more general antipathy to apriority in epistemology and necessity in metaphysics (Mill, Putnam and Quine all spring to

mind here). Tymoczko (1979) provides a different sort of challenge, taking as its cue a development within mathematics itself, rather than being based on philosophical scruples over apriority or necessity.

Tymoczko's challenge famously uses the (Appel et al. 1977) computer-assisted proof (CAP) of the Four Color Theorem (4CT) as its starting point. The problem to which the 4CT provided the solution was the problem of whether all countries on a map could be colored with only four colors in such a way that no neighboring countries were of the same color. The positive answer to this question, established in 1977, was provided, in part, with the essential aid of a computer. Appel, Haken and Koch built on work by earlier researchers, to the effect that certain configurations of countries (the "reducible" configurations) are not possible in the smallest five-colored maps, because they can be replaced by smaller configurations (resulting, contradictorily, in a yet smaller map). Note next that a configuration is said to be unavoidable if every map contains a member of the set. (Appel 1984, 36–7) notes that the theorem would be proved once an unavoidable set of reducible configurations could be obtained. He continues:

> Our proof consisted of providing such a set of reducible configurations (and checking by computer that all members of the set were reducible) and showing by hand that the set was unavoidable.

Put simply, the CAP of the 4CT shows that "every map contains a reducible configuration and hence there can be no smallest map requiring five colors, thus no map at all can require five colors" (Appel 1984, 36). Crucially, because there were between 1400 and 1500 configurations, and 1200 computer hours (at the time) were needed to check these configurations, the proof is too long to be surveyed by a human mathematician.

2 Tymoczko's Conclusions: The New Four Color Problem

The old Four Color Problem has thus been solved. The New Four Color Problem, arising from consideration of certain aspects of the 4CT is a philosophical question about what a proof is — whether it must be surveyable, formalizable, convincing, and whether our understanding of proof must be revised in the aftermath of the 4CT, and, if so, how (and if not, why not). Broadly speaking, it is a philosophical question about the essential nature of proof and how that nature is affected by the role of computers in mathematics. Tymoczko (1979, 57) tells us that his goal is "to raise the question of whether the 4CT is really a theorem." He is quick to add that he agrees that the CAP of the 4CT has definitively established its result, and that he has no desire to dictate to mathematicians what is or is not a theorem. However, Tymoczko (1979, 58) suggests that:

> [I]f we accept the 4CT as a theorem, we are committed to changing the sense of 'theorem', or, more to the point, to changing the sense of the underlying concept of "proof.

As Tymoczko (1979, 59) sees it, the three main criteria of traditional proofs are that they are convincing, surveyable, and formalizable. One way in which the 4CT creates trouble for the traditional view of proof as Tymoczko has characterized it is that it "does drive a wedge" (Tymoczko 1979, 59) between the latter two criteria. More troubling still for the traditional view of proof (Tymoczko 1979, 63) finds the appeal to an unsurveyable CAP means that the 4CT has been established "on grounds that are in part empirical."

Thus, on the assumption that the 4CT is indeed a genuine proof, a number of what the traditional view of proof held to be essential characteristics of proof seem to fall away. Most obviously, the proof does not seem to be surveyable. And, if surveyability is required for apriority, then the proof does not seem to be knowable a priori. Nor can it be said to be convincing, at least not in any sense beyond being convinced that the software and hardware have functioned correctly to give us the correct answer to the problem. Moreover, due to the possibility that an undiscovered error may lurk somewhere in the unsurveyable proof, it seems that the knowledge provided by the theorem is merely probable rather than certain. The new 4CT problem, then, is that of how we should understand proof in the light of such unsurveyable CAPs being accepted as proofs.

Before proceeding to the main body of the article which examines the various responses made to this new 4CT problem, I want to briefly consider an analogy Tymoczko uses in support of the claim that unsurveyable computer results must be established on empirical grounds, and thus are not knowable a priori (Thanks are due to an anonymous referee for pushing me to include discussion of the Simon analogy here.). Tymoczko (1979, 71) considers the hypothetical history of Martian mathematics, which proceeds much as our own, until the arrival on Mars of a genius named Simon. Under Simon's guidance, Martian mathematics made great strides. Eventually, however, Simon began producing proofs which included phrases such as "Proof is too long to include here, but I have verified it myself." On occasion, Martian mathematicians could not reconstruct the reasoning which had gone on behind these new "lemmas," but such was Simon's prestige that they accepted these results under the general heading "Simon Says." Tymoczko concludes firstly that Martian mathematics under Simon is not a legitimate development of mathematics, and secondly, that we are in a similar position with respect to our appeal to unsurveyable computer proofs.

Given Tymoczko's description of the case, the first of his conclusions seems unobjectionable. The second, however, is dubious. A natural response here is to note (as Tymoczko 1979, 72–74) does) that there are important differences between the position we are in with regard to computers, and the one that the Martians are in with regard to Simon. One such difference is that we (i.e., members of our community) designed the computer. The fact that we designed the computer gives rise to other, more significant differences between the computer case and the Simon case. The computer is designed to do a certain job: it is designed to follow programs. We know what program the computer is supposed to be executing. We can, therefore, as often as we choose, check to ensure that the computer is in fact executing this program. Furthermore, the proofs a given computer discovers can be checked by others.

Random portions of these proofs can be hand-checked by human mathematicians. The program may be tested by having a computer verify already established proofs. If the computer failed such tests, we would no longer believe its results. In the case of Simon, the Martian mathematicians did not design him, and at least some of the tests available in the case of computers are not available in his case. They cannot, for example, open him up and examine his inner workings. Nor can they assume, from the fact that he has given the correct answers in verifiable cases, that his answers in the unverifiable cases are likewise correct. He may be lying. He may have lost his ability, and be attempting to protect his prestige. It is true that, in the case of the computer, it might somehow have lost its ability, but this is exactly the sort of thing that can be checked, if desired, simply by running tests on whether it is executing its program. No such check is available in the case of Simon, since no-one knows what his "program" might be.

Having considered some of these differences between Simon's case and our own, Tymoczko (1979, 72) observes that computers are, unlike Simon, not just authority, but *warranted* authority. And this leads us to the real point of the analogy: if we accept unsurveyable CAPS but not Simon's appeals to his own authority, that can only be because we have evidence for the reliability of the former, but not the latter. We thus "admit evidence for the reliability of computers into a philosophical account of computer-assisted proofs" (Tymoczko 1979, 72). And, for Tymoczko (1979, 74), that evidence, being largely a matter of engineering, physics and program checking, is empirical. These claims, about whether and how the ineliminable use of computers introduces an empirical element in our warrant for unsurveyable CAPS will be taken up in detail in Sects. 4, 5, and 6 below.

3 Response 1: Denying the Legitimacy of the CAP of the 4CT

Faced with the claim that we now have an unsurveyable proof knowable only a posteriori, one forthright defense of the traditional view of proof in mathematics would be to simply deny that the 4CT is a proof. (Brown 1972, xii), for example, claims that the CAP of the 4CT is not a proof, since it has failed to establish a crucial proposition. However, as Swart (1980, 698) notes, Brown doesn't say which proposition it is that the CAP fails to establish, so we cannot evaluate his reasoning here. Shanker (1986, 410) also denies that the CAP of the 4CT is a proof. He takes a Wittgensteinean view according to which the role of proof in mathematical language is to "establish the rules for applying mathematical concepts." To play this role, proofs must be surveyable. Since this CAP is unsurveyable, it cannot play the essential role in mathematics that proof does, and thus is not a proof at all:

> (I)t makes no sense to speak, as Tymoczko supposes, of Appel and Haken 'proving' the 'four-colour theorem,' let alone of their 'proof' forcing us to modify our understanding of the concepts of proof and theorem.

Azzouni (1994, 170) also expresses doubts that CAPs are proofs at all. For Azzouni, unsurveyable verifications such as that of the 4CT "are really not proofs at all." Rather, computers supply:

> empirical existence claims for mathematical proofs, existence claims that, because of the limitations of human capacity, cannot even be checked *by the mathematical community as a whole* by examining the proof the computer has purportedly generated.

Rather than being genuine proofs, unsurveyable CAPs are "empirical demonstrations that certain proofs exist."

A less strident version of this strategy is to hold that even if the 4CT is indeed a proof, it is not a proof in the fullest sense — perhaps because it is insufficiently enlightening, or fails to shows unexpected connections between previously disparate areas of mathematics, or seems unlikely to prompt further fruitful research. For example, Rota (1997, 186) observes that verifications (i.e., arguments that list all possible cases relevant to establishing the truth of a particular assertion, and show that, for each case, the assertion holds true) are not all accepted as proofs. In particular, for our interest here, the 4CT is a verification which "falls short of being accepted as a proof—despite its undeniable correctness." For Rota, what is missing for such a verification is that it fails to give "satisfying reasons why a conjecture should be true" (Rota is sometimes willing to apply the term 'proof' to a verification like that of the 4CT, but he always qualifies such usage: "Verification is proof, but verification may not give the reason." (i.e., a verification may not give satisfying reasons why the relevant conjecture is true (Rota 1997, 220). Sometimes quotation marks are called in to do the qualifying: "This "proof" was the first verification of a major mathematical theorem by computer."). Rota (1997, 190) compares Appel and Haken's CAP with Wiles's proof of Fermat's last theorem:

> The actual value of what Wiles and his collaborators did is far greater then the mere proof of a whimsical conjecture. The point of the proof of Fermat's last theorem is to open up new possibilities for mathematics. . . . They develop a host of new techniques that will lead to new connections between number theory and algebraic geometry. Mathematicians of the future will benefit from Wiles's lead. They will find untold new applications of these newly found methods to the solution of other problems, even to problems of great practical interest. The value of Wile's proof lies not in what it proves, but in what it opens up, in what it makes possible.

In contrast, Appel and Haken's CAP "fails to open up any significant mathematical possibilities."

Along similar lines, Rav (1999, 2) sees the "essence of mathematics" as residing in:

> [I]nventing methods, tools, strategies and concepts for *solving problems* which happen to be on the current internal research agenda or suggested by some external application. [note elided] But conceptual and methodological innovations are inextricably bound to the search for and the discovery of proofs, thereby establishing links between theories, systematising knowledge, and spurring further developments.

Merely arriving at a truth value for a putative theorem by means of an unsurveyable CAP, we fail to "convey the links, inter-theoretical connections, strategies and overall mathematical knowledge embodied in these methods" (Rav 1999, 26) ((Hirsch et al. 1994, 189) is another who sees the 4CT as a diminished form of proof. In his response to (Jaffe and Quinn 1993), he asks rhetorically, "Are we now to consider the 4-color theorem as proved in the same sense as, say, the prime number theorem?" Though (Hirsch et al. 1994, 188) is also skeptical of the human produced, but unsurveyed Finite Simple Groups proof (Mackenzie 2001) and (Mackenzie 1999) are good sources for other views of this kind. (Mackenzie 2001, 321) quotes Yuri I. Manin: "A good proof is a proof that makes us wiser. If the heart of the proof is a voluminious (sic) search or a long string of identities, it is probably a bad proof." Paul Halmos is cited as remarking that "The present proof relies in effect on an Oracle, and I say down with Oracles! They are not mathematics'" (Mackenzie 2001, 102). A final example is taken from Bariwise, who, while discussing automated formal proofs in general rather than the 4CT specifically, observes that: (I)t could be that the best proofs (in the sense of being most enlightening or easiest to understand) of a program's correctness will use methods, like symmetry considerations, that are not adequately modeled in the logician's notion of formal proof, and so which would not be deemed correct by some automated proof checker designed around the formalist's model (Barwise 1989, 849).).

However, whatever view one takes as to whether the CAP of the 4CT is or is not a proof, denying that it is one doesn't so much dissolve the problem as relocate it. For, suppose we agree that the CAP of the 4CT is not a proof. Then Tymoczko's claim that we must rethink proof doesn't follow —there is, ex hypothesi, no empirical, less-than-certain unsurveyable *proof* which forces such a rethinking. But we are left facing similar issues about mathematical methodology in general. For even if not a proof, the CAP has established the truth of the theorem in a way that is arguably empirical, less than certain and unsurveyable. We must rethink our view of mathematical methodology to accommodate the undeniable fact that mathematicians accept this way of doing things (even if it is not their preferred method).

Unless, of course, we think the 4CT hasn't introduced into mathematical practice anything significantly novel.

4 Response 2: Nothing New Under the Sun

A second common line of response to Tymoczko's paper argue that the features Tymoczko sees as raising new challenges to our view of proof are in fact already present in human produced mathematics ((Prawitz 2008, 87–88) and (Secco 2017, 294) observe that one can categorize the majority of early responses to 4CT according to whether the author thinks the CAP introduces anything new into mathematics, and, amongst those who deny that it does, according to their view as to whether mathematics has always been either a posteriori or a priori.). Teller (1980) is an early example of a response to the effect that the 4CT does not introduce any philosophically new element into mathematics. For Teller (1980, 798), the role of the

computer in the 4CT is simply an extension to our surveying capacities — not a change in our concept of proof. Such novelty as there is in the 4CT "is in the means of surveying, not in the means of proof" (Teller 1980, 799). Levin (1981, 84) points out that even unsurveyability is not new. After all, "the whole of traditional mathematics may already be unsurveyable by one man in a lifetime" (Moreover, there are humanly produced proofs which have not been surveyed by any individual human. See for example, the proof of the Classification of the Finite Simple Groups. This proof was announced in 1979 by a group of mathematicians lead by Daniel Gorenstein. The proof consisted of a collection of connected results written down in various places, totaling over 10,000 pages (Barendregt and Wiedijk 2005, 2532).). For Levin (1981, 86), the moral of the introduction into mathematics of CAPs, whether unsurveyable or not, is merely that " the speed of computation has increased, but no qualitative change has taken place in mathematical method." One might here object, with Bassler (2006, 117) that such moves pay insufficient attention to the tension Tymoczko finds between surveyability and formalizability. Indeed to argue in the way Teller and Levin do here is in effect to reject Tymoczko's claim that surveyability is properly conceived of as a criterion of traditional proof. Teller (1980, 802), however, does not see unaided human surveyability as being criterial for what counts as a proof, and offers a slippery slope argument to the effect that it cannot be:

> Consider a race of organisms very like humans who do something which certainly looks just like what we call mathematics, and a second race similar to the first, and so on until we get to objects that look more like computers than people. Is mathematics a sliding conception, or are we really to suppose that we can draw the line somewhere and say the creatures on our side of the line do mathematics and those on the other side do something else?

Teller (1980, 798) is explicit: "surveyability is not part of what it is to be a proof in our accustomed sense."

However, regardless of whether surveyability is properly taken to be criterial for proof, unsurveyability does raise the possibility of there being hidden errors within the proof. Here, defenders of the traditional view (e.g., (Teller 1980, 800) have once again denied that this introduces a novel factor into mathematics; after all that we might raise similar worries about humanly surveyable proofs. Swart (1980, 703) too tells us that the possibility of hidden errors due to bugs or hardware problems are "nothing other than errors of logic, no different in essence from errors that crop up in proofs that have nothing to do with computers." And, while the computer is fallible, and we can raise worries about software and hardware malfunctions, Teller 1980, 801) observes that "Tymoczko gives us no grounds for thinking that the fallibility of computers and mathematicians are relevantly different."

Levin (1981, 82) argues that any argument from the possibility of error due to machine or program error would apply just as easily to traditional mathematics:

> This undesirably strong consequence is due to his emphasis on the fact that the computer is a physical object. For surely human beings and their workings are also physical objects, just as subject to physical laws as computers. If error is possible in computer results because of the

> (highly confirmed but) unproven theories that describe them and their programs, then the same possibility presents itself whenever human mathematicians work out proofs by themselves. . . . . Our wiring is subject to physical laws; indeed, we humans are prey to all sorts of mishaps- inattention, boredom, forgetfulness, slips of the pen or tongue, unconscious urges to fail – that computers escape.

(Levin notes that this line of argument might appeal to some empiricists (as of course it does to Detlefsen and Luker). Though she does not argue that such a position is false, she notes that Tymoczko could not accept it, as he is arguing that the 4CT gives us a *novel* line of argument against apriority.) Detlefsen and Luker (1980, 817) agree that CAPs introduce nothing essentially new, but contra Swart and Levin, they hold that this is because human proof has always been empirical in character. Approvingly citing work by Cerutti and Davis, they note that properties that are "in principle quite like those attributed by Tymoczko . . . to computer-assisted proofs can, with equal warrant, be attributed to human proofs" (Detlefsen and Luker 1980, 806). In particular, while we might worry, regarding CAPs, about faulty or buggy programs, or false initial data, human mathematicians are subject to fatigue, and to limits regarding memory and knowledge ((Resnik 1997, 151) makes a similar claim to argue that all of mathematics is empirical.).

Detlefsen and Luker (1980, 807–808) argue further for the claim that the introduction of computers to mathematics does not change its epistemological status on the grounds that both calculation and the act of surveying a proof are empirical. With respect to calculation, they note that, when a mathematician follows (e.g.,) Gauss's proof that the sum of the first 100 integers is 5050, she undertakes a "substantial" amount of calculations. And, for Detlefsen and Luker (1980, 808), our confidence in these calculations is based on four assumptions:

(i) That the underlying algorithm to be used is mathematically sound
(ii) That the particular program to be used is a correct implementation of this algorithm
(iii) That the computing agent correctly executes the program
(iv) That the reported result was actually obtained

Whether we are talking about a computer or human produced proof, (ii)–(iv) concern facts ascertainable only empirically. If these are part of the warrant in a proof like Gauss's, it would follow that proofs involving calculation — whether undertaken by human or computer — are empirical, and thus that at least much of traditional, human produced mathematics is empirical.

Moving to the argument from the act of surveying a proof, Detlefsen and Luker (1980, 816) argue as follows:

> If, as Tymoczko says, a proof is a unit of reasoning that needs nothing outside itself to be convincing and if, as seems clear, in order for a proof surveyed first hand to be convincing we must believe in the reliability of our survey, then, since that reliability is not something amenable to traditional, surveyable proof, we may conclude that the appeal to first-hand

> survey introduces the same kind of method into mathematics as is introduced by the appeal to computers.

If, then both computation and surveying a proof are themselves empirical forms of warrant, then all of traditional mathematics cannot avoid "the presence of empirical elements in mathematical proof" (Detlefsen and Luker 1980, 817).

Detlefsen and Luker's arguments that both the 4CT and traditional mathematics are empirical cannot be assessed without paying closer attention to the issue of what makes a sequence of reasoning a priori or empirical. It is to this latter issue that we now turn.

5 Response 3: Proofs Are A Priori if They Involve Only A Priori Steps

One obvious way of understanding a piece of reasoning to be a priori is to count it as such provided all of the steps contained within it are a priori licensed steps, which make no warranting use of sensory observation. Swart (1980, 701), for example, has it that mathematical theorems are a priori truths, regardless of how they are discovered, where for him, such truths are *in principle*, if not in practice, discoverable "without recourse to sense experience of the physical world." Various authors have issued a challenge to make precise what is meant by this type of 'in-principle' clause. For example, Kripke (1972, 34–35) asks what is meant when we say that something may possibly be known a priori: "And possible for whom? For God? For the Martians? Or for People with minds like ours?" Resnik (1997, 155), along similar lines, urges that the issue about apriority is an issue about what *we*, rather than some ideal being (or some in-principle version of us), can know a priori. Resnik grants that ideal beings could have a priori knowledge of humanly unsurveyable proofs, but insists that *we* cannot. However, Swart has a response here. For Swart, what makes a sequence of reasoning a posteriori or a priori is the nature of the steps in the reasoning. If all of the steps in a given proof are a priori, then that proof — even if unsurveyable — is a priori (I have defended a move of this type (though without Swart's commitment to this being equivalent to "in principle" a priori knowable). (Johansen and Misfeldt 2016, 119) criticize this kind of view as an unacceptable form of logicism. Mathematics, according to this reading of my view, is a matter of proofs and axioms, and the latter are true by definition. Thus, CAPs are a priori, because they are analytically true. In the two papers they cite (McEvoy 2008; McEvoy 2013), my main goal was to defend the apriority of mathematics, and I thus did not focus on where mathematics fell on the analytic/synthetic divide. But I am not committed to a logicism about arithmetic. For consider, axioms, may be synthetic, rather than analytic. This may hold, moreover, not only for established axioms, but for novel candidate axioms, which owe (a significant part of) their plausibility to fruitfulness considerations. See, e.g., (Gödel 1983), (Katz 1998, 197).). Moreover, for Swart (1980, 701), if we do not add the "in principle"

clause to our understanding of apriority, then mathematics has been a posteriori since early mathematicians first drew drawings in the sand.

How does this view of apriority handle Detlefsen and Luker's arguments that calculation and surveyability (whether undertaken by human or computer) render mathematics empirical? Let us take these in order. To begin with the former, it is difficult to see why the presence of calculation of instances should render empirical a piece of mathematical reasoning. After all, there seems no reason why one calculating instances involved in a relatively brief proof would not have a priori knowledge of the conclusion of that proof. One could assure oneself, for example, that there is only one even prime in the first one hundred natural numbers, and one could do this by mentally calculating instances. The knowledge one would arrive at by this process seems archetypical a priori knowledge ((Prawitz 2008, 92) holds that once the number of calculations required in a proof gets to the point where they cannot simply be incorporated into the body of a humanly surveyable proof, but instead require a computer "then the proof is not entirely deductive, and there is the undeniably epistemological consequence that the theorem is known only a posteriori." At least some of the critics of Tymoczko (e.g., (Swart 1980), (Levin 1981), (McEvoy 2008), and (Krakowski 1980)) do not contest the claim the proof is known only a posteriori (even while arguing that is nonetheless an a priori proof). But why think the proof is not deductive? (Prawitz 2008, 84) operates with a view of proof that is tightly connected to our grounds for making assertions (rather than with a view of proof as being a formal structure). For him, the "most crucial epistemological function of deductive inferences and proofs" is that they "furnish us with conclusive grounds for asserting the conclusions." And, given that nobody could survey the proof in its entirety, no-one has such conclusive grounds. In this connection, Prawitz holds that derivations are "codifications of proofs" rather than "answering the question of what a proof is." However, if one does not share Prawitz's view of the relative centrality to proof of grounding assertions as opposed to formalization, one need not concede that the 4CT is not deductive.). And, with respect to factors (ii)–(iv) from Detlefsen and Luker's list above, we can here, following Burge (1998) distinguish between what is actually part of the warrant in a given proof or sequence of reasoning, and what merely allows one access to that warrant. In a proof, the warrant is based on the inferential connections between lines (and the apriority of the premises); if these are a priori, then so is the proof. The appeal to the reliability of the computer—or to the reliability of the human mathematician's brain—is a background assumption which "need not be a part of the warrant for our mathematical result" (Burge 1998, 6).

What of the claim that surveying a proof itself renders warrant a posteriori? Similar remarks hold here; the fact that, in order to access the proof, a mathematician needs a functioning brain, or computer processor to survey the proof is not itself part of the warrant. Burge (1998, 12–13) offers useful remarks on the difference between warrant and the role of perception in accessing that warrant:

> We do have to hear the words of others, just as we have to read the print-outs of computers. But perceiving the words need not be, and normally is not, part of the fundamental

> entitlement for understanding what intentional content they convey, or for understanding them as presentations-as-true. The words are like diagrams or symbols that help one see the point of a mathematical claim: They call to the recipient's mind the thoughts of the interlocutor that they express. . ..But perception of them does not normally enter into the recipient's entitlement for relying on understanding of them or their assertive force.

This line can be pressed into service here: the act of surveying the proof, while an empirical act, is not itself part of the warrant for a proof. Surveying a proof merely allows one to access the relevant warranting inferential relations in the proof.

This view of apriority must address the claim of Tymoczko (1979, 63) that an appeal to computers is an empirical premise, a report *on an experiment*. Here the defender of the a priori must ask whether the 4CT is accurately described as an experiment, and, if so, whether this would imply that it was a posteriori, proof. Tymoczko (1979, 78) himself notes one strange consequence of seeing the 4CT along the lines of an experiment. Having claimed that the 4CT blurs the distinction between an alleged a priori discipline like mathematics and natural science, Tymoczko runs up against the problem of what to say about experiments in pure mathematics:

> It is easy to see how experiments play a role in the arguments of physical theory. The physical theory can predict phenomena of space-time which equipment can be designed to register. Are we to say that the computer registered a phenomenon of mathematical space? If not, then how else are we to explain the role of experiment in mathematics?

Tymoczko (1979, 78), naturally, does not conclude that the 4CT has indeed registered a phenomenon in mathematical space, instead opting to "simply note these puzzles as among the consequences of the 4CT." But the fact is that these puzzles are among the consequences of the 4CT only if that theorem really is accurately describable as an experiment. If we do not classify it as such, the puzzles disappear. Moreover, there are stark disanalogies between physical experiments and the use of computers in proving the 4CT (See, e.g., Levin (1981, 81), Swart (1980, 706), Teller (1980, 802). A rough characterization of what an experiment is in the physical sciences would be that it is an attempt to control and isolate part of nature, in order to learn, through observation, about that part of nature, or about some other part of nature to which the controlled and isolated part is causally connected. That is, an experiment, in the sciences in which the notion has a reasonably well-understood use, involves all of the following: the control and isolation of nature, observation, prediction, and the correlation of causes and effects. None of these features is present in the appeal to computers in the 4CT.

As to the second challenge, as one might expect, the proponent of this view of the a priori argues just that if the proof of the 4CT consists of a priori true propositions connected logically by valid a priori rules of inference, then the proof is a priori, even if one wishes to count it as being in some sense experimental (e.g., if one wished to count it as belonging to the subfield of experimental mathematics) (For a useful introduction to the field of experimental mathematics, see (Baker 2008), reprinted in (Marcus and McEvoy 2016). (Swart 1980) and (McEvoy 2013) offer detailed

arguments to the effect that CAPs cannot be considered experimental in any sense that occludes their apriority, even if they may be said to be experimental in certain senses consistent with that apriority.).

6 Response 4. Unsurveyable CAPS (Can) Give A Priori Knowledge

Tymoczko finds it obvious that the appeal to a computer renders one's knowledge of the 4CT a posteriori. As we have just seen, some of his critics argue that, while our knowledge of the proof is indeed a posteriori, due to the appeal to the computer report, the proof itself is an a priori proof, since each of the steps in the proof (assuming it is sound) is licensed by an a priori rule of inference. However, some philosophers have argued that we can actually (and not just in-principle) know a priori unsurveyable CAPs. For example, Burge (1998, 12–13) grounds his response to the New Four Color Problem on his Burge (1993) view of testimony. According to Burge (1998, 4), testimony, under the right conditions, transmits a priori warrant:

> If one's source knows a proposition a priori and there is no reason to doubt the source, one can in certain cases know it a priori by accepting the source's word**.**

For Burge, given that the source is sufficiently reliable, it "preserves content" and thus allows the hearer to have a priori warrant of a report, provided the source has a priori entitlement to its report. Barberousse and Vorms (2014, 3601) explain the point in regard to mathematical knowledge transmitted by human testimony or memory:

> The content of the knowledge is not altered by its being acquired through a process relying on memory, or testimony. . . . As a consequence, acquiring mathematical knowledge through memory or testimony does not ipso facto make the pieces of knowledge so obtained empirical. It remains a priori, whenever its justification (before its being transmitted through memory or testimony) was itself a priori.

Thus, if my mathematics teacher has a priori understanding of the proof of the infinity of primes, and informs me of this, then, on the assumption that I have no reason to doubt this testimony, I can come to have a priori warrant for my belief in the conclusion of this proof, despite not having come to know the proof by reading and understanding it.

How is this applied to a case like the 4CT, where only computers have surveyed the entire proof? Well, again, assuming the proof is in fact sound, and thus that the computer has correctly carried out the steps, then the computer's output report can "preserve content" for the reader who can thus come to have a priori warrant for her belief in the soundness of the theorem (See (Barberousse and Vorms 2014) for an attempt to extend Burge's arguments to computer simulations.).

Burge's view is controversial. There are two main sources of criticism. First, one may, with Hume, see testimonial knowledge as resting on empirical grounds, and thus reject the idea that testimony yields a priori knowledge under any circumstances. But even if one is willing to accept that human testimony can provide a hearer with a priori warrant, there are reasons to balk at so doing when the "testimony" is due to a computer**.** Burge (1998) discusses a number of such reasons, including the fact that the computer is not an autonomously rational agent, and the possibility of error in running the program. With respect to the latter, Burge offers a similar line to that we have already seen above: such errors are analogous to errors in humanly produced proofs. With respect to the former, Burge (1998, 9) appeals to the rationality and intentionality the computer derives from its human designers:

> The meaning of the machine's activities, and indeed the nature of its rational powers, are derivative from intentionality and rationality of rational beings. Such activities provide an amplification of the designers' and programmers' rationality. In understanding the machine's offerings, we have an apriori entitlement to rely on the rationality of these offerings, and the justifications backing these offerings.

Symons and Alvarado (2019, 50–51) raise another difference between human and computer "testimony," which they see as undermining claims of apriority. In a discussion of computer simulations in science they argue that because mathematical content is discretized by computers, simulations cannot count as preserving content in a way relevantly similar to human testimony and so, on Burge's account, cannot yield a priori knowledge. Thus:

> [C]omputer simulations cannot [preserve content] given Burge's characterization because justificatory elements distinct from the ones warranting the original content do in fact enhance, decrease or constitute the epistemic warrants of the manipulated content.

And, for Symons and Alvarado, given that content preservation is required for a priori testimonial knowledge, one's warrant from a computer simulation cannot be a priori. Symons and Alvarado (2019, 50 n.24) extend the argument to CAPs. First they observe that the alteration of content involved in coding introduces an empirical element. They then note a remark from McEvoy (2008, 380) that "[i]f the method of inference for any of the steps in the proof is a posteriori, [the proof] is a posteriori." Symons and Alvarado take these points together to concede the point that CAPs are a posteriori.

There are two parts to this objection, one specific to Burge's version of apriorism, with its attendant notion of content preservation and one more general, to the effect that the process of coding required to translate the premises of a proof into computer code (and from computer code back into mathematical propositions) will involve inferential steps that are not a priori mathematical steps, but are instead empirically grounded pieces of computer science.

Faced with the objection that CAPs do not preserve content, one might give up Burge's notion of content preservation. One might maintain instead the view (presented in Sect. 5) that once the steps of the proof are all a priori inferences from a

priori propositions, the proof itself remains a priori (even if our knowledge of it is a posteriori). This view does still face the more general objection, however. But the fundamental question for this approach that is raised by issues of transformation of content between formal proofs and coding is whether what the encoded program produces is a sound proof. If it is, then the proof is warranted by the a priori inferential steps between premises, and is a priori. If not, then we do not have a proof (and so the question of its apriority is moot).

Thus the view outlined in Sect. 5 above survives the objection. It is not, however, consistent with the general thrust of this section, that we can have a priori knowledge of unsurveyable proofs. One wishing to maintain this might instead turn to Arkoudas and Bringsjord (2007, 186) who argue that unsurveyable CAPs do not differ in terms of warrant from human produced surveyable proofs " as long as the algorithms that the computers execute are known to be correct in the traditional sense" ((Arkoudas and Bringsjord 2007, 195) point out "that rigorous, surveyable, and convincing proofs of correctness are possible for some algorithms is not controversial; it has been established by the work of theoretical computer scientists and logicians such as Hoare, Dijkstra, Manna, and Scott."). Once this condition is satisfied, then, granted that surveyable proofs can provide a priori mathematical warrant, unsurveyable CAPS can too (Arkoudas and Bringsjord 2007, 189). Arkoudas and Brinsjord exploit the fact that modern proof checking programs are compact enough to be themselves surveyable, allowing a priori knowledge of their correctness. They argue that if one knows a priori that the checker is correct, and one also knows that it has established some theorem—even by means of a humanly unsurveyable proof, then one can know the theorem a priori. They are quick to acknowledge that Appel and Haken's proof of the 4CT does not satisfy the condition; however, they maintain that the proof due to Gonthier (2005) — using the mechanized COQ proof checker — does (See also (Gonthier 2008).). Knowledge that is obtained in such manner, Arkoudas and Bringsjord (2007, 193) label "computational a priori":

> Knowledge obtained by computations is a priori as long as we know what the relevant algorithms do and can prove mathematically—using traditional, surveyable proofs—that the algorithms produce correct results. If that is the case, then the justificational structure of our knowledge is similar to that which obtains for knowledge produced by surveyable proofs."

7 Response 5: The Future

A different way of arguing that the proof of the 4CT is a priori despite being unsurveyable, and despite currently allowing only a posteriori knowledge of its conclusion is to appeal to future surveyable versions of the same proof. Here, for example, is Swart (1980, 700):

> As of now the 4CT itself (must be carried out by computer). But no one has proved that this is a permanent categorization, ... and the development of more powerful mathematical techniques may, in the course of time, change the existing categorization of theorems out of all recognition. Who can say what might not happen in a hundred or even fifty years' time?

> . . . Are we to assume that the 4CT is, as of now, an a posteriori theorem but that it may in time become an a priori one? This is surely a most odd use of the term a priori.

McEvoy (2008, 377–9) uses the possibility of notation change to illustrate the same issue. He notes that the (surveyable) CAP of the Robbins problem, originally formulated in standard Boolean notation, has been translated by Kauffman (2000) into a variant of C.S. Peirce's graph logic (For detailed and discussion of Peirce's graph logic, see (Kauffman 2000), and (Corfield 2003, pp. 53–55).). Kauffman's reformulation of the proof of the Robbins problem translates some extremely complex and lengthy Boolean algebra into far shorter and more easily comprehensible Peircean graphs. Kauffman himself holds that his translation "makes a mathematical domain accessible to human beings that has heretofore been only accessible to computers'" (Kauffman 2000). Thus, suitable notation change may render surveyable some previously unsurveyable proofs. For any such reformulated proof, a human mathematician might well survey, and thus come to know a priori the warranting inferential relations that obtain between premises and conclusions. It seems there are three things we might say about this situation

(a) The proof is and always has been an a priori proof.
(b) The proof *was* an a posteriori proof, but it has now become an a priori proof.
(c) The proof was and remains a posteriori.

Unless we have additional grounds for arguing that proofs are a posteriori (i.e., grounds independent of surveyability) (c) is clearly false, as the proof now has been reformulated as a surveyable a priori proof.

(b) seems equally implausible. We are here considering two formulations of the very same proof. The difference, apart from the difference in surveyability, is only a difference in notation. But the fact that the same sequence of reasoning expressed in different notation can be surveyed and so known a priori shows that the inferential relations obtaining between premises and conclusion in that sequence of reasoning are a priori. If the original proof were not a priori, merely translating equivalent symbols could not make it so.

Since (b) and (c) are both false, we are left with (a): the proof is and always was a priori, despite the unsurveyability of the original formulation of the proof. The falsity of (b) and (c) thus shows that the surveyability of a proof is not a necessary condition on its apriority. If this line of reasoning is correct, this tends to support the view outlined above in Sect. 5 that what makes a proof a priori is not the contingent fact that it can be surveyed and understood by beings like ourselves, but is instead the fact that the each of the steps in the proof is a priori warranted.

Such a line of thought clearly does not accept surveyability as being criterial for proof (or for apriority). And we have seen already Bassler (2006, 117) argue that this is mistaken (and that one fundamental insight of Tymoczko (1979) is that the 4CT drives a wedge between two of the main criteria of proof, surveyability and formalizability. The next section thus examines whether the 4CT might be in some sense surveyable.

8 Response 6: The CAP of the 4CT Is Surveyable, in a Sense

We have thus far been following along with the seemingly quite obvious assumption that the proof of the 4CT is unsurveyable. However, a number of authors have challenged this, at least when the unsurveyability of the 4CT is to be understood as the introduction of a new element in mathematics. Margarita Levin, for example, notes that the entirety of human-produced mathematics is, taken as a whole, unsurveyable by any one human mathematician. Of course, given that it is human-produced mathematics, it all has been surveyed by different mathematicians. Something similar could conceivably be done with the CAP of the 4CT. It is unsurveyable by any one human mathematician, but not by many of them acting together, each surveying a relatively small portion. Thus, the 4CT is, like the full set of human produced mathematics, unsurveyable by any one human mathematician, but surveyable by many acting together (Various other authors have suggested this as a method of surveying proofs too lengthy to be surveyed by any individual human mathematician. See, e.g., (Swart 1980, 705), (McEvoy 2008, 381).). Were this to be carried out in practice, the proof would be in the same boat as the above mentioned Finite Simple Groups proof, which, while fully human-produced, has not been surveyed by any individual mathematician, and consists of "connected results written down in various places, totaling 10,000 pages" (Barendregt and Wiedijk 2005, 2532).

More realistically, the 4CT may be — and indeed has been — surveyed by other computers. Swart (1980, 703) notes that even by that time, Appel and Haken's proof had been "indirectly surveyed in a manner very little different from the hand surveying of other proofs involving a large amount of case testing, namely, by means of independently written computer programs run on different computers." Swart concludes that the proof has been "fairly effectively surveyed" and finds the proof to be "no worse off in this regard than theorems concerning other equally intractable problems" (Swart 1980, 704); see also (Teller 1980, 798–9).

Krakowski (1980, 93) argues likewise:

> [I]nsofar as I understand the notion of surveyability, computers can survey proofs and that the proof of the crucial lemma has been surveyed. What is essentially required is that it be checked that each step follows from the previous one; and this the computer certainly has done.

Indeed, Krakowski (1980, 92) finds the suggestion that the proof has not been surveyed (because not humanly surveyed) to be chauvinistic.

Some critics have noted that this kind of computer verification of lengthy CAPs sets us off on a regress. Mackenzie (2005) notes that:

> [A]utomated theorem provers are themselves quite complicated computer programs which may contain faults in design or implementation. In interviews for this research, designers of automated theorem provers often reported experience of 'bugs' in their systems that would have allowed 'theorems' that they knew to be false nevertheless to be proven.

((Mackenzie 2001, 288) cites an interview with Alan Robinson, developer of the fundamental theorem-proving procedure of 'resolution'), in which Robinson colorfully inveighs against computer verification: "You've got to prove the theorem-proving program correct. You're in a regression, aren't you? And that's what people don't seem to realize when they get into verification. They have a hairy great thing they're in doubt about, so they produce another hairy great thing which is the proof that this one's ok. Now what about this one which you've just used . . . ? I say that serves them jolly well right. They shouldn't be doing it that way.") That is, if our worry is that an unsurveyable CAP may contain errors due to software or hardware errors, then surely these worries arise also for the computer program that carries out the verification. However, this particular worry may be overblown, as contemporary automated theorem checkers have relatively short programs that can fairly easily be surveyed to ensure that they are error free and working correctly. Arkoudas and Bringsjord (2007, 186) describe "small and simple" proof-checking algorithms which "emit low-level correctness proofs—called "certificates"—that can be verified by simple proof checkers." Once such a certificate is produced, then, we need "no longer care how the search was performed, in how many pages of C code it was encoded, or what resources it used; our only care is whether the certificate is valid" (Arkoudas and Bringsjord 2007, 199). The computer then need only "know" how to check the validity of the certificates, which can be done in first order logic with identity. The required proof-checking algorithm, they note is "of trivial conceptual and computational complexity. It can be implemented in a page or two of an advanced programming language such as ML or Haskell. . ." (Indeed, as the authors note, Georges Gonthier's 2005 proof of the 4CT, can be checked by small and simple proof checkers. The proof is available here: http://www2.tcs.ifi.lmu.de/~abel/lehre/WS07-08/CAFR/4colproof.pdf).

Here is how Hales et al. (2011) puts the point in connection with the HOL Light proof assistant on the Flyspeck homepage:

> The system is built on a small kernel, and the type checking insures that no fatal bugs can occur outside the kernel. That is, if you leave a bug in your code, the worst that can happen is that you will fail to prove a theorem you hoped to prove. You can never put a bug in your code that yields a false statement. The system becomes self-checking after the first thousand lines of code. The source code is short and quite readable (Hales (2008, pp. 1375–1376) notes that the kernel for HOL light involves fewer than 500 lines of computer code. See also Harrison (2008, 1405) and Pollack (1997).).

Once the kernel of the system has been shown to be free of bugs, one can be certain that a formal proof found to be sound by the assistant is in fact sound. Thus, with the advent of proof assistants, there is surveyability of a kind even for very long proofs: one surveys the proof assistant, and the proof assistant surveys the proof. Moreover, proofs produced or checked by one proof assistant can be translated and "exported" for checking by a different system (Hales 2008, 1376; Pollack 1997, 3).

To the extent that one shares Tymoczko's view that surveyability is important not only because it allows detection of error, but also *because a surveyed well understood proof is convincing*, these responses may be felt to miss the point. A recent

attempt to argue that the CAP of the 4CT is surveyable in a sense which may allow for a human mathematician to survey, understand and thus become convinced of the proof is due to Bassler (2006). (Bassler (2006, 100) first distinguishes between global and local surveyability:

> (L)ocal surveyability requires the surveying of each of the individual steps in a proof in some order, while global surveyability requires the surveying of the entire proof as a comprehensible whole.

This may not seem to take us very far. After all, one might well think that in order to survey an entire proof as a comprehensible whole, one must first survey (and understand) each of the individual steps. This sort of understanding of the relation between global and local surveyability, Bassler (2006 112) rejects as reductive, preferring instead a relation between the two types of surveyability that allows for a proof to be globally surveyable without being locally surveyable. Indeed, the CAP of the 4CT is taken to be an example of a globally, even if not locally, surveyable (Bassler 2006, 126). What makes the CAP of the 4CT unsurveyable are the computer calculations for the unavoidable configurations. As Bassler (2006, 123) observes, Appel and Haken have surveyed the proof with the exception of these calculations. Assuming that the calculations are sufficiently routine, then the proof is globally surveyable — that is, distinguishing between mere calculation instances and proof steps, the whole proof is surveyable as a comprehensive whole, even though it is not locally surveyable (where this *would* require surveying each individual calculation). Bassler (2006, 125) takes Haken to have offered an article length description of the proof that is "conceptually surveyable":

> In the course of an article-length description, Haken has arrived at a global description of the strategy by way of which he and Appel set up the proof of the 4CT. . . . The logical structure of the argumentation at the level of Haken's expository article is easily globally surveyable: we see what tasks are required in a global sense and why these tasks will collectively provide a proof of the 4CT.

For one convinced that human surveyability of a kind is criterial for proof, Bassler's view seems quite promising. If Bassler's non-reductive understanding of the distinction between global and local surveyability can be maintained, it allows for the elimination of Tymoczko's wedge between formalizability and (at least global) human surveyability. What, on this view, we are to say about whether the 4CT is a priori or empirical will depend on the details of the relationship between apriority, global surveyability and local surveyability. On the one hand, it may still make most sense for the apriorist to say that the 4CT is an a priori proof but is known only empirically. On the other hand, however, Bassler's view may make room for the idea that one can have a priori knowledge of the globally surveyed proof. And, if the calculations are sufficiently routine, and if one understands the overall character of these calculations (despite being unable to survey them all), globally surveying the proof might allow one, after all, to arrive at a kind of a priori knowledge of the 4CT.

9 Certainty

I will close with some brief remarks on certainty. Tymoczko (1979, 77–8) tells us that that our knowledge must be qualified by the uncertainty of our instruments. And, there are, he tells us, truths from electrical engineering which have a higher degree of certainty than the 4CT. Tymoczko takes our lack of certainty regarding our instruments undermine that aspect of the traditional view of mathematics that its truths are certain, in contrast to those of the empirical sciences. "Certainty" here may mean one of two things. On the first reading, "certainty" means objective certainty. To say, in this sense, that the truths of mathematics are certain is to say that their truth is objectively certain, regardless of what we happen to think about them (For more on the notion of objective certainty, see (Katz 1998, 63–64).). It is objectively certain, for example, that seven times seven is 49, and this truth would be certain even if everyone came to believe otherwise. In this sense of certainty, the truths of mathematics are objectively certain, and thus cannot be less certain than any truths of electrical engineering. On the assumption that the proof of the 4CT is a truth of mathematics, it cannot be less objectively certain than any other.

On the other hand, by "certainty" Tymoczko may have in mind our degree of confidence in the truth of the 4CT. In this sense, he is correct to say that there are truths of engineering with a higher degree of certainty than the 4CT. But it isn't clear that this represents a novel threat to the traditional view. Our confidence may be higher in certain obvious empirical truths than in the correctness of very long proofs, but this is true even for humanly produced proofs, like the Finite Simple Groups proof. Moreover, as others have noted (e.g., Arkoudas and Bringsjord (2007, 200), Barberousse and Vorms (2014, 3602)), the computing powers of modern computers, in comparison to the human capacity for fatigue, distraction, and so on, suggest that computers are more reliable than humans for many tasks. Granted that the production of lengthy proofs is one such task, we should actually have more confidence (i.e., hold in a higher degree of certainty) in CAPs than in lengthy and complex human proofs.

Abstract

In this chapter, I will discuss the role of examples in Euler's mathematical practice. In modern mathematics, examples have the function of clarifying findings, procedures, and theorems; instead, in Euler's writings, they could also have two other different functions. Firstly, he used examples as a proof for a general statement, namely, he considered a proposition as proved if verified for some examples. Euler felt the need of general and rigorous proofs even pointed out that proofs by example could give rise to errors; however, he never rejected proofs by example entirely and limited himself to advising caution in their use. Secondly, Euler used examples as verification and persuasion tools. In certain cases, he checked the validity of a proof by appropriate examples. In these cases, examples did not substitute the general proof of a statement; rather their aim was to convince the reader of the correctness of certain procedures of the calculus and of the internal coherence of the various branches of the analysis of infinities.

1 Summary and Introduction

In this chapter, I will discuss the role of examples in Euler's mathematical practice. (For a discussion of the main features of Euler's mathematics, and, in particular, of what can be termed as Euler's analytical program, see Capobianco et alia (2017); Ferraro (2020).) In modern mathematics examples have the function of clarifying findings, procedures, theorems; instead, in Euler's writings they could also have other different functions: more precisely, Euler used examples as proofs and as persuasion tools.

In Sect. 2, I will deal with the use of examples as a proof for a general statement, namely, I will investigate the praxis by which a proposition was considered as proved if verified for some examples. I will also show that Euler felt the need of general and rigorous proofs, namely, the need of deductions strictly derived by principles and not by the observations of particular cases. Euler even pointed out that proofs by example could give rise to errors; however, he never rejected proofs by example entirely and limited himself to advising caution in their use.

In Sect. 3, I will investigate the use of examples as verification and persuasion tools. In certain cases, Euler gave a proof of a theorem, but then he checked the validity (the "truth" – he said) of that theorem by appropriate examples. More specifically, given a theorem *T*, Euler first applied this theorem to some specific problems, which could also be solved by means of another theorem *Q* (usually, a more elementary theorem than *T*). Then he verified that that the different theorems gave the same result. In these cases, examples did not substitute the general proof of a statement; rather their aim was to convince the reader of the correctness of certain procedures of the calculus (though the doubts on the foundations of this field of mathematics). The use of examples as persuasion and verification tools also showed the internal coherence of the various branches of the analysis of infinities.

2 Proofs by Example

In his *The Calculus as Algebraic Analysis*, Craig G. Fraser investigated the mathematical work of Euler and Lagrange and observed:

> A theorem is often regarded as demonstrated if verified for several examples, the assumption being that the reasoning in question could be adapted to any other example one chose to consider. (Fraser (1989, p. 328))

(On Lagrange's, see Ferraro and Panza (2012)) Fraser's words highlight a remarkable feature of Euler's mathematical practice: the proof by example. However, it is to be observed that the use of an example as a proof did not necessarily imply an inappropriate generalization. Indeed, a distinction should be drawn between arbitrary exemplifications and inductive generalizations. Let us take the function $y = x^3$. In order to calculate the differential ratio $\frac{dy}{dx}$ of this function, a seventeenth-century mathematician could consider the quantity. (In this chapter, following Euler, I use the term "differential ratio" to denote what today is named

as "derivatives." Euler understood the differential ratio of the function $y(x)$ as the ratio of two differentials, dy and dx.)

$$y(x+\omega) = (x+\omega)^3.$$

Then he could calculate the ratio

$$\frac{(x+\omega)^3 - x^3}{\omega} = 3x^2 + 3x\omega + \omega^2$$

Set $\omega = dx$, he could applied the principle of cancellation of infinitesimals and so he would obtain the differential ratio:

$$\frac{dy}{dx} = 3x^2.$$

In the above procedure no specific property of the natural number 3 is used; for this reason, the number 3 can be replaced by any other natural number n and so the above reasoning can be considered as the proof that the differential ratio of $y = x^n$ is

$$\frac{dy}{dx} = nx^{n-1}$$

for any natural number n. Indeed, it suffice to calculate the nth power of $(x+\omega)^n$ – by using Pascal's triangle – and to repeat the procedure.

This is a case of arbitrary exemplification: one presents a typical example, or a few examples, in place of a general proof. In an arbitrary exemplification the demonstration of a general proposition

$$P(x), \forall x \in \mathrm{A},$$

where A is a given set, is reduced to the proof of some particular proposition

$$P(a_1), P(a_2), P(a_3), \ldots, P(a_n)$$

where a_1, a_2, a_3, ..., a_n are sufficiently generic or paradigmatic examples without any apparent particularity toward the statement.

Now let us consider the function $y = x^\alpha$ where α is a real number. (I use the term "real number" for the sake of simplicity. The notion of real numbers did not exist in seventeenth century. Euler would have spoken of any quantity (rational or irrational), but this is not essential in our discussion.) The above described procedure cannot easily be generalized to the case where the exponent is a real number α. The function $y = x^3$ is not an arbitrary exemplification of $y = x^\alpha$ when α is a real number. Therefore, if one deduces the rule

$$\frac{dy}{dx} = \alpha x^{\alpha-1}$$

for any real number α, from the example $\frac{dy}{dx} = 3x^2$, then one does not perform an arbitrary exemplification. In this case, it is preferable to speak of inductive generalization.

In arbitrary exemplifications, particular examples are used in place of a general proof of a theorem: however, the selected examples are sufficiently generic and have no any apparent particularity toward the statement to be proved. In other terms, the examples have properties (at least as concerns the properties used in the proof) that make them indistinguishable from any other example that one could be selected. Consequently, the reasoning or procedure used in those examples is repeatable in every other example and the validity of the general statement is guaranteed.

Instead, in inductive generalizations, a general statement arises from the investigation of some particular examples that are not sufficiently generic, that is, they are not representative of all possible cases. Inductive generalization is, in fact, a form of induction similar, in some way, to that of the empirical sciences.

Proofs by example were certainly typical of the algebraic tradition. (For example, see (Bombelli 1966).) In Euler's mathematics, the use of examples in place of a proof (both inductive generalizations and arbitrary exemplifications) could take a rather complex form.

Let us consider Euler's discussion of the partial fraction decomposition of rational functions in his *Introductio in analysin infinitorum*. For instance, in proposition 39, Euler considered a proper rational function $\frac{f(x)}{g(x)}$ such that $g(x) = p(x) \cdot q(x)$ and $p(x)$ and $q(x)$ have no common factor. He stated that any rational function of this type may be decomposed into the sum of two proper rational functions, the denominators of which are equal to $p(x)$ and $q(x)$, respectively. He also noted that such a decomposition is unique (Euler 1748, I, p. 23).

Euler did not provide a general demonstration of this proposition since "the truth of this matter may be understood more clearly from an example than by reasoning." ("rei veritas ex exemplo clarius quam per ratiocinum perspicietur" (Euler 1748, I, p. 23).) As an example Euler (1748, I, pp. 23–24) considered the function

$$\frac{1 - 2z + 3z^2 - 4z^3}{1 + 4z^4} \tag{1}$$

He stated that since $1 + 4z^4 = (1 + 2z + 2z^2)(1 - 2z + 2z^2)$, this function could be written as

$$\frac{\alpha + \beta z}{1 + 2z + 2z^2} + \frac{\gamma + \delta z}{1 - 2z + 2z^2},$$

where α, β, γ, δ were appropriate constants. Indeed, by supposing that

$$\frac{1-2z+3z^2-4z^3}{1+4z^4}=\frac{\alpha+\beta z}{1+2z+2z^2}+\frac{\gamma+\delta z}{1-2z+2z^2}.$$

Euler solved this equality for α, β, γ, δ, by equating the coefficients of terms involving the powers of x and found

$$\alpha=\frac{1}{2};\beta=-\frac{5}{4};\gamma=\frac{1}{2};\delta=-\frac{3}{4}.$$

In this example Euler did not rely on the specific properties of the particular rational function $\frac{1-2z+3z^2-4z^3}{1+4z^4}$, which played the role of a generic function satisfying the hypothesis of the theorem. It was implicit that the procedure used in that example could be repeated in any other example. In the subsequent sections of the *Introductio in analysin infinitorum* (1748, I, pp. 24–35), Euler modified the hypothesis on the function $\frac{f(x)}{g(x)}$ and thus provided other theorems on the decomposition of rational functions. He never gave general proofs of these propositions but always illustrated them by appropriate examples.

A case of inductive generalization can be found in *Consideratio progressionis cuiusdam ad circuli quadraturam inveniendam idoneae*. In this paper (1739, pp. 357–359), Euler computed the approximate value of π by means of the asymptotic series. He considered $\arctan t=\int_0^t\frac{dt}{1+t^2}$ as a sum of the type $\sum\frac{dt}{1+t^2}$ and, using relations concerning the sums of powers of integer numbers, derived

$$\pi=\frac{4n}{n^2+1}+\frac{4n}{n^2+4}+\ldots+\frac{4n}{n^2+n^2}+\frac{1}{n}+\sum_{h=o}^{\infty}(-1)^h B_{4h+2}\frac{1}{2^{2h}(2h+1)n^{4h+2}} \quad (2)$$

where B_n are the Bernoulli numbers. (Bernoulli numbers B_r are defined by the relation $\frac{t}{e^t-1}=\sum_{r=0}^{\infty}\frac{B_r}{r!}t^r$.) Euler understood the asymptotic nature of series (2). He observed that, although (2) seems to be the more convergent the greater the number n, it actually "converges" (he meant that the terms decrease in absolute value) only up to a certain term, after which it begins to diverge (namely, the terms increase). (This statement is based upon the observation that $\frac{B_{2h+2}}{B_{2h}}>\frac{(h-1)(2h-3)}{2\pi^2}$ (for $h>0$) and that if $h=\infty$ the ratio holds $\frac{h^2}{\pi^2}$ (i.e., $\frac{B_{2h+2}}{h^2B_{2h}}$ approaches asymptotically $\frac{1}{\pi^2}$). On these relations, see Euler (1755, pp. 428–430).) Euler suggested using (2) by calculating its first terms (according to Euler's terminology: the terms that "converge") and neglecting them as soon as they "begin to diverge" (1739, p. 357). More specifically, the terms of (2) must be considered up to the index $s\approx\frac{\pi n}{\sqrt{2}}$ (approximately $s\approx 2n$).

Euler gave the value 1, 3, 5 to n. He noted that, in such cases, the number of exact figures of π was about $3n$. Basing only on these three examples, Euler stated that, by induction (*per inductionem*), formula (2) provided about $3n$ exact figures of π. Euler

validated this inductive generalization by considering three other examples (precisely $n = 2, 4, 6$).

A more complex case of inductive generalization is found in chapter I of the first part of the *Institutiones calculi differentialis*, where the validity of a theorem P_f for a generic function f is inferred from the validity of the proposition P_f for some functions (Euler, 1755, pp. 3–38). In this chapter of the *Institutiones*, Euler dealt with the first differences of a function $y(x)$

$$\Delta y = y(x + \omega) - y(x)$$

where ω is the finite increment of the independent variable x. He stated that if $y(x)$ is any function, both algebraic and transcendent, then $\Delta y = y(x + \omega) = y(x)$ can be expressed in the form:

$$\Delta y = P\omega + Q\omega^2 + R\omega^3 + S\omega^4 + \text{etc.} \tag{3}$$

where P, R, S, ... are appropriate functions of x.

Formula (3) played a crucial role in the Eulerian foundation of the calculus, since the definition of differential ratio $\frac{dy}{dx}$ was based upon it. I do not dwell on this. Here I limit myself to observing that Euler derived (3) by induction on some specific cases.

Indeed, Euler firstly proved formula (3) for the functions $y = x^n$, where n was an integer, by expanding $(x + \omega)^n$ (see Euler 1755, pp. 13–16). Because of the additivity of the operator Δ, this was sufficient to prove that (3) held for integer functions (Euler 1755, p. 11).

Secondly, Euler (1755, p. 18) stated that formula (3) could be generalized to the functions $y = x^n$ for any number n. In effect, he (1755, 19) provided eight examples:

$$y = x^{-1}, \quad y = x^{-2}, \quad y = x^{-3}, \quad y = x^{-4},$$

$$y = x^{\frac{1}{2}}, \quad y = x^{\frac{1}{3}}, \quad y = x^{-\frac{1}{2}}, \quad y == x^{-\frac{1}{3}}.$$

Thirdly, Euler (1755, pp. 20–22) showed that (3) was valid for the functions

$$\frac{1}{a^2 + x^2} \text{ and } \frac{1}{\sqrt{a^2 + x^2}}.$$

He thought that this fact was sufficient to infer (*colligimus*) that any algebraic functions could be expressed in the form (3) (Euler 1755, p. 22).

Finally, Euler stated that (3) was valid for transcendental functions, too:

> Nor are the differences of transcendental functions excluded from this form, what will appear clearer from the following examples. (Neque etiam ex hac forma differentiae functionum trascendentium excluduntur, id quod ex sequentibus exemplis clarius apparebit (Euler 1755, p. 22).)

The examples concerned the logarithmic, exponential, sine, and cosine functions. Even if Euler's argument was affected by his conception of a function, (In Euler's conception, the only functions in the strict sense of the term were elementary functions and their composition (see Fraser 1989; Panza 1996, Ferraro 2007a).) it is clear that a general proof of (3) was lacking. The validity of (3) for any function was a mere inductive generalization grounded upon several examples.

Euler had often used inductive procedures in his early years, but after 1750 these procedures were felt to be problematic and not entirely reliable. For instance, let us consider the binomial series

$$(1+x)^n = 1 + nx + \frac{n(n-1)}{1\cdot 2}x^2 + \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}x^3 + \dots \tag{4}$$

Formula (4) was already well known in the case that n was a natural number when Newton generalized to the case where n was any number. Newton had given no proof of (4) for a real number n and had derived it by inductive generalization (see Newton 1712, pp. 67–86 and 1967, 1, pp. 104–111).

In his *Demonstratio theorematis newtoniani* (1774), Euler attempted to prove (4). He preceded his proof with an explanation why an inductive generalization was not a sufficient proof of the binomial theorem and it was necessary what he called a "rigorous" proof. He (1774, pp. 104–105) noted that certain formulas $F(n)$ were true for a natural number n; however, they became false when n was a non-integer number. This is the case of the series:

$$\begin{aligned}&\frac{1-a^n}{1-a} + \frac{(1-a^n)(1-a^{n-1})}{1-a^2} + \frac{(1-a^n)(1-a^{n-1})(1-a^{n-2})}{1-a^3}\\ &+ \frac{(1-a^n)(1-a^{n-1})(1-a^{n-2})(1-a^{n-3})}{1-a^4} + \dots\end{aligned} \tag{5}$$

Euler calculated the sum $f(n)$ of (5) for $n = 0, 1, 2, 3$, and found:

$$f(0) = 0;$$

$$f(1) = \frac{1-a}{1-a} = 1;$$

$$f(2) = \frac{1-a^2}{1-a} + \frac{(1-a^2)(1-a)}{1-a^2} = 1 + a + 1 - a = 2$$

$$\begin{aligned}f(3) &= \frac{1-a^3}{1-a} + \frac{(1-a^3)(1-a^2)}{1-a^2} + \frac{(1-a^3)(1-a^2)(1-a)}{1-a^3}\\ &= 1 - a + a^2 + 1 - a^3 + 1 - a - a^2 + a^3 = 3.\end{aligned}$$

In the same manner – he stated – one could show that

$$f(n) = n \text{ for any natural number } n.$$

An inductive generalization would lead us to the conclusion

$$f(n) = n \text{ for any } n.$$

But Euler observed $f\left(\frac{1}{2}\right)$ was not equal to $\frac{1}{2}$. It was clear that inductive generalization did not hold in this case. For this reason, a rigorous proof of (4) was necessary when n was not a natural number.

To modern eyes, example (5) appears unnecessarily complicated. In order to have a function that equals to n for an integer n and differs from n for a non-integer n, it suffices to consider

$$g(n) = n + \sin 2\pi n.$$

This function was known by Euler already when he wrote *De serierum determinazione seu nova methodus inveniendi terminos generales serierum* (1750). In this paper Euler had noticed that not only could the general term $y(n)$ of the series

$$1 + 2 + 3 + 4 + 5 + \ldots$$

be expressed by means of the function

$$y(n) = n \text{ for a positive integer } n,$$

but also it could be given by a formula of the type

$$y = n + \sum_{i=0}^{\infty} \mathrm{F}_i(n) \sin i\pi n,$$

where $\mathrm{F}_i(n)$ is any function of n. In the last series, when n is not integer, $y(n)$ assumes different values depending on how we choose the function $\mathrm{F}_i(n)$.

Another interesting case is the following. In his *Institutiones calculi differentialis*, Euler derived the formula today known as Euler-Maclaurin summation formula. (On Euler-Maclaurin summation formula, see (Ferraro 1998).) In section 111, he obtained the series

$$S(z) = \int z dx + \alpha z + \beta \frac{dz}{dx} + \gamma \frac{d^2 z}{dx^2} + \delta \frac{d^3 z}{dx^3} + \varepsilon \frac{d^4 X}{dx^4} + \ldots \tag{6}$$

where $z(x)$ was a generic function (of course, the term "function" has to be understood in Eulerian sense), $S(z) = \sum_{n=1}^{x} z(n)$ and α, β, γ, δ, ε ... were appropriate coefficients (Euler 1755, pp. 408–409). These coefficients were iteratively defined by an infinite sequence of equations. Euler (1755, pp. 409–410) explicitly provided the first six equations:

$$\alpha - \frac{1}{2} = 0,$$

$$\beta - \frac{\alpha}{2} + \frac{1}{6} = 0,$$

$$\gamma - \frac{\beta}{2} + \frac{\alpha}{6} - \frac{1}{24} = 0,$$

$$\delta - \frac{\gamma}{2} + \frac{\beta}{6} - \frac{\alpha}{24} + \frac{1}{120} = 0,$$

$$\varepsilon - \frac{\delta}{2} + \frac{\gamma}{6} - \frac{\beta}{24} + \frac{\alpha}{120} - \frac{1}{720} = 0,$$

$$\zeta - \frac{\varepsilon}{2} + \frac{\delta}{6} - \frac{\gamma}{24} + \frac{\beta}{120} - \frac{\alpha}{720} + \frac{1}{5040} = 0.$$

Thus Euler was able to compute the first five coefficients α, β, γ, δ, ε:

$$\alpha = \frac{1}{2}, \beta = \frac{1}{12}, \gamma = 0, \delta = -\frac{1}{720}, \varepsilon = 0.$$

The observation of the first terms of the sequence of the coefficients led Euler to state that the subsequent odd terms were equal to zero (1755, p. 410). However, according to Euler, "this sequence of values seems to violate the law of continuity" (haec valorum series contra legem continuitatis impingere videtur (Euler 1755, p. 410).).

At a first glance, induction seemed to be in contrast with continuity (understood in Euler's sense, since the law of formation of coefficients could not be reduced to one single formula). (Euler understood the law of continuity as the uniqueness of the law that expresses a certain relationship. See (Ferraro 2000a; Panza 1996).) For this reason, Euler thought that in this case induction was not sufficient and it was necessary to prove rigorously that all odd terms, except for the first, necessarily vanished (Euler 1755, p. 410).

In order to obtain a "rigorous" demonstration, Euler set

$$V = 1 + \alpha u + \beta u^2 + \gamma u^3 + \delta u^4 + \varepsilon u^5 + \ldots,$$

where α, β, γ, δ, ε, ... were the coefficients of (6), and showed that

$$V - \frac{1}{2}u = \frac{u\left(e^{\frac{u}{2}} + e^{-\frac{u}{2}}\right)}{2\left(e^{\frac{u}{2}} - e^{-\frac{u}{2}}\right)}$$

Since $\frac{u\left(e^{\frac{u}{2}}+e^{-\frac{u}{2}}\right)}{2\left(e^{\frac{u}{2}}-e^{-\frac{u}{2}}\right)}$ was equal to

$$\frac{1+\frac{u}{2\cdot 4}+\frac{u^4}{2\cdot 4\cdot 6\cdot 8}+\frac{u^6}{2\cdot 4\cdot\ldots\cdot 12}+\frac{u^8}{2\cdot 4\cdot\ldots\cdot 16}+\ldots}{1+\frac{u^2}{4\cdot 6}+\frac{u^4}{4\cdot 6\cdot 8\cdot 10}+\frac{u^6}{4\cdot\ldots\cdot 14}+\frac{u^8}{2\cdot 4\cdot\ldots\cdot 18}+\ldots}$$

and there was no odd power in this fraction, the expansion of $V-\frac{1}{2}u$ had only even powers of u. In this way, according to Euler, it was proved that all odd terms of (6), except for the first, were equal to zero (Euler 1755, pp. 410–413).

Euler was aware that induction can lead to errors. He himself pointed out a "remarkable example of false induction" (*exemplum memorabile inductionis fallacis*) in his *Observationes analyticae* (1765). In this paper, Euler investigated the coefficients of x^j in the expansion of $(1+x+x^2)^n$. Today these coefficients are termed as trinomial coefficients and are denoted by $\binom{n}{k}_2$, with $n \geq 0$ and $-n \leq k \leq n$. In particular, Euler investigated the central trinomial coefficient $\binom{n}{0}_2$ and proved that

$$\binom{n}{0}_2 = 1 + nx + \frac{n(n-1)}{1\cdot 1} + \frac{n(n-1)(n-2)(n-3)}{1\cdot 2\cdot 1\cdot 2} + \frac{n(n-1)(n-3)(n-4)(n-5)}{1\cdot 2\cdot 3\cdot 1\cdot 2\cdot 3} + \ldots$$

Euler considered the first 10 terms of the sequence $\binom{n}{0}_2$ and wrote the rows:

1	1	3	7	19	51	141	393	1107	3139	...(T)
	3	3	9	21	57	153	423	1179	3321	… (B)
	2	0	2	2	6	12	30	72	182	… (C)

The row (T) is the sequence $\binom{n}{0}_2$ for $n = 0, 1, 2, \ldots, 9$. The nth entry of the row (B) is obtained multiplying (T) by 3 and shifting one to the right. The third row is the difference between the first and the second row starting with the two-entry column. According to Euler, "not without reason it seems to turn out" (*non sine ratione evenire videtur*) that all the numbers in the row (C) are of the type $m^2 + m$, where m is equal

$$1 \quad 0 \quad 1 \quad 1 \quad 2 \quad 3 \quad 5 \quad 8 \quad 13 \ldots (\mathrm{F})$$

Euler observed that (F) is a recurrent sequence, and any term is the sum of two preceding terms (in effect, it is the Fibonacci sequence with the first two terms $F_{-1} = 1$ and $F_0 = 0$). (Euler did not use the expression "Fibonacci sequence.") Therefore, the investigation of the first 10 terms of the given sequence leads one to a rule, which in modern terms can be written as

$$3\binom{n+1}{0}_2 - \binom{n+2}{0}_2 = F_n(F_n+1), \quad n=-1,0,1,2,\ldots \tag{7}$$

Euler rhetorically asked:

> "since the rule is obtained by examination of the first ten terms of the given sequence, who can ever doubt that the same rule holds for the whole of series? Less certain inductions were often successful" (Qui ordo cum in decem primoribus terminis deprehendatur, quis dubitaverit eundem universae seriei tribuere? Saepe profecto inductiones minus certae successu non fuerunt destitutae (Euler 1765, p. 54).)

By using the property of the Fibonacci sequence, Euler derived the following direct formula for $\binom{n}{0}_2$:

$$\binom{n}{0}_2 = \frac{3^n+(-1)^n}{10} + \frac{1}{5}\left(\frac{3+\sqrt{5}}{2}\right)^n + \frac{1}{5}\left(\frac{3-\sqrt{5}}{2}\right)^n + \frac{1}{5}\left(\frac{1+\sqrt{5}}{2}\right)^n + \frac{1}{5}\left(\frac{1-\sqrt{5}}{2}\right)^n$$

Then, he provided a recursive formula

$$\binom{n}{0}_2 = 6\binom{n-1}{0}_2 - 8\binom{n-2}{0}_2 - 8\binom{n-3}{0}_2 + 14\binom{n-4}{0}_2 + 4\binom{n-5}{0}_2 - 5\binom{n-6}{0}_2$$

At this point, Euler observed that these formulas, obtained by induction, were false. Indeed, the 11th term of the sequence the sequence $\binom{n}{0}_2$ is 8953; however, the formula (7) is false. Indeed

$$8953 - 3\cdot 3139 = 464 \neq 21^2 + 21 = 462 \text{ (Euler, 1765, p.55)}.$$

(On Euler's example of misleading induction, see Andrews (1990).) Euler returned to this question in Varia artificia in serierum indolem inquirendi (1783). In this paper, he observed that the above example of false induction "was worthy of being noted because no similar cases had been found in which a so beautiful induction failed." Since induction is misleading, Euler investigated the sequence of the central trinomial coefficients by its same nature (*ex ipsa eius natura*) (Euler 1783, p. 386). In effect Euler was able to prove easily that:

$$\binom{n}{0}_2 = \binom{n-1}{0}_2 + \frac{n-1}{n}\left(\binom{n-1}{0}_2 + 3\binom{n-2}{0}_2\right).$$

However, Euler did not reject this kind of induction completely, rather he preferred to limit himself to advising caution in using it (Euler 1783, p. 51).

Now, let us go to examine how Euler dealt with mathematical induction. Let us consider the following theorem. Given the continued fraction

$$a_1 + \cfrac{b_1}{a_2 + \cfrac{b}{a_3 + \cfrac{b_3}{a_4 + \ldots}}}$$

and let

$$C_k = \frac{p_k}{q_k} = a_1 + \cfrac{b_1}{a_2 + \cfrac{b}{\ldots + \cfrac{b_{k-1}}{a_k}}},$$

then the numerator p_k and the denominator q_k of the convergent C_k are defined by the iterative relationship

$$\begin{cases} p_k = a_k p_{k-1} + b_{k-1} p_{k-2} \\ q_k = a_k q_{k-1} + b_{k-1} q_{k-2} \end{cases}, \tag{8}$$

with $p_1 = a_1$, $p_0 = 1$, $q_1 = 1$, $q_0 = 0$.

In *De fractionibus continuis dissertatio*, Euler (1737, p. 103) proved the theorem by computing the first four convergents C_1, C_2, C_3, C_4. Euler wrote the convergents according the following Scheme **S** (of course, Euler did not use the indicial notation but the 10 letters a, b, c, d, e, α, β, γ, δ, ε):

$$\begin{array}{ccccc} a_1 & a_2 & a_3 & a_4 & a_5 \\ \frac{1}{0} & \frac{a_1}{1} & \frac{a_1a_2+b_1}{a_2} & \frac{a_1a_2a_3+a_3b_1+a_1b_2}{a_2a_3+b_2} & \frac{a_1a_2a_3a_4+a_3a_4b_1+a_1a_4b_2+a_1a_2b_3+b_1b_3}{a_2a_3a_4+a_4b_2+a_2b_3} \\ b_1 & b_2 & b_3 & b_4 & b_5 \end{array}$$

where the first fraction $C_0 = \frac{1}{0}$ gives the initial conditions $p_0 = 1$, $q_0 = 0$.

Euler (1737, p. 104) formulated the recursive law (8) verbally: the product of a numerator with the corresponding upper indicator, added to the product of the preceding numerator with the lower indicator, yields the succeeding numerator. A similar rule applies to the denominators. Then, Euler stated:

> This law is easily observed from the inspection of these fractions if they are continued further, but it is possible to deduce their nature from the continued fractions themselves; however, I believe there is no point in including the proof here. (Lex quidem haec ex ipsa inspectione harum fractionum, si ulterius continentur, facile observatur; sed eadem ex ipsa fractionum continuarum natura deduci potest; quam demonstrationem autem hic apponere superfluum iudico (Euler 1737, p. 104).)

This is the usual Eulerian approach toward demonstrations by mathematical induction: he limited himself to verifying the validity of the proposition $P(n)$ in some cases (in the *De fractionibus continuis dissertatio*, Euler verified the validity of theorem for $k = 1, 2, 3,$ and 4). He thought that this was sufficient to infer $(P(n), \forall\, n \in N)$. The mention of a demonstration that there was no point in including in the paper seems to indicate that Euler grasped the difference between mathematical induction and arbitrary exemplifications. In other terms, Euler understood the need of proving that the procedure is effectively repeatable (namely, $P(n) \rightarrow P(n + 1)$). However, he did not provide such a proof (see Netz 1999, p. 269). On the contrary, when Euler dealt with this theorem in his *Introductio in analysin infinitorum* (see Euler 1748, I, pp. 296–299), he no longer mentioned the possibility of including a demonstration and seemed to consider the Scheme **S** as clearly satisfactory.

3 Examples as Persuasion Tools

In this section, I dwell upon the use of example as persuasion tool. In Euler's mathematics, and in particular in his great treatises, *Introductio in analisyn infinitorum*, *Institutionum calculi integralis*, and *Institutiones calculi differentialis*, the mere logical reasoning was often accompanied by a myriad of examples and various applications: These examples played an important role: they showed the coincidence of results obtained with different techniques. In this way, the examples contributed to convince the reader of correctness and internal coherence of the calculus, which at the time was still a young and not well-founded science.

In order to accomplish his goal, Euler sometimes did not hesitate to use circular reasoning. In chapter IV of the second part of the *Institutiones calculi differentialis* (1755, pp. 359–402), Euler derived the series expansions of various functions by using the Taylor series

$$y(x+\omega) = y(x) + \frac{\omega dy}{dx} + \frac{\omega^2 d^2 y}{2dx^2} + \frac{\omega^3 d^3 y}{6dx^3} + \frac{\omega^4 d^4 y}{24dx^4} - \ldots, \tag{9}$$

which he proved in the previous chapter III (Euler 1755, pp. 335–336). In particular, Euler obtained the developments of several elementary functions, such as $(x + \omega)^n$, *log x*, a^x, *cos x*. However, in the context of Euler's treatises, the derivation of these expansions was vitiated by *petitio principii*.

In fact, to obtain the expansion of an elementary function by applying (9), one must know the differential ratio $\frac{dy}{dx}$ of that function. In the *Institutiones calculi differentialis*, part I, chapter IV (1755, pp. 98–107), Euler derived the differential ratio $\frac{dy}{dx}$ of an elementary function starting from (3). Euler set $\omega = dx$ in (3), namely, he considered the finite increment ω as an infinitesimal *dx*, and applied the principle of omission. (The principle of omission of differentials is the rule according to which

$dx^n + dx^m = dx^n$ if n < m.) Therefore, in Euler's construction, (3) was a necessary premise to the derivation of the differential ratio $\frac{dy}{dx}$ of a given function $y(x)$.

As seen above, in the chap. I of the *Institutiones calculi differentialis* (1755, pp. 3–38) Euler obtained (3) by using the power series expansions of elementary functions that he had proved in the *Introductio in analysin infinitorum*. In other terms, Euler derived the expansions of elementary functions by applying (9); however, these expansions were necessary to prove (3) and (9).

For instance, in the second part of the *Institutiones calculi differentialis*, chapter IV (1755, pp. 367–369), Euler derived the expansion of the function $y = \log_{10} x$, by calculating the differential ratios

$$\frac{d \log_{10} x}{dx}, \frac{d^2 \log_{10} x}{dx^2}, \frac{d^3 \log_{10} x}{dx^3}, \ldots.$$

and so obtained

$$\log_{10}(x + \omega) = \log_{10} x + \frac{m\omega}{x} - \frac{m\omega^2}{2x^2} + \frac{m\omega^3}{3x^3} + \ldots, \tag{10}$$

where $m = \log_{10} e = 0.4342944819032$. However, in the first part of the same book, chapter 1 (1755, pp. 22–23), Euler had derived the first difference of the logarithmic function in this way. He had noted that

$$\Delta y = \log(x + \omega) - \log x = \log\left(1 + \frac{\omega}{x}\right) \tag{11}$$

In the *Introductio in analisyn infinitorum* (1748, I, pp. 85–90), Euler had proved that

$$\log(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} \ldots \tag{12}$$

Euler applied (12) to (11) and so got

$$\Delta y = \frac{\omega}{x} - \frac{\omega^2}{2x^2} + \frac{\omega^3}{3x^3} - \frac{\omega^4}{4x^4} + \ldots \tag{13}$$

In chapter VI of the first part of the *Institutiones calculi differentialis* (1755, p. 152), Euler did not apply formula (13) in order to derive the differential ratio of the logarithmic function. He preferred to replace ω by dx in (11) so to obtain

$$dy = \log(x + dx) - \log x = \log\left(1 + \frac{dx}{x}\right) \tag{14}$$

Then he applied (12), (13), and (14) and so got

$$dy = \frac{dx}{x} - \frac{dx^2}{2x^2} + \frac{dx^3}{3x^3} - \frac{dx^4}{4x^4} + \ldots$$

At this juncture, he used the principle of omission, namely, he neglected high order infinitesimals, and got

$$d(\log x) = dy = \frac{dx}{x}.$$

However, (10) is only a trivial transformation of (12), since

$$\log_{10}(x+\omega) = \log_{10}\left[x\left(1+\frac{\omega}{x}\right)\right] = \log_{10}x + \log_{1\,0}\left(1+\frac{\omega}{x}\right)$$
$$= \log_{10}x + m\log\left(1+\frac{\omega}{x}\right)$$

In conclusion, the knowledge of the expansion of the logarithmic function presupposes the knowledge of the differential of the logarithmic function; however, the differential of the logarithmic function presupposes the knowledge of the expansion of the logarithmic function.

Euler's procedure is circular. It, however, is to be seen in the attempt to show that the various parts of analysis formed a coherent structure. Given the ease with which (10) could directly be deduced from (12), it is probable that the goal of Euler's derivation was to convince the reader of the substantial correctness of the computations, showing the uniqueness and non-contradiction of the findings of the calculus, although its foundations could appear uncertain.

This approach is often found in Euler's writings. It is closely linked to Euler's use of the examples as tools for verification of results and persuasion of the reader. In fact, even there existed a proof of certain theorems, Euler sometimes made use of examples to verify and check the validity of these theorems. These examples, well-placed in some critical points of his works, also had a rhetorical effect that contributed to promote the new analysis of infinities. They connected the various parts of analysis and showed its overall coherence also through the a posteriori agreement of the results.

Let us consider the Eulerian treatment of the so-called de l'Hôpital rule. Already in *Analyse des Infiniment petits* (1696, p. 146), the Marquis de l'Hôpital had clarified the rule that today bears his name by applying it to the function $y = \frac{aa-xx}{a-\sqrt{ax}}$ for $x = a$. He had then showed that the same result could also be obtained by algebraic ways and that, therefore, the results of the new Leibnizian calculus coincided with the results obtained by now more consolidated methods.

Euler approached the matter in a similar way. In his paper (1755, pp. 746–750) Euler used the de l'Hôpital rule to calculate the value of rational functions such as

$$\frac{x-x^n}{1-x}, \frac{x-x^{2n+1}}{1-x^2}, \frac{x-(n+1)x^{n+1}+nx^{n+2}}{(1-x)^2}, \ldots, \text{for} x = 1.$$

He found that the sought values were n, n, $\frac{n(n+1)}{2}$, ... In order to better persuade the reader of the correctness of these results, Euler showed that they could also be obtained by employing the following elementary identities:

$$\frac{x - x^n}{1 - x} = x + x^2 + \ldots + x^{n+1},$$
$$\frac{x - x^{2n+1}}{1 - x^2} = x + x^3 + \ldots + x^{2n-1},$$
$$\frac{x - (n+1)x^{n+1} + nx^{n+2}}{(1-x)^2} = x + 2x^2 + \ldots + n\,x^n,$$
$$\ldots$$

For $x = 1$, the right-hand sides of these identities, respectively, becomes

$$1 + 1 + 1 + \ldots + 1 = n,$$
$$1 + 1 + 1 + \ldots + 1 = n,$$
$$1 + 2 + 3 + \ldots + n = \frac{n(n+1)}{2},$$
$$\ldots$$

Euler explicitly observed:

> Since ... the same sums are observed by using other methods, the truth of this method will be further evident from the agreement [of the results]. (Quoniam ... eaedem summae aliunde constant, ex consensu veritas huius methodi magis elucebit Euler (1755, p. 747).)

After validating the 'truth' of the de l'Hospital rule by the a posteriori agreement of this rule and elementary methods, Euler applied the rule to transcendent functions. He thus showed the effectiveness of the rule by means of another series of examples, which now only performed the function of clarifying the method (and no longer the function of showing its correctness):

> The same method will be required to be used, if in the given fraction P/Q, the numerator or the denominator or both were a transcendent quantity. In order to explain these operations more clearly, it has been considered to add the following examples. (Eadem methodo erit utendum, si in fractione proposita P/Q vel numerator vel denominator vel uterque fuerit quantitas trascendens. Quae operationes, quo clarius explicentur, sequentia exempla adiicere visum est (Euler 1755, pp. 750–751).)

Another case of the use of examples as a tool of persuasion and verification is found in Euler (1755, p. 336). Immediately after having proved formula (9), Euler stated:

the truth of this expression can checked in examples in which the higher differentials of y vanish at last; for, in these cases the number of terms of the above expression will become finite. (veritas huius expressionis comprobari poterit eiusmodi exemplis, quibus differentialia altiora ipsius y tandem evanescunt: his enim casibus numerus terminorum superioris espressionis fiet finitus (Euler 1755, p. 336).)

Euler (1755, pp. 336–338) provided three examples concerning the functions

$$x^2 - x, \quad x^3 + x^2 + x, \quad x^2 + 3x + 1$$

He computed the values of these functions when one set $x + 1$, $x + 2$, x-3 in place of x in $x^2 - x$, $x^3 + x^2 + x$, $x^2 + 3\,x + 1$, respectively. The computation was performed twice. Firstly, Euler used formula (9). Secondly, he employed elementary algebra. Both in the case, he got the same results and this was considered as a validation of expansion (9).

For instance, let us consider the function $y = x^2 - x$. The differential ratio of this function are

$$\frac{dy}{dx} = 2x - 1, \quad \frac{d^2y}{dx^2} = 2, \quad \frac{d^3y}{dx^3} = 0, \ldots$$

By applying (9), one gets

$$y(x + 1) = x^2 - x + 1(2x - 1) + \frac{1}{2} \cdot 2 = x^2 + x$$

The same result is obtained setting $x + 1$ in place of x. Indeed x^2 changes into $(x + 1)^2$ and x into $x + 1$; then $(x + 1)^2 - (x + 1) = x^2 + x$.

In (1755), Euler used other examples to show the 'truth' of some infinite series which he had derived from the Taylor series. More precisely, Euler, first, formally manipulated the Taylor series and obtained an infinite series. Then, in order to persuade the reader of the correctness of his investigations, he applied his finding to some particular cases in which the infinite series was reduced to a finite series or to the sum of the series was already known.

For instance, in his (1755, p. 353) Euler noted that if one put $\omega = -x$, formula (9) changed into

$$y(0) = y(x) - \frac{xdy}{dx} + \frac{x^2d^2y}{2dx^2} - \frac{x^3d^3y}{6dx^3} + \frac{x^4d^4y}{24dx^4} - \ldots \tag{15}$$

He asserted that "the following examples will illustrate the truth of which (15)" ("cuius veritatem sequentia exempla illustrabunt" (Euler 1755, p. 353).). The examples concern the functions

$$x^2 + ax + ab, \; x^3 - 2x + 3, \; \frac{x}{1 - x}, \quad e^x, \sin x$$

(Euler 1755, pp. 353–356). I do not dwell on Euler's interpretation of (9) and (15), which was very different from the modern interpretation. I limit myself to observing that, according to Euler, his interpretation of (15) was true because it was verified by five functions.

For instance, in case of the function $y \sin x$, Euler showed that the right-hand side of (15) was precisely equal to the value of the function at x 0. In the same way, Euler (1755, p. 357) provided the formula

$$v(t) = y(x) + \frac{(t-x)dy}{dx} + \frac{(t-x)^2 d^2 y}{2dx^2} + \frac{(t-x)^3 d^3 y}{6dx^3} + \frac{(t-x)^4 d^4 y}{24dx^4} + \ldots,$$

where $v(t)$ is the function arising from $y(x)$ on setting t in place of x, and stated that "the truth of which can be proved by any example" ("cuius veritas quibuscunque exemplis comprobari potest" (Euler 1755, p. 357)).

In his *Institutiones calculi differentialis*, Euler also applied (9) in order to derive what he termed "the well-known Newtonian expression," namely, the Taylor series of $y = x^n$:

$$(x+\omega)^n = x^n + \frac{n}{1}x^{n-1}\omega + \frac{n(n-1)}{1\cdot 2}x^{n-2}\omega^2 + \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}x^{n-3}\omega^3 + \ldots, \tag{16}$$

When Euler proved this formula at pp. 360–361 of his treatise on differential calculus (1755), he had already used it several times in the previous pages. This derivation is to be considered a further verification of (9) and, more generally, of the validity of the calculus. Indeed, this derivation was superfluous in the context of the second part of the *Institutiones calculi differentialis*. In section 73, chapter IV (1755, p. 361), Euler applied (16) in order to determine the following expansion of $(x+u)^n$

$$(x+u)^n = x^n + \frac{nx^n u}{1(x+u)} + \frac{n(n+1)x^n u^2}{1\cdot 2(x+u)^2} + \frac{n(n+1)(n+2)u^3 x^n}{1\cdot 2\cdot 3\cdot (x+u)^3} + \ldots \tag{17}$$

(In fact, formula (17) was derived from (16) by the substitution $\omega = -\frac{ux}{x+u}$). Expansion (17), useful for numerical applications, was the final objective of chapter IV of the *Institutiones calculi differentialis*. However, (16) was not essential to derive (17): in the subsequent section 74 (1755, pp. 362–363), Euler himself gave another proof of (17) where (16) was not applied.

Expansion (16) was, therefore, superfluous whether Euler's goal was the derivation of (17). More significantly, the proof of (16) was also vitiated by a circular

reasoning, as Euler himself noted some years later. Indeed, in his *Demonstratio theorematis newtoniani de evolutione potestatum binomii* (1774, pp. 105–106) he stated that this proof of (16) derived from analysis of infinite quantities; however, analysis of infinite was grounded upon this theorem. (The binomial theorem was used to prove (9) and (3).) For this reason, he asserted:

> I now recognize that this *petitio principi* is to be completely rejected. (eam tanquam petitionem principia penitus reiiciendam nunc agnosco (Euler 1774, p. 106).)

In (1774) Euler provided a new demonstration of (16) free of this error and observed: (Another demonstration of the binomial theorem was later given by Euler in his (1787). On the history of the binomial theorem, see Pensivy (1987).)

> I am confident that geometers will like my demonstration, because nothing is based on induction in it (meam demonstrationem Geometris eo gratiorem fore confido, quod in ea nihil plane induction tribuitur (Euler 1774, p. 106)).

Therefore, in the *Institutiones calculi differentialis*, the proof of (17) can be viewed as a rhetorical tool to convince the reader of the internal coherence of the analysis of the infinities and of the interlocking of its various parts. Thus, when in the *Demonstratio theorematis newtoniani* Euler admitted the existence of a circular reasoning, it seems that he felt the need to overcome certain methods of persuasion.

Euler used the above-described approach in other cases. Sometimes, the selected examples are not appropriate to substantiate the general proposition. This occured in *De usu functionum discontinarum in Analysi* (1765b), where Euler gave one only example in order to eliminate any possible doubt about the differential ratio of discontinuous functions (the example is the function $y = ax^2 + bx + c$):

> Since this notion of differentials and the investigation of the ratio between evanescent quantities seem to be extremely suspect to most, all doubts disappear with an example. (Cum plerisque haec differentialum notio, et rationis, quae inter quantitates evanescentes intercedit, investigatio, maxime suspecta videri soleat, unico exemplo omnio dubia evanescet (Euler 1765b, p. 12).)

In his *De summis serierum reciprocarum* (1734), Euler determined the sums of the series

$$\sum_{i=1}^{\infty} \frac{1}{n^{2k}} (k = 1, 2, \ldots)$$

(on Euler's theory of series, see Ferraro (2007b)). His procedure was the object of various criticisms. In his *Démonstration de la somme de cette suite* $1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \frac{1}{25} + \frac{1}{36} +$ etc. (1743a), Euler replied to these criticisms and stated:

> The method I gave in the Comments of the Petersburg Academy to find the sum of this sequence, when the exponent n is an even number

$$1 + \frac{1}{2^n} + \frac{1}{3^n} + \frac{1}{4^n} + \frac{1}{5^n} + \frac{1}{6^n} + etc.$$

has something extraordinary, because it is drawn from a principle that has not been used much in the researches of this nature. However, it is as sure and grounded as any other method which is ordinarily used in the summation of infinite sequences: I have also shown this by the perfect agreement of some cases already known elsewhere and by the approximations, which provide us with an easy way to examine the truth in practice.

> La méthode que j'ai donnée dans les Commentaires de l'Académie de Pétersbourg pour trouver la somme de cette suite, lorque l'exponant n est un nombre pair
>
> $$1 + \frac{1}{2^n} + \frac{1}{3^n} + \frac{1}{4^n} + \frac{1}{5^n} + \frac{1}{6^n} + etc.$$
>
> a quelque chose d'extraordinaire, parcequ'elle est tirée d'un principe dont on n'a pas encore fait beaucop d'usage dans les recherches de cette nature. Elle est cependant aussi sûre et aussi fondée que toute autre méthode dont on se serve ordinairement dans la sommation des suites infinies: ce que j'ai fait voir aussi par le parfait accord de quelques cas déjà connus d'ailleurs et par les approximations, qui nous fournissent une manière aisée d'examiner la vérité dans la pratique (Euler (1743a, p. 177).

In (1743a) – but in other papers too (for example Euler (1743b)) – Euler validated his method by performing the same sums by a different method; the coincidence of the results should have persuaded of the validity of the method. No one, in reality, doubted the accuracy of the sums

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6};$$
$$\sum_{n=1}^{\infty} \frac{1}{n^4} = \frac{\pi^4}{90};$$
$$\dots$$

Criticisms concerned the proof, not the result (Cf. Euler (1743b, pp. 138–141).). To modern eyes, it is clear that exhibiting new different demonstrations, in itself, is not a valid defense of the original demonstration. Euler again made an a posteriori justification which was a persuasion tool for the reader and checked the validity of the obtained results. (In a similar way in his *De seriebus divergentibus*, Euler used four different metods in order to sum 1–1 + 2–6 + 24 + ... The different methods achieved the same result: thus each of these methods supported the others (on this, see Ferraro 2000b).)

Abstract

We propose a characterization of mathematical experiments in terms of a setup, a process with an outcome, and an interpretation. Using a broad notion of process, this allows us to consider arithmetic calculations and geometric constructions as components of mathematical experiments. Moreover, we argue that mathematical experiments should be considered within a broader context of an experimental research project. Finally, we present a particular case study of the genesis of a geometric construction to illustrate the experimental use of hand drawings and computers in mathematical practice.

1 Introduction

Mathematics can be regarded as an a priori science that proceeds deductively from certain indubitable truths. However, while this might be an idealized generalization of how a particular mathematical subject is presented, it is quite far from being an adequate characterization of how mathematics is practiced. Indeed, not much acquaintance with mathematics is needed to realize that establishing new mathematical results frequently starts with a generalization of some systematically obtained instances (Polya 1954), that the formulation of a system of axioms is frequently the eventual outcome of trying out various possible sets of candidates (Schlimm 2013), and that definitions are frequently obtained by a gradual honing in on the those formulations that are deemed most fruitful (Tappenden 2008). In addition, the increased use of computers in mathematical research in recent years has emphasized again certain analogies between mathematics and the natural sciences, and motivated mathematicians and philosophers to reconsider their view of mathematics (Secco 2017; McEvoy 2023). This challenge is highlighted by the claim that experiments, which are deemed a cornerstone of the scientific method, also play a crucial role in mathematics (Borwein and Bailey 2004). In reaction to this claim, philosophers of mathematics have suggested and discussed various characterizations of the notion of a *mathematical experiment* (Van Bendegem 1998; Baker 2008; Sørensen 2010). In this chapter, we first propose a refinement of these characterizations into different components. In addition, we extend the notion of computation used in one of these components to include geometric constructions, and we embed mathematical experiments into a broader context of experimentation (Sect. 2). Then, in the second part, we illustrate our framework by presenting the genesis of a geometric construction (the Midpoint Path Construction) with a focus on how mathematical experiments done on paper and computer contributed to its development (Sect. 3).

2 Mathematical Experiments and Experimental Research Projects

2.1 Mathematical Experiments

To set the stage, let us consider an individual *mathematical experiment* to consist of the following three components: (i) a setup, (ii) a process with an outcome, and (iii) a conclusion, i.e., an interpretation of the outcome. For the sake of simplicity, this characterization omits further layers of complexity that have been addressed by philosophers of science, such as the theory-ladenness of observations, the

interactions with artifacts and measuring instruments, and the role of models.[1] Nevertheless, we maintain that our three components provide a focused and useful framework for the further discussion of experiments in mathematics. Let us now take a closer look at these components.

The **(i) setup** of a mathematical experiment consists in the specification of an initial mathematical situation or configuration, such as a formula or algorithm with some initial parameters. In addition, the setup can also include certain expectations about the outcome of the experiment. Such expectations are typically expressed in terms of a *hypothesis* that is to be confirmed or rejected on the basis of the outcome and which is embedded in a set of background assumptions, such as a theory, which is formulated more or less explicitly. Because experiments that are intended to test a hypothesis by providing evidence for its acceptance or rejection are typically employed in the natural sciences, we shall refer to them as *scientific* experiments. In contrast, experiments that are conducted without any particular expectations regarding their outcome are *exploratory* experiments (Sørensen 2010).[2] The latter are frequently performed at the beginning of a new research project and are used to gather additional data for determining regularities and for subsequent conjecturing.

The **(ii) process** of an experiment is the part about which the experimenter should have no influence beyond setting the initial conditions and specifying the procedure.[3] In the case of a mathematical experiment, the process typically consists of a computation or construction that yields a certain **outcome**, i.e., a mathematical situation or configuration that results from applying a determinate procedure to the setup.[4] However, the nature of the experimental process can vary considerably: it can be carried out by the mathematician on paper, on a computer, or in the mind (e.g., as a thought experiment[5]), or it can be carried out completely automatically on a computer. In Baker's account of mathematical experiments, these processes are the "means" of calculation (Baker 2008, 340). In the natural sciences, the process traditionally involves some physical interaction with the world, but it has also

[1] As examples for the rich taxonomies of scientific experimentation developed by philosophers of science, see Hacking (1988, 508) and Galison (1988, 525), in which many different relations between experimentation, theory, and instrumentation are discussed. For a more recent overview, see Feest and Steinle (2016). In light of the turn in philosophy of science towards research processes and knowledge generation, one can see the present chapter as a contribution towards bringing together analyses of scientific and mathematical experimental practices.

[2] In philosophy of science, we find this distinction under the labels of "theory-driven" and "exploratory" experiments (Steinle 1997, S70); for a discussion of the epistemological significance of exploratory experiments, see Steinle (1997, S72).

[3] If the experiment is carried out by hand or as a thought experiment, the experimenter is directly involved in the process, but this should not affect the outcome.

[4] Notice that a computation, understood as a process, is only a *component* of a mathematical experiment; this might answer in part Van Bendegem's worry that "it seems that it is very difficult to make any sense out of the idea of considering a computation (whether aiming for a numerical result or a visual image) as a form of mathematical experiment" (Van Bendegem 1998, 178).

[5] See Starikova and Giaquinto (2018) and Starikova (2023) for a discussion of mathematical thought experiments.

become common practice to regard explorations using mathematical models and computer simulations as experiments.[6]

Finally, for an activity to count as an experiment, its outcome has to lead to a certain **(iii) conclusion**, i.e., an appropriate interpretation of the outcome. For example, we can interpret the outcome as new data to be studied in the case of exploratory experiments or as evidence for the confirmation or rejection of a hypothesis in the case of scientific experiments. What distinguishes an experiment from, say, an exercise is the nature of the conclusion that is drawn from the outcome. In an exercise, the outcome is simply accepted as the result, reflecting the correct or incorrect application of the process; in an experiment, the outcome is interpreted in relation to a hypothesis or taken as a data point for further investigations. In the case of scientific experiments, and in contrast to exploratory ones, the experimenter needs to have a clear conception of the expected outcome (hypothesis) and to retain a principled openness with regard to the possibility that the actual outcome might violate this expectation.

To illustrate the various components of mathematical experiments discussed above, let us briefly consider a simple activity and how it can be considered to feature in a mathematical experiment. As *setup*, we have two collections of pebbles that we have individually counted to consist of 3 and 5 pebbles. The experimental *process* consists in putting these two individual collections together and counting the pebbles in the new collection, resulting in the outcome of a count of 8.[7] Now, if we had the expectation that the all pebbles together will yield a count of 8 as part of the setup, then the outcome corroborates this hypothesis and we arrive at the *conclusion* that, when counting pebbles, $3 + 5 = 8$. Notice, however, that the same process and outcome could be interpreted in different ways. On the one hand, we might already be convinced that $3 + 5 = 8$, but we are not sure whether this arithmetical fact is applicable to counting pebbles. In this case, the conclusion of the experiment is support that pebbles are indeed things that obey the laws of arithmetic. Further support would be gained by repeating the experiment. On the other hand, the process might be part of an exploratory experiment, where the setup does not contain any expectations about the outcome. This could be the case when we are only beginning to learn about addition of numbers and we genuinely do not know what the result is of adding three things to five things. In this case, the experiment gives us an additional data point that we can use in support of the general fact that $3 + 5 = 8$, which may lead to further generalizations or investigations. These three different interpretations of the same process and outcome show that the conclusion drawn from a particular outcome depends to some extent on what kind of assumptions and expectations are part of the initial setup. In particular, this illustrates that our

[6] See Morgan's discussion of different "materialities" of experiments in Morgan (2003): material, semi-material, nonmaterial, and mathematical; for a discussion of computer simulations, see Barberousse et al. (2009).

[7] Van Bendegem considers such "real-world-experiments" but concludes that "they are quite uninteresting" for mathematics, "rather trivial," and that "no serious implications should be drawn from them" (Van Bendegem 1998, 179).

characterization of experiments implies that the same process and outcome can be considered to constitute an experiment in some cases but not an experiment in others (e.g., when no particular conclusion is drawn from the outcome). In other words, whether something counts as an experiment depends on the context determined by the setup and the conclusion.[8]

2.2 Mathematical Experimental Research Projects

While it can be useful to consider individual mathematical experiments in isolation in order to identify their characteristics (as we did above), we also believe that this idealization actually hinders our understanding of their role in mathematical practice. Indeed, experiments are rarely conducted in isolation but are typically part of an experimental research project embedded in much more elaborate practices, including background assumptions, techniques, and goals.[9] For example, in practice, the setup of an experiment is rarely based on an arbitrary hypothesis, but on one that is part of a *guided investigation*, which typically consists of numerous iterations of experimenting and theorizing.[10] Such an investigation could proceed as follows: The initial spark might be a fortuitous observation of some pattern that is generalized to form a conjecture; this leads to an experiment with a slight variation of the original setup, which is expected to result in a pattern that also falls under the generalization; the result of this experiment, besides supporting a confirmation or refutation of the hypothesis, yields new data that can be used to suggest conceptual innovations or refinements as well as new generalizations; and so on. This iterative account of what we shall call a *mathematical experimental research project* provides us with a rough sketch for discussing the context of mathematical experiments.[11] Such a context is usually acknowledged also by researchers who focus on the characterization of individual experiments: for example, Sørensen speaks of "an *integrated process* of experimentation, concept formation, and conjecturing" (Sørensen 2010, 354; emphasis added).

In the literature, mathematical experimental research has been discussed frequently in relation to mathematical discovery, in particular in the seminal work of George Polya. For him, the iterative character of such research is analogous to the experimental practice in the natural sciences, which he describes as follows:

[8] This view about the context-dependency of experiments is not shared by everyone; Van Bendegem, for example, considers it "slightly, if not simply, odd" (Van Bendegem 1998, 175).

[9] See Ferreirós (2015) and Wagner (2017) for general accounts of mathematical practices.

[10] In the case of investigations directed at the solution of specific questions or problems, Detlefsen and Arana speak of "directed investigations" (Detlefsen and Arana 2011, 9); see also the notion of a "trial" in a mathematical thought experiment (Starikova and Giaquinto 2018, 263).

[11] The iterative nature of experimental research in science has been emphasized by Chang (2004); see also Elliott (2012) for a discussion.

> If a naturalist observes a striking regularity, which cannot be reasonably attributed to mere chance, he conjectures that the regularity extends beyond the limits of his actual observations. [...] The following step may be prediction. On the basis of his former observations and their concordance with conjectural law, the naturalist predicts the result of his next observation. (Polya 1954, 49)

In his discussion of Euler's formula for polyhedra, which is satisfied by nine different polyhedra, Polya explicitly draws an analogy between research in mathematics and the scientific practice of a naturalist, who will doubt even a plausible hypothesis that has been occasionally verified: the scientist "will question it and collect new observations or design new experiments to test it." Accordingly, Polya suggests to his mathematical reader: "We may do the very same thing" (Polya 1954, 38). Even after further corroboration of the hypothesis, "a conscientious naturalist would feel satisfaction over the success of his experiments, but would go on devising further experiments," in particular ones that are more likely to refute it (Polya 1954, 38–41).[12] Similar accounts of mathematical research can easily be found in mathematicians' own reflections, as well as in studies of their research practices. An example of the latter is Haffner's recent investigation of unpublished manuscripts by Dedekind that document the path towards his introduction of lattices (or, as he called them, "Dualgruppen"), which she describes as "Dedekind's *systematic experimentations*" (Haffner 2021, 15; emphasis added).[13] Haffner explicitly identifies several phases of explorations in Dedekind's work using "computations and diagrams as ways to experiment to better understand the laws of module theory by manipulating simple cases, testing on progressively more general cases, trying to identify the laws susceptible to hold in the general case, and the ones that do not." These were followed by conceptual developments, which were "then followed by new phases of experimentation and clarification," to finally end in his theory of Dualgruppen (Haffner 2021, 10–11).

2.3 Experiments with Diagrams

Recall that a crucial component in our characterization of mathematical experiments was a *process with an outcome*. Now, in the field of "experimental mathematics," as understood by Borwein and Bailey (2004), this process is carried out by a computer. However, as Baker has plausibly argued, the use of computers should not be considered a necessary condition for mathematical experiments. We agree with Baker that the process of a mathematical experiment may consist of computations by computer or by hand, but we push his conclusion even further by suggesting also the use of other means of mathematical reasoning. In general, we can understand mathematical reasoning as the drawing of consequences from mathematical

[12] These passages are also referred to in Lakatos (1976, 7).

[13] Similarly, Dedekind's contemporary Cantor also speaks of his "experiments [Versuche] which have lasted many years" (Cantor 1883, quoted from the translation in Ewald 1996, 890).

situations within certain prescribed boundaries. Because mathematical situations can quickly become too complex for us to keep before our mind's eye, so to speak, we represent them externally by symbols, formulas, or diagrams. In doing so, we extend our cognitive capacities, but such representations also allow us to keep a durable and shareable record of the reasoning process and they can be used to determine the boundaries of accepted inferences, such as the inferential steps within a regimented language or the restriction to a set of tools, e.g., compass and straightedge. Moreover, rather than just representing a mental reasoning process, external representations can themselves be the vehicles of epistemic inferences.[14]

An impressive example of mathematical experimental research using geometric representations has been reported about the late Fields medalist Maryam Mirzakhani: "As she thought about mathematics, Mirzakhani constantly doodled, drawing surfaces and other images related to her research" (Klarreich 2018, 151). Since hyperbolic surfaces with slight spatial variations could have different geodesics, Mirzakhani produced numerous drawings of slightly different variations to study them. According to her husband, Jan Vondrák, "[s]he has these huge pieces of paper on the floor and spends hours and hours drawing what look to me like the same picture over and over" (Klarreich 2018, 151). The fact that each drawing is part of an overarching experimental project comes out in the "over and over" passage of the previous quote. As we shall see in our case study below, using computers can greatly facilitate and enhance this aspect of an experimental practice.

3 The Genesis of the Midpoint Path Construction

Geometric constructions with compass and straightedge date back to at least the times of the ancient Greeks. These are based on combinations of the following constructions, which correspond to the first three postulates of Euclid's *Elements*:[15] drawing a line segment between two points, extending a line segment by any length in a straight line, and drawing a circle with a given point as center that also passes through another given point. A more complex construction from antiquity, which in addition also relies on drawing parallel lines and which is justified by the Intercept Theorem (also known as Thales' Theorem), allows one to draw a line segment whose length is a rational multiple of the length of a given segment. Recently, an alternative construction that yields the same result was put forward (Fernández

[14] See, e.g., Giardino (2018), Carter (2019), and Vold and Schlimm (2020). Because of the predominance of presenting mathematical reasoning in terms of external representations, some philosophers, such as Peirce and Wittgenstein, have claimed that *all* mathematical reasoning is ultimately based on observations.

[15] Heath warns against interpreting the object of the postulates purely as limiting possible constructions (Heath 1968, 124).

González 2016).[16] The Midpoint Path Construction makes it possible to multiply the length of a line segment by a rational number between 0 and 1 by constructing only midpoints and a straight line. It is also based on the use of compass and straightedge but does not require the drawing of parallel lines.

In the present section, we describe the genesis of the Midpoint Path Construction as a case study to illustrate and discuss the use of experiments in mathematics. Section 3.1 presents the construction and the main stages of its discovery process. Then, in Sects. 3.2 and 3.3, we take a closer look at the use of mathematical experiments by hand and by computer in the emergence of the construction.

3.1 Genesis and Explanation of the Construction

We present here a simplified narrative of the process of discovery of the Midpoint Path Construction. According to Juan Fernández González, the second author of the present chapter who developed the construction in question, the process began when he doodled in his school agenda without expecting any particular result and found what seemed to be a way to divide a line segment into three equal parts.[17] The diagram on the right of Fig. 1 shows this initial construction. Given a line segment $[UV]$ with endpoints U and V, and an arbitrary point M_0 not on $[UV]$, a series of

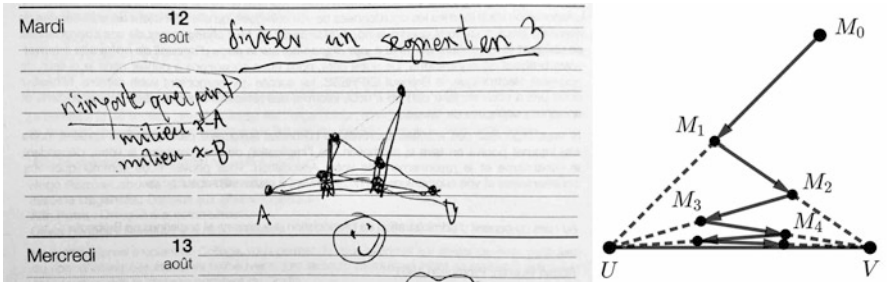

Fig. 1 Left: One of Juan's first doodles showing a construction to divide a line segment into three equal parts, drawn on his school agenda. Right: Computer drawing of the doodle in which A and B were respectively renamed U and V to be consistent with Fernández González (2016). (This and other figures were used in Fernández González and Schlimm (2023) and are used here with permission of the authors)

[16] The background of the development of this result is presented in the form of an interview in Fernández González and Schlimm (2023). Some of the reproductions from Juan's notebooks shown in that article are also used below with permission from the authors.

[17] As reported by Martin Gardner (1983, 82–83), Stanislaw Ulam's discovery of particular patterns in the distribution of prime numbers (Stein et al. 1964) began in a similar, absent-minded kind of way: During a "long and very boring" conference talk, Ulam "doodled a grid of horizontal and vertical lines on a sheet of paper," then numbered them in a specific way, circled the prime numbers, and "to his surprise the primes seemed to have an uncanny tendency to crowd into straight lines." We are thankful to David Waszek for pointing us to this example.

midpoints is constructed: M_1 is the midpoint of $[M_0U]$, M_2 is the midpoint of $[M_1V]$, M_3 is the midpoint of $[M_2U]$, M_4 is the midpoint of $[M_3V]$, and so on, always alternating between U and V in each step. The series of points M_0, M_1, M_2, ..., which was later called a *midpoint path*, will get closer and closer to the line segment $[UV]$. If this construction would be continued forever, Juan conjectured that the points would end on the line segment $[UV]$, dividing it into three equal parts.

By varying the construction process (i.e., by not only simply alternating between U and V in the construction of the midpoints), Juan was able to obtain different outcomes, such as a division of the line segment by the midpoint path into five and seven equal parts (see Fig. 2). For example, to divide $[UV]$ into five equal parts, the midpoint path must go twice toward V, then twice toward U, and so on. In other words, the midpoint path goes toward V, V, U, U, ... repeated indefinitely, as opposed to V, U, ... repeated indefinitely, as was the case in the construction that divides the segment into three equal parts. The representation of a midpoint path in terms of the endpoints of the segments of each constructed midpoint, such as "V, V, U, U, ..." turned out to be fruitful later, because it is independent of the location of the starting point M_0 and is called a *midpoint series*. In particular, since a midpoint series consists of only two symbols, it suggested a link to the representation of numbers in binary notation, which was pointed out by Gilbert Labelle.[18] After many such variations, Juan found other midpoint series that made it possible to divide a line segment into different whole numbers other than 3, 5, and 7.

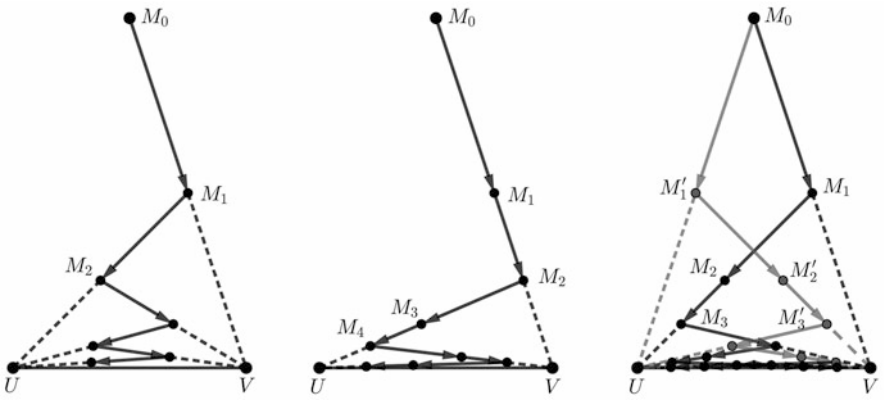

Fig. 2 Constructions using midpoint paths whose lengths tend to infinity to divide a line segment into three, five, and seven equal parts. Each midpoint path starts at point M_0 and is composed of successive constructions of midpoints M_i, which are either the midpoints of $[M_{i-1}U]$ or $[M_{i-1}V]$, for $i = 1, 2, \ldots$. The rightmost construction shows two midpoint paths: one composed of points M_0, M_1, M_2, ..., and one composed of points $M_0, M_1', M_2', \ldots$. Both are needed to divide $[UV]$ into seven equal parts

[18] Gilbert Labelle, emeritus professor at the Department of Mathematics at the *Université du Québec à Montréal*, helped Juan with the writing of the published article.

A drawback of these constructions was that they ultimately required an infinite number of midpoints. Thus, while the end results in the limit could be *seen* in the diagrams, they could actually never be reached after only a finite number of construction steps. Through inspection of various instances of such constructions, Juan realized that the same outcome could be obtained after only a finite number of steps. In fact, he noticed that in the diagrams, some of the midpoints seemed to be aligned, such as M_0, M_2, M_4, M_6, M_8, ... in Fig. 2 (left). Thus, it seemed that one needed to construct only the first two points of this midpoint path, namely M_1 and M_2, and then to draw a straight line passing through M_0 and M_2. This *convergence line*, Juan conjectured, would then intersect the segment $[UV]$ at one-third of its length (see Fig. 3; also for the constructions of 1/5 and 1/7). With this insight, it became possible to use only a finite number of steps to obtain the same result that originally had required an infinite process. Moreover, the construction was also simplified in another respect: to construct the point at 1/3 of $[UV]$, one did not have to simultaneously also construct another point at 2/3.

After much experimentation (i.e., varying the setup, carrying out the same construction or process, and evaluating the results), the idea of a special type of midpoint paths, which start and end at the same point, emerged. More precisely, their existence was observed when Juan drew midpoint paths that started at the newly constructed point P. These paths eventually named *midpoint loops* and were essential to further develop the construction. By drawing midpoint paths and midpoint loops in the same diagram, new spatial relationships became visible, which helped Juan formulate new conjectures and advance his research. Figure 4 shows the same examples from Fig. 3, but with added midpoint loops on the segment $[UV]$. In the diagram on the left of Fig. 4, we see a midpoint path consisting of points M_0, M_1, and M_2, and the corresponding midpoint loop with points P and P_1 (such that the loop begins and ends in P). Both are defined by the midpoint series V, U, such that P_1 is the midpoint of $[PV]$ and P is the midpoint of $[P_1U]$. From observing the behavior of midpoint loops, Juan realized that for any midpoint series, there are infinitely many

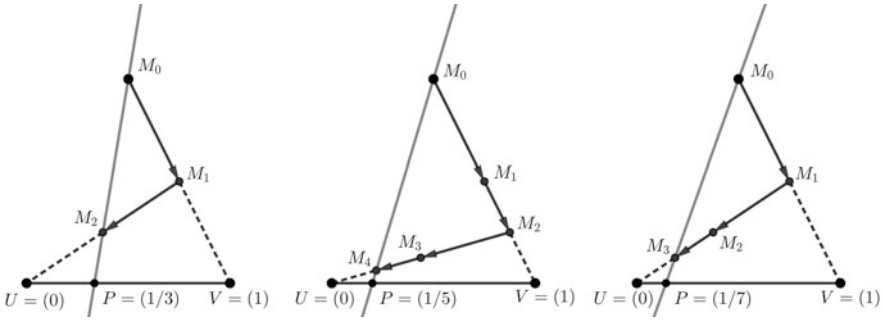

Fig. 3 Constructions using midpoint paths with a finite number of points M_i to construct the points $P = (1/3)$, $P = (1/5)$, and $P = (1/7)$, respectively, from left to right, with $U = (0)$ and $V = (1)$. This is done with the help of a convergence line

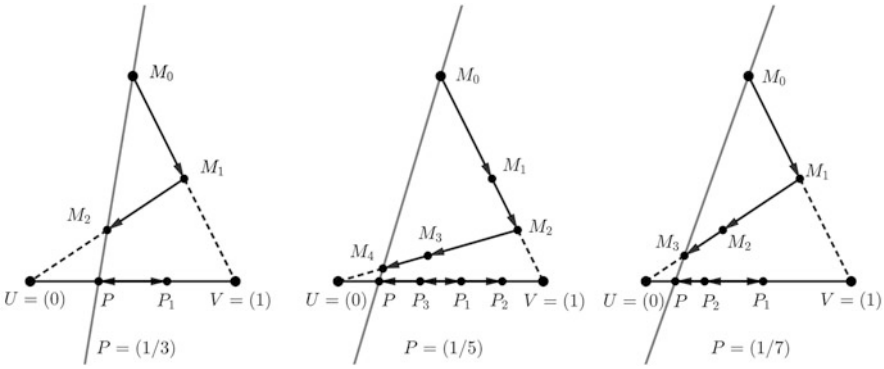

Fig. 4 Three midpoint paths (composed of points M_i) and their corresponding midpoint loops (composed of points P_i, each starting and ending at point P). These midpoint paths are the same as those in Fig. 3

midpoint paths (because the starting point M_0 could have an arbitrary position not on the straight line (UV)) but only one midpoint loop.

The developments sketched in the previous paragraphs ultimately led to a further generalization, called *homothetic paths*. For these, Juan was able to prove the Homothetic Path Theorem, which establishes a relationship between an infinite number of midpoint paths and a single midpoint loop. The Midpoint Path Theorem establishes the link between a midpoint series and the point P on a line segment $[UV]$, such that the length of $[UP]$ is a fixed rational multiple of the length of $[UV]$.[19]

3.2 Geometric Experiments on Paper

Let us now look in more detail at the role played by mathematical experiments in the development of the Midpoint Path Construction. While it is not difficult to think of a single line segment and its midpoint, imagining a series of midpoint constructions is more challenging, and so it should not come as a surprise that Juan's constructions were initially drawn on paper. This allowed him to visually represent complex mathematical situations, to trace the construction process, and to study the result of the outcome. In fact, Juan drew on various media for his experiments, such as his school agenda, napkins, and a bus's frozen window, but the great majority of the creative process behind the discovery was documented in small notebooks that were easy to carry around (Figs. 5 and 6 show spreads these notebooks). It is a characteristic feature of Juan's notebooks that they are very detailed, perhaps more so than the notes of a more experienced researcher, whose guided investigations would be honed by previous experiences.

[19] These results are presented in Fernández González (2016).

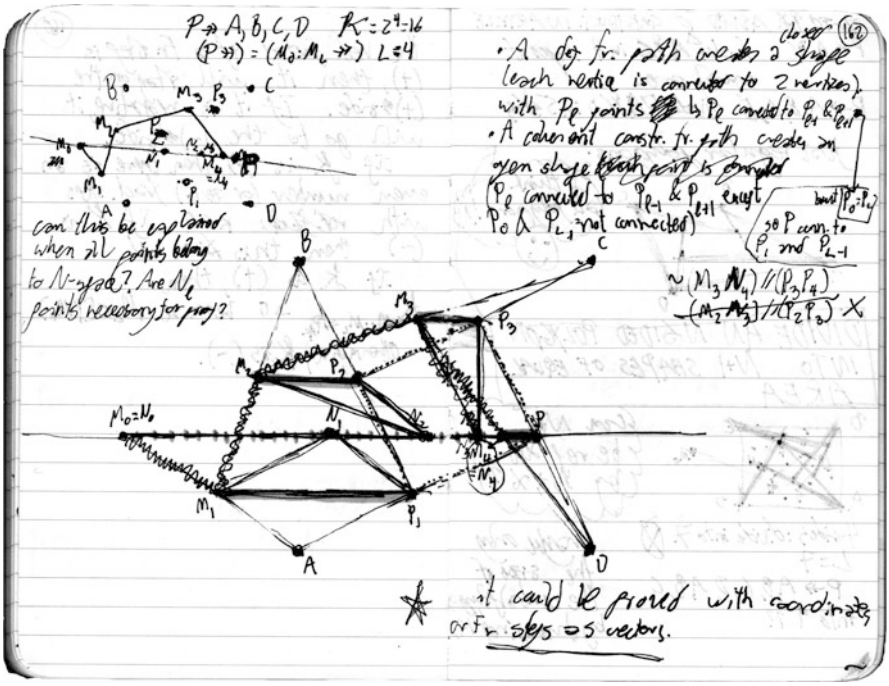

Fig. 5 In the central drawing, one can see a midpoint path M_0, M_1, M_2, M_3, M_4 and a midpoint loop P, P_1, P_2, P_3, P. Instead of having two points U, V defining the construction of each new midpoint like in the previous examples, there are four arbitrary noncollinear points A, B, C, and D that play the same role. As a result, the points of the midpoint loop P, P_1, ... are not collinear either. This allowed Juan to visualize similar triangles (such as PM_0A and P_1M_1A) that were essential to his first proof of the Homothetic Path Theorem

The very first drawing that sparked Juan's investigations was a simple doodle, drawn almost absentmindedly without any expectations about a particular outcome or insight (see Fig. 1, on the left). Recognizing a possible pattern formed by the points and lines was a serendipitous discovery (for a similar case, see Sørensen 2010, 354). From then on, however, each drawing was motivated by particular intentions: either to explore the outcome of variations of the construction (e.g., repeating the pattern U, U, V, V, instead of U, V) or to test a certain conjecture about the outcome. Thus, Juan's drawings fit the characterization of a mathematical experiment (first exploratory, then scientific) given in Sect. 2.1 in terms of a setup (i.e., the initial configuration of points and lines, and the instructions for the construction), process and outcome (i.e., the carrying out of the geometric construction), and a conclusion as the interpretation of the result. Evidence for the latter is frequently found in the text that accompanies a drawing in the notebooks. Juan's interpretations of the results are formulated in sentences that express general propositions. Reversing the well-known dictum that a picture is worth a thousand words (see Larkin and Simon 1987), Juan suggested that "a theorem is worth a thousand

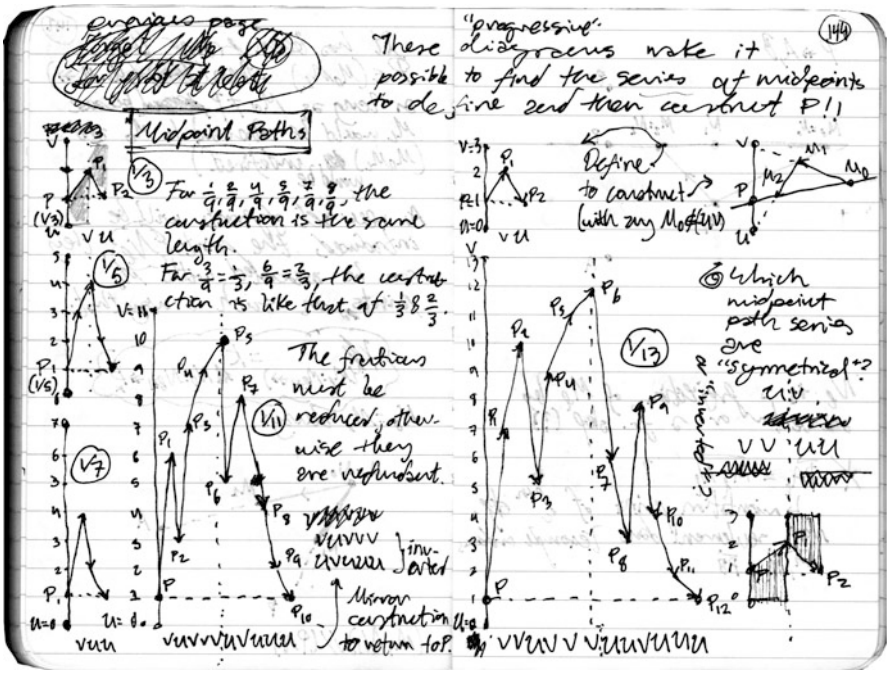

Fig. 6 This spread shows some hand-drawn experiments in which Juan aimed to determine the midpoint series associated to different rational numbers

doodles" (Fernández González and Schlimm 2023). Here, a single theorem can describe many (indeed, infinitely many) instances or individual geometric constructions, thus encapsulating the numerous experiments that motivated its formulation.

We now turn our attention to some particular aspects of the mathematical experiments that led to the formulation of the Midpoint Path Theorem, namely the permanent nature of drawings that allows for the careful study of the process and outcome, and how the experiments contributed to the observation of new patterns and the formation of concepts.

In contrast to experiments that yield an outcome but leave no trace of the process that led to it, geometric experiments that involve the drawing of a diagram produce an artifact that can be inspected after its construction process (similar considerations also apply to written computations, etc.). On the one hand, this allows us to retrace the entire process with special attention on how particular features of the setup affect the result. On the other hand, the diagram itself might reveal certain patterns that can be observed and studied. In Juan's case, the permanent nature of the drawings is further emphasized by his preference of drawing with a pen in order to avoid anything to be erased: "It is not trial and error, because nothing is wrong. Since it's all a creative process, I believe that 'trial and better' is a more fair description" (Fernández González and Schlimm 2023).

The following three examples illustrate how new patterns emerged from Juan's experiments that lead to new concept formations. One of the first patterns is the one that led to the notion of a convergence line. While it might seem obvious in retrospect, when Juan conceived of his construction as a potentially infinite process, he was not yet aware of the alignment of certain points of the midpoint paths. Only after observing these alignments in various diagrams did he conjecture that some of the points of a midpoint path lay on a line. He then went back to the earlier diagrams to corroborate this insight and he added the convergence lines (e.g., the darker lines on Fig. 1 were added to the original drawing during this process).

A second example involves the formation of the concept of midpoint loops. These are particular midpoint paths that begin and end at the same point (see Sect. 3.1). By simultaneously drawing a midpoint path and a midpoint loop in the same figure, new patterns appeared. To bring out these patterns, Juan connected the midpoint paths and midpoint loops by a series of similar triangles (as shown in Fig. 5). The idea of constructing these triangles came to Juan only during the experimental process itself and turned out to be crucial for the later proof of one of the theorems. The notebook spread shown in Fig. 5 documents the evolution of this approach: The smaller drawing on the top-left of the spread was drawn first in order to quickly capture the general idea and is a less elaborate version of the main drawing. Moreover, Juan captured his observations immediately after drawing the diagrams in the accompanying text: on the top-right of the spread he discusses the difference between midpoint paths and midpoint loops. These observations again proved to be essential for the formulation and proof of some of the theorems in Fernández González (2016).

Our third example of the emergence of new patterns illustrates how a change of representation (here, into a different type of diagram) can bring out new insights. As can be seen in Fig. 4, all the points of a midpoint loop are on the line segment $[UV]$. However, as the number of points increases, more and more arrows need to be drawn on the segment, which makes it increasingly difficult to keep them apart visually and to understand the diagram. To improve this situation Juan developed a two-dimensional representation of midpoint loops, as shown in Fig. 6. Despite lacking geometrical accuracy, these diagrams provide a more perspicuous visualization of midpoint loops and thereby helped to advance the investigations. On the top-right corner of the shown spread, Juan wrote: "These 'progressive' diagrams make it possible to find the series of midpoints to define and then construct P!!", where P corresponds to the start and end point of a midpoint loop.

3.3 Geometric Experiments with Computers

The drawings shown in the previous figures are mainly qualitative in nature: the lines are not straight and the points have irregular shapes. Indeed, the drawings were not intended to approximate a geometric ideal, but to capture a particular instance of a geometric construction and to exhibit the relevant relations between the setup and the outcome of the experiment. Nevertheless, to improve the accuracy, Juan began at

some point to use the computer program GeoGebra for his experiments.[20] In addition to the higher accuracy that can be obtained by the use of computers in the experimental process, they also allow for quick manipulations of the setup and process, thereby considerably increasing the speed in which different constructions could be carried out. This, in turn, also increased the number of experiments that could be performed. Note that in our discussion, the computer is used as a tool for conducting experiments interactively, not for independently carrying out calculations or simulations.

For Juan's constructions, only four tools were required from GeoGebra's numerous functions in the *Geometry* two-dimensional workspace: (1) *point*, which places a point at any position, or at the intersection of lines and/or curves; (2) *line segment*, which draws a line segment between two given points; (3) *straight line*, which draws a straight line passing through two given points; and (4) *midpoint*, which places a midpoint between two given points. With these tools, any drawing of a Midpoint Path Construction could be reproduced on the screen. Thus, like with the hand drawings described above, GeoGebra allowed Juan to visually represent the mathematical setup, to perform the construction, and then to observe the outcomes.

In addition, because GeoGebra allows the user to zoom in and out in a diagram, several operations became possible that had been inconceivable with drawings on paper.[21] For example, whereas drawing several midpoints on a piece of paper could quickly lead to overlaps in the drawing, this never happened with the computer, because it was always possible to zoom in until the points were far enough apart. The zoom function also made it possible to get as close as desired to a point in order to determine its coordinates. Juan reports of having been fascinated by zooming into a point with coordinate 0.333333333333, because the precision increased with the zooming, which strongly supported that it was indeed at 1/3 of the length of the desired segment. Through numerical calculations performed by the software, which gave the coordinates of points, it became possible to simply read off the positions of points. Thus, in addition to providing an enhanced means for the visual representation, GeoGebra provided numerical accuracy at a level unattainable by constructions on paper.

The use of the computer also facilitated greatly the drawing of multiple constructions that started with different spatial configurations. For example, Fig. 7 shows three different constructions of a midpoint path that divide a line segment $[UV]$ at point P, located at 1/3 of its length. First, these diagrams demonstrate that the construction works indeed for those three different positions of the starting point M_0. Second, moving the starting point around the workspace by clicking on it and progressively dragging it to different locations generated an array of further instances, which could easily be manipulated and studied. This added a dynamic understanding of the relations in the diagram that could otherwise only be obtained

[20] For more information about this freeware software package, see https://www.geogebra.org

[21] See Starikova and Giaquinto (2018, 273–274) for a discussion of the importance of zooming in and out in mathematical research.

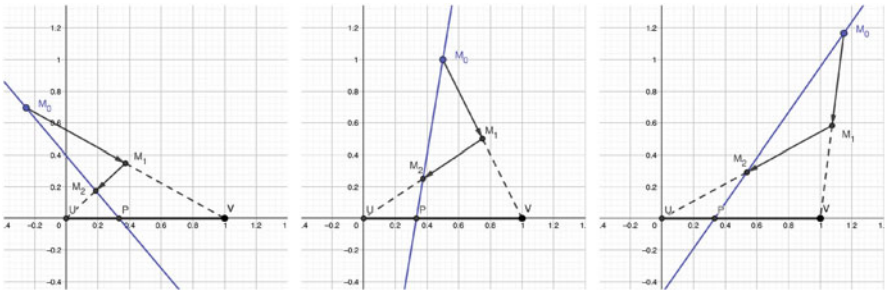

Fig. 7 Midpoint Path Constructions that multiply the length of a line segment [*UV*] by 1/3 at point *P* that differ in the position of M_0, without affecting the position of *P*

by mentally combining several static instances drawn on paper. Because the construction did not have to be redrawn each time, as was the case for drawings on paper, this significantly increased the speed with which conjectures could be corroborated. In fact, Juan's overall confidence in the correctness of the conjectures was greatly increased by the geometric experiments by computer.[22]

3.4 The Broader Experimental Research Project

Juan's drawings, both by hand and computer, can be considered to be parts of mathematical experiments according to our discussion in Sect. 2.1. However, to understand the process that led to the formulation of the Midpoint Path Construction, the experiments cannot be considered in isolation. In fact, the individual diagrams presented above were part of a larger context, namely Juan's mathematical experimental research project, which ultimately led to the publication of the article *Chemins homothétiques* (2016).

Throughout Juan's notebooks one easily notices that each drawing is often found among a group of similar drawings, illustrating how each experiment was part of a guided investigation. For example, Fig. 6 shows a spread in which different experiments are drawn side by side. These particular drawings were used to determine the series of midpoints that were used for the Midpoint Path Construction. They illustrate the series of midpoints needed to multiply the length of a line segment by 1/3, 1/5, 1/7, 1/11, and 1/13. This systematic increase of the values of the denominator illustrates the iterative nature of the experimental research, as described by Polya.

The hand drawings in Fig. 5, and most notably the text that accompanies the drawings, also illustrate the broader context of Juan's mathematical experimental research project. On this spread, he aimed to study the relationship between a

[22] This last remark echoes a sentiment about mathematical proofs expressed in Hume's *Treatise* (Norton and Norton 2007, 121).

midpoint path and a midpoint loop, both defined by the same midpoint series. His notes on the spread suggest future experiments, such as "Are N_I points necessary for proof?" In fact, the N_I points, which correspond to projections of the points of a midpoint path on its convergence line, disappeared in the following research stages, because they did not contribute to any new insight. Discarding unsuccessful avenues of exploration was important during the process of discovery. Another note on the same spread shows the emergence of a new idea: it states that "vectors" could be used to study these configurations. Indeed, linear algebra and vectors were a crucial ingredient of the presentation of the published proofs, whereas similar triangles, which are used in the diagram, play only a minor role in the published paper. Thus, the observations and suggestions captured in Juan's notebooks show the links between the individual experiments, the context of experimentation, the conceptualization of the process, and later stages of research.

4 Conclusion

Building on previous work on experiments in mathematics by Baker (2008), Sørensen (2010), and others, we began this chapter with a characterization of mathematical experiments in terms of three different components: a setup, a process with an outcome, and a conclusion. To remind, the (i) setup consists in the specification of an initial mathematical situation or configuration, as well as possible expectations regarding the outcome (hypotheses, conjectures); the (ii) process is, in a sense, the part of the experiment that is set in motion once the setup is specified and that is independent of the researcher (e.g., an algorithm, computation, or construction); and the (iii) conclusion is the interpretation of the outcome, which can be the corroboration or refutation of a conjecture, or simply new data to be considered. Using this simple framework (which can easily be refined to include additional aspects of mathematical experiments), we discussed the distinction between *scientific* experiments, which are closely tied to a hypothesis, and *exploratory* experiments, which are conducted without particular expectations regarding their outcome. *Thought experiments* also fit nicely into this framework, as they can be characterized by the absence of any empirical restrictions on the experimental process. For example, this absence allows to consider the result of completing an infinite process. However, the conclusion is more speculative in such cases, due to fewer constraints on the outcome. Moreover, due to the essentially human nature of thoughts, thought experiments are not completely independent of the researcher. We argued that mathematical experiments are rarely conducted in isolation, but that they are typically embedded in a wider context of mathematical experimental research projects. To illustrate various aspects of geometric experiments in mathematical practice, we discussed some steps in the genesis of the Midpoint Path Construction (Fernández González 2016), drawing on handwritten notes and computer-drawn diagrams that were produced by its author during the discovery and elaboration of the mathematical result.

In general, we have seen in our case study how mathematical experiments contributed to increasing confidence in conjectures and to rejecting hypotheses about the outcome of certain processes. Complex mathematical situations can be made accessible through the drawn figures, which also constitute traces of the geometric constructions and which can be studied after the construction process itself is finished. In particular, the visual traces of the experiments in our case study (i.e., the diagrams) gave rise to novel patterns that could be observed and that led to further conceptual innovations (e.g., the convergence line). Experiments with different initial conditions allow to explore how such variations affect the outcome of the construction processes. The use of computers in mathematical experiments enhances the accuracy of the drawings and, by increasing the speed with which a construction can be performed, allows for a considerably greater number of experiments. In addition to these practical advantages, the interactive use of computers can also introduce new qualitative dimensions, for example, by allowing for the direct manipulation of figures. Through such manipulations of figures on the screen, variations of the experimental process can be displayed dynamically. Similarly, computer renderings of diagrams can easily been zoomed in and out, which allows again for dynamic interactions with figures that would otherwise be possible only in thought. While our case study focused on geometric experiments, the general framework proposed in Sect. 2 easily accommodates many other kinds of mathematical experiments, e.g., in which the process consists mainly of calculations or graphical visualizations. Indeed, since experiments in the natural sciences also fall under the notion of experiment proposed in this chapter, some similarities between research in mathematics and in science, which were also emphasized by Polya, are made apparent. By considering mathematical experimental research within a broader context of experimental research projects, the analogy to experiments in the natural sciences becomes even more pronounced.[23]

Abstract

As in science and philosophy, thought experiments in mathematics link a problem to new epistemic resources that are unavailable in a given practice, e.g., Euclidean geometry. Thought experiments invite us to perform an imaginary scenario involving counterfactual, deductive and sensory elements. This chapter aims to pinpoint the beneficial peculiarities of thought experiments in mathematics in comparison with inferences, diagrams and calculative procedures. Reflection about thought experiments assists us to realize both the limits and opportunities in mathematical thinking. Henceforth, the analysis of examples suggests a broader understanding of *mathematical*, *thought* and *experiment*.

Thought experiments · Mathematical experimenting · Picture proofs · Sensory imagination · Mathematical practice · Informal proofs · Mathematical intuition

1 Introduction

Mathematical thought experiments are a method that allows epistemic progress through experimental thinking, which extends the rules prescribed by a given practice. They often involve sensory imagination as a means of eliciting the benefits of past perceptual experience. Usually, thought experiments are undistinguished from other types of reasoning that use pictures or models. However, they deserve to be valued as an independent method. The importance and the special status of mathematical thought experiments has been stressed by both philosophers and mathematicians. According to Árpád Szabó (1958), as cited in Lakatos (1976): "Thought-experiment [...] was the most ancient pattern of mathematical proof. It prevailed in pre-Euclidean Greek mathematics."[1] More recently, Yuri Manin (2002, p. 6) pointed out that "Successful thought experiments produce mathematical truths which, after being accepted, solidify into axioms, and the latter start working on the treadmill of logical deductions."[2] The intriguing question, which will be addressed in this chapter, is to investigate what is so special about "the most ancient pattern."

"A mathematical thought experiment" appears to be a philosophically challenging concept. It implies that mathematics could be experimental, and moreover, experimental in thought. The two following *observations* raise doubts.

(1) An *experiment* is an a posteriori method, whereas mathematics is usually conceived as an a priori discipline.
(2) Pure mathematics is generally understood to be "processed in thought" anyway; and if *thought* is refined down to "imagination" we are back to square one, because the latter is not an a priori source for gaining strict mathematical knowledge.

No surprise therefore that philosophers question the very existence of mathematical thought experiments, and tend to fit apparent candidates into traditional mathematical species such as proofs. For example, Norton (2004) regards all thought experiments as illustrated arguments, and Brown (1991, 2007) takes picture proofs as analogues for thought experiments in science. Observation (1) about *experiments in mathematics* is addressed by Van Bendegem in this volume. This chapter however is concerned with Observation (2), and will demonstrate that thought experiments do exist in mathematics as an original form of reasoning.

[1] This encouraging claim of Szabó is quoted in Lakatos (1976) footnote 10.
[2] Manin (2002, p.6).

The question to start with is therefore, do the independent species of mathematical thought experiments, as praised by Manin and Szabó, exist at all? In short, the answer to this question has been inclining from No to Yes along with the development of each constituent part of the concept: *mathematical*, *thought* and *experiment* (M-T-E). In this chapter, the understanding of these terms will help us to realize that mathematical thought experiments contain features that inferences, visual proofs and calculations do not have. In particular, they are:

- *Mathematical* for solving mathematical problems, but not restricted to a priori evidence.
- *Thought* for the variety of narratives, imaginary tools and experience which can be involved, but not reduced to the prescribed algorithms of a given practice.
- *Experiments* with varied epistemic aims, but not only for accepting/refusing a hypothesis.

To unfold these properties, one can start with phenomenology. What is noticeably distinctive of thought experiments is that they are typically expressed in the form of a *narrative* starting with "Imagine. . .." The narratives in mathematical thought experiments, which guide the reader via the imaginary scenario, are often based on visualizations. This has been stressed by Brown and Fehige (2019) and Buzzoni (2011). Starikova and Giaquinto (2018) pinpoint thought experiments in mathematics that involve physical properties similar to those in science. Others, such as Heinzmann (2022) and Glas (2009) accept also formula-based mathematical thought experiments. The examples will demonstrate a variety of narratives in mathematical thought experiments based on diagrams (understood as visualizations of an established practice), pictures (free-style visualizations), metaphors, fictions and formulas. This chapter will be structured around the M-T-E and the types of narratives. The properties specific for mathematical thought experiments will be discussed under this structure.

2 Mathematics

2.1 Use of Sensory Experience

It is usually assumed that mathematical beliefs cannot be justified by empirical experience, which would imply either deductive or heuristic but not evidential roles of mathematical thought experiments. Meanwhile, mathematical facts can be known without empirical justification or with it, for example, in replying to the question: How many vertices does a cube have? Inspection of a material (or imaginary) cube and counting its vertices provides evidence for the conclusion that a cube has eight vertices. But is this really a *mathematical* fact? Why not? It is a very simple fact, but we can extend the problem: Do all platonic solids have the same Euler characteristic? Surely the answer to this question is a mathematical fact. And it can be verified in the same way. Physical models of each of the five platonic solids can be visually inspected to find out whether $V - E + F$ is the same for all of them.

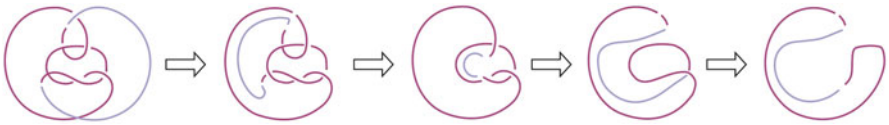

Fig. 1 This diagram depicts a possible thought experiment: imagine if you were step by step unfolding the initial diagram; after a few steps you end up with a diagram without crossings, which is known as an unknot

The visual inspection provides empirical evidence for a positive answer. Similarly, single-digit addition facts can be acquired empirically, from experiences of counting.[3] Such empirical evidence can be also provided by thought experiments. In the following, more examples are presented.

2.1.1 Knot or Unknot?

In knot theory, by trying a series of moves, one can find out whether the original diagram is a diagram of the unknot or not (Fig. 1).

Here we accompany the thought experiment by the diagram to demonstrate all the steps, but one should really experiment on one's own: performing a series of actions in order to test the hypothesis that the original diagram is a diagram of the unknot. In this example we are imagining a *physical* possibility, at least partly based on experience with string, yarn, thread etc. Imagining makes it reasonable to believe the mathematical claim and leads to the discovery. This is possible because visual thought experiments take place in the context of background knowledge about links between idealized physical objects and transformations that can be visualized. These links belong to the foundational aspects of knot theory, and often the exposition of the foundations reveals that the mathematical definitions are tailored to represent the former. In imagination we apply our past sensory experience of dealing with objects similar to the diagram's objects, to make the unfolding moves. In the following mathematical thought experiment, the diagram is also treated as a physical object.

2.1.2 Visual Symmetry in Graphs

Below is a graph and we want to know whether it is homogeneous, i.e., all the vertices have the same structure in terms of outgoing and incoming edges. This can be quickly done by a simple thought experiment. Imagine rotating the graph in respect to its center in the plane, where it is depicted. The vertices will move around but the graph will stay the same (Fig. 2).

Treating a diagram as a physical rigid object is widely used in mathematical practice and is very similar to scientific experiments. For example, referring to experimental studies of mental transformations, Shepard (2008, p. 5) points out that "[T]he cognitive processes in the cases of physics and mathematics are often

[3] Starikova and Giaquinto (2018).

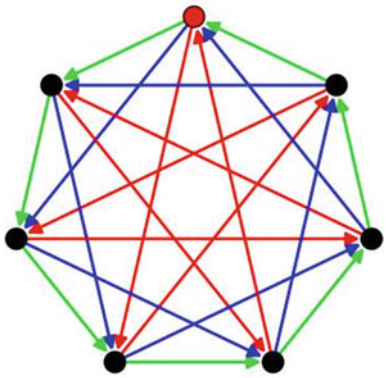

Fig. 2 An imaginary rotation of this graph helps us to notice that all the vertices are the same, in respect to the number, the colors and directions of the edges

more similar than the traditional distinction between mathematical and the empirical sciences would suggest."

To sum up, *mathematical* thought experiments do not have to be limited to a priori evidence, but instead can be understood in a broader sense: i.e., searching for evidence to resolve a *mathematical* problem. More examples will follow; as for a *non*-example, *Achilles and the Tortoise* by Zeno is a good one. It provokes new insights into our understanding of motion and space-time relation, but it contributes more to metaphysics and physics than it does to mathematics (Buzzoni 2011).

3 Thought

3.1 Mathematical Thought Experiments and Imagined Proofs and Calculations

Thought experiments are often understood as being limited to performances of physical experiments in the mind. Such a reading leaves no room for thought experiments in pure mathematics, because they lack real physical counterparts. This view has been defended by Buzzoni (2008) and revised in Buzzoni (2011).[4] Although almost

[4] As Buzzoni (2008, p. 71) put it: "Mathematical counterexamples, however, do not arise from experimental practices, because they involve no interaction between our body (or the computer as its extension) and mathematical objects." And also "The actual performance of a mathematical thought experiment intended to demonstrate or to offer an 'argument' for a theorem coincides with the proof of, or argument for that theorem, thus leaving no room for a separate real performance of the experiment." Buzzoni (2008, 77). Later Buzzoni accepted mathematical thought experiments under certain conditions: "1) The distinction between logical-formal thinking and experimental-operational thinking must not be underestimated. 2) The separation between the context of discovery and that of justification – a separation advocated by logical empiricists but difficult to support after the "pragmatic turn" – must be rejected. 3) The distinction between mathematical thought experiments and formal proofs must be regarded as one of degree, and not as a distinction in principle, however important this distinction may be de facto for particular or local purposes." Buzzoni (2011, p. 6).

any experiment is preconceived, "...[t]hought experiments should be distinguished from thinking about experiments, from merely imagining any experiments to be conducted outside the imagination. . ." Brown and Fehige (2019). Not only are some thought experiments physically unrealizable even in principle, as in *Schrödinger's Cat* or the *Ship of Theseus*, they are designed as unrealizable (Sorensen 1992, p. 74).

Understanding a *thought experiment* as being just an "experimenting in mind" misses the point, as the mind's lab for thought experiments can be as well-equipped as any lab, but with its own instruments. (Mathematical) thought experiments involve sensory experience, imagination and various types of reasoning, such as counterfactual, inferential and analogical. In each particular case, these come in degrees. For example, Balcerak Jackson (2016) develops the view that different thought experiments have different functions and depending on the function they can be based more on imagining, supposing or conceiving. Murphy (2020) also argues for a variety of thought experiment types and cognitive modalities involved, depending on the problem. A fundamental function of thought experiments is to evoke relevant past experience or "tacit knowledge," as defined in Polanyi (1966). He argued that this type of knowledge may come from any part of one's personal background, but is often related to sensory (i.e., visual) activity and once articulated, may lead to a crucial insight. Imagination itself can be of various types, each with its own role (e.g., Arcangeli 2010).

To see that "mathematical thought experiments" are more than just a preview of a proof, it may be useful to start with a variety of narratives that they can have. The two examples above have a narrative based on diagrams. The following cases demonstrate a richer diversity of the physical elements involved.

3.1.1 A Graph Diameter

Graphs, that are considered in the mathematical field of graph theory, are combinatorial objects containing collections of vertices and edges. It is further possible to introduce the notion of *distance* between two vertices: the number of edges in the shortest path between them. Take a cyclic graph as depicted in Fig. 3. One can also introduce the notion of a *diameter* of a graph, being the maximum of all distances. In this small graph one can count the diameter ostensibly as "one, two, three," but a

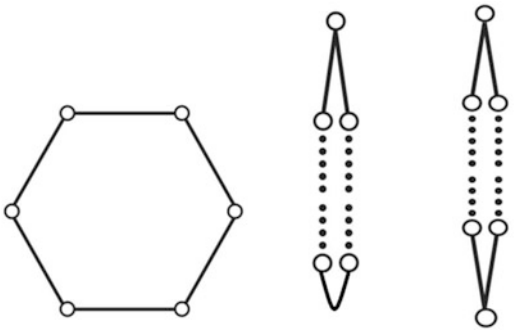

Fig. 3 The first figure is the canonical visualization of a cyclic graph of six vertices. The other two figures demonstrate the two cases: odd and even number of vertices

thought experiment reveals a general formula. Just imagine that the graph is heavy, like a necklace – hold it by any pearl, and let the rest of it go. What will happen? The rest will fall as far as the thread will let it, and we observe that the maximum distance between the top pearl (the held pearl) and any other will be *n/2* or *(n-1)/2*, where n is the number of vertices in the graph. Since the top vertex is chosen randomly and we assume that all the edges have the same length, the result does not depend on the choice of pearl held.

Why are there two solutions? They appear from a finer-grained examination of the graph. Finer-grained imagery results from taking into account the coupling of pairs, i.e., that the graph's vertices will hang down in pairs as in the figure above. The shapes of the lower end of the necklace in both cases are revealed to us by visualization. This series of cognitive actions performed helps us to find the shapes that the necklace would take, and we use these shapes to find the general formula.

Furthermore, we do not know which vertex is the *antipode* (the most distant from the one chosen). When we dangle it down, it is the *gravity* that helps to articulate the paired arrangement of the vertices and the antipode. The sensory experience reveals something new: that there are two options for the number of vertices, one odd and one even.

One may ask if thought experiments are possible with objects that do not have a visual representation within mathematical practice. One option is first to visualize such objects, e.g., as graphs, and then some new perspectives may occur. Here is an advanced case where graphs are used as *mediators* between algebraic groups and geometric spaces.[5]

3.1.2 The Large Scale Geometry of Groups

The large-scale geometry of groups is a revolutionary idea that originated in the work of Mikhail Gromov and gave rise to a new powerful branch of mathematics, geometric group theory.[6] Let G be any infinite group that has different finite sets of generators S, T and maybe others, where generators are some elements of the group. Each set generates the group with a particular structure, which can be depicted by a Cayley graph (after Arthur Cayley, to whom we owe this important concept connecting groups and graphs). In a Cayley graph each vertex corresponds to a group element, and each arrow corresponds to the multiplication of an element by a generator, and each generator is represented by a unique color.

From a visual representation of a Cayley graph of generated groups (G, S) or (G, T) – it does not matter which – we can try zooming out in our imagination, in so far as the fine details of the Cayley graph get lost and the features of the object's large-scale geometry now come into view. The picture below represents a typical section of three Cayley graphs of the group of integers over addition generated by

[5] The mediating function of graphs appears in various cases. For example, it has been exploited by Arthur Cayley and John Sylvester in applying group theory to studying chemical structures. More recently, Carter (2018) provided an example of directed graphs serving as mediating objects between graph algebras and their K-groups.

[6] For a more detailed philosophical discussion of this example see Starikova and Giaquinto (2018).

sets {1}; {1,3} and {1,2} correspondingly, i.e., Cayley graphs of **Z**(+,{1}); **Z**(+,{1,3}) and **Z**(+,{1,2}).

The thought experiment invites us to imagine that from faraway all three look roughly linear, i.e., roughly similar to a section of the real line. Mathematically speaking there is a quasi-equivalence between integers and reals, which may sound nonsense at first, but this reasoning can go even further. While we are zooming out from the picture, the large-scale geometry looks the same for whichever Cayley graph we start with, that is, regardless of a generating set. At least to a geometer's imagination it is possible. This suggests that properties that are invariant with respect to a generating set, can be discovered by attending to the coarse geometry of the object we reach by zooming out. In Gromov's (1993) own words:

> This space [the space of the Cayley graph of $\Gamma = (G, S)$ with the shortest path metric] may appear boring and uneventful to a geometer's eye since it is discrete and the traditional local (e.g., topological and infinitesimal) machinery does not run in Γ. To regain the geometric perspective one has to change his/her position and move the observation point far away from Γ. Then the metric in Γ seen from a distance d becomes the original distance divided by d and for $d \to \infty$ the points in Γ coalesce into a connected continuous solid unity which occupies the visual horizon without any gaps or holes and fills the geometer's heart with joy.

To get Gromov's idea one must bear in mind that neither groups, nor the corresponding Cayley graphs, are geometric objects. *Edges* (in set-theoretic terms) are not line segments, but just pairs of vertices and so contain no points between endpoints. In order to make a graph a metric space we can introduce a *metric* in a graph as the length of the shortest path between any two vertices (given that each edge has a unit length). For example, the distance between elements 1 and 4 in the Cayley graph of Z(+,{1}) in Fig. 4 is equal to 3. Still this metric is discrete and does

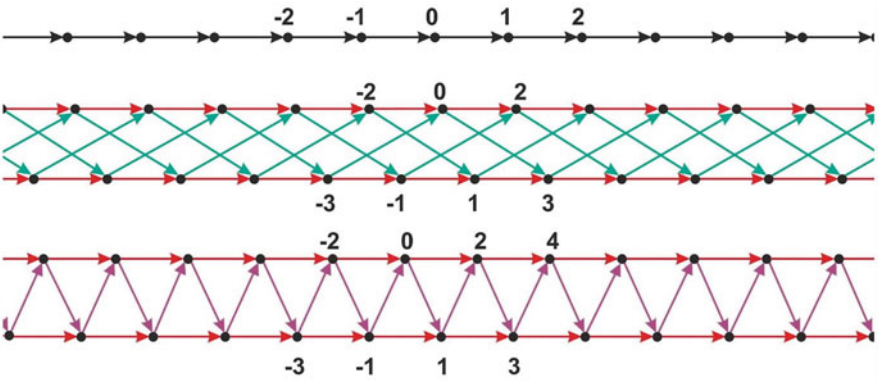

Fig. 4 Here are three Cayley graphs of the group of integers over addition **Z**(+) generated by sets {1}; {1,3} and {1,2} correspondingly: **Z**(+,{1}); **Z**(+,{1,3}) and **Z**(+,{1,2}). Although the different generating sets determine the different structure of the graphs (in respect to the number and the colors of outgoing and incoming edges), from a distance, all three have the same linear appearance, i.e.,, the same large-scale geometry

not help us to discover any interesting geometric relation, as the distance between any two vertices is just an integer (an example will be given in the next subsection). However, by zooming out from the group Γ in our imagination, the discrete object can be transformed in appearance into a space with continuous metric, i.e., having (non-negative) real values. The Cayley graph of integers transforms into a continuous line (Fig. 5), and in the two-dimensional case, which corresponds to a grid of integers, it transforms into a plane (Fig. 6).

This thought experiment is not limited to Euclidean metric spaces. Zooming out can result also in a non-Euclidean metric space. Look at the Cayley graph of the group F_2, which is the free group with two generators, *a* and *b* (Fig. 7 on the left). It is a graph that depicts the set-theoretic information about the group and curvature is not among this information. We may be reminded however of the Poincaré disc model of the hyperbolic plane H_2. The Poincaré open disc model of hyperbolic geometry represents geodesics (i.e., the shortest paths) as diameters or arcs of circles orthogonal to the boundary. The unit distance is represented by ever shorter *Euclidean*

Fig. 5 This figure suggests the similarity between a Cayley graph of (**Z**, +, {1}) and the line **R**

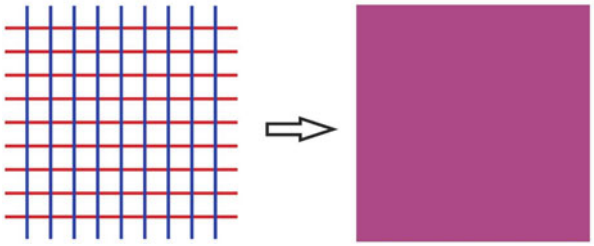

Fig. 6 This figure suggests the similarity between a Cayley graph of ($\mathbf{Z}^2$, +, {1}) and the Euclidean plane $\mathbf{R}^2$

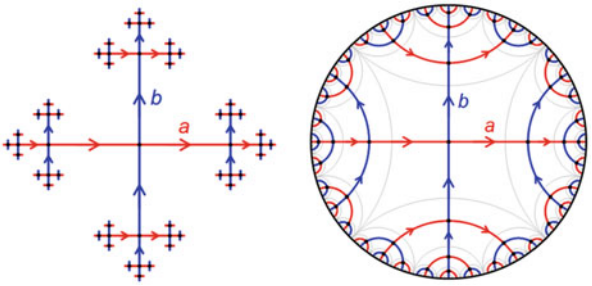

Fig. 7 From https://en.wikipedia.org/wiki/User:Jim.belk/Draft:Free_group. This figure depicts mapping of the Cayley graph of the group F_2 to the hyperbolic Poincaré disc model of the hyperbolic plane H_2. It suggests that the graph, and therefore the correspondent group F_2, have a hyperbolic structure

distances as one moves from the center out towards the boundary (where the boundary is not part of the model). In the graph drawing too we have to decrease the length of edges to avoid overlaps. If we zoom out from the graph we can imagine it embedded in a Poincaré disc (Fig. 7 on the right). This leads to an insight that F_2 is similar to a hyperbolic plane H_2 regarding their large-scale geometry.

3.1.3 Zooming into a Hyperbolic Group

As soon as we talk about a hyperbolic space we have to obey *the triangle condition*, i.e., that the sum of the inner angles of a hypo-triangle is less than π, in contrast to a Euclidean triangle. Except there are no *triangles* in graphs in the sense of geometry. Nevertheless the following thought experiment helps to circumvent the discrete nature of groups (and their Cayley graphs) and see that a graph does not need to be a geometric object to be *hyperbolic*.

As well as zooming out, we can zoom back into the details of a graph, but this time with the geometric perspective in mind. Imagine that you pinch an arbitrary Euclidean triangle by its side's middle points towards the center, as in the left-hand side Fig. 8. It will become *hyperbolic*. Then pinch it until the middle points collapse into one. The already thin hyperbolic triangle will become a tripod. Now zoom into the graph of F_2 and try to tune your eye into a geometric perspective: you may notice or imagine that the graph consists of tripods, i.e., 0-thin triangles, as in the right-hand side Fig. 8. As all triangles are thin in any hyperbolic space (with at least one side pinched in), then all triangles in this graph are also 0-thin. Therefore, the graph is hyperbolic.

To put it in mathematical terms, the Cayley graph of a finitely generated group can be treated as a metric space. The metric space S is *hyperbolic* if and only if for some non-negative real δ, all triangles of S are 'δ-thin' and a triangle is δ-thin if and only if for each side of the triangle every point on that side is no greater than δ from some point on one of the other two sides. This definition makes room for spaces with all triangles 0-thin, which includes the Cayley graph of F_2.

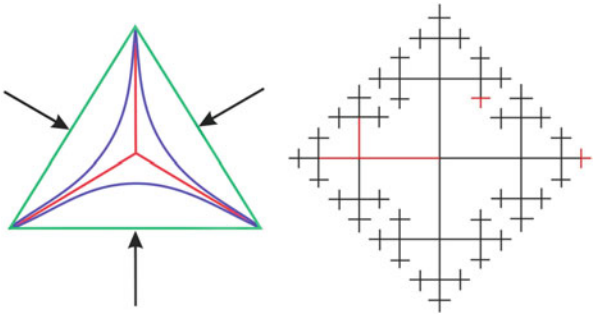

Fig. 8 In our imagination, we pinch the middle points of the green triangle's sides towards its center. Then we observe that this will lead to a thin hyperbolic triangle and, if pinched further, it will lead to a tripod. Such tripods are similar to segments of a Calyley graph of the free group F_2, as depicted on the right

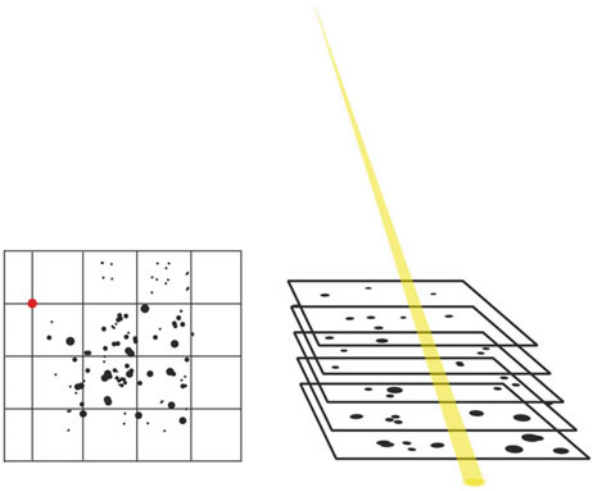

Fig. 9 The first figure depicts the ink blot on the grid with step n. In the second figure, the plane is cut into squares along the grid and they are stacked using only parallel translation. Imagine looking through them to the light. There must be at least a tiny ink-free spot, through which the light will go. Otherwise, the total area of the blots would be no less than n^2, and would contradict the condition of the problem

The graph diagrams in this example are only a basis for mathematical thought experiments, visual representations of the abstract structure. It is not at all obvious how one can drop all the important properties of the graphs that closely look so different. It is zooming out that helps us to see something as a whole and it is the zooming in that makes the triangles noticeable. Finally, it is pinching the triangle that reminds us of the alternative (*thinness*) test for hyperbolicity, and helps to make sense of the *triangles* in a graph.[7]

3.1.4 The Ink Blot Problem

In the case above, the set of objects to experiment with has been formed by visualized graphs. Are mathematical thought experiments still possible in non-diagramatic domains such as algebra or number theory? Here is an example to consider.

On the transparent plane, on which a rectangular grid with step n is applied, ink is poured in the form of a multitude of blots of different sizes and shapes (Fig. 9). The total area of the blots is less than the area of one square. Is it always possible to move the whole array of blots so that ink does not cover any grid point? The thought experiment is the following: cut the plane along the grid into separate squares and put all the squares with ink in a stack (using only parallel translation to do so). Look through them to the light. If we do not see at least a tiny ink-free spot, then the total area of the blots is no less than n^2, which contradicts the condition of the problem. So now, thinking of all the grid squares reassembled as at the start, each grid square has an ink-free area in the same relative position as every other grid square, positioned from its lower left corner (for example), x units to the right and y units above. Now visualize moving the whole array of ink spots rigidly as x units left and y units down.

[7] For more details on this case see Giaquinto (2020).

As every grid node (intersection point of grid lines) is the lower left corner of some grid square, the result of the move will put every grid node into an ink-free spot.

This puzzle is a variation of the famous *Minkowski's theorem,* which gave rise to the geometry of numbers[8]; and the thought experiment is a reconstruction of the argument of the proof. Independently of whether Minkowski used this or something similar to discover the argument or not, the thought experiment explains the proof and brings conceptual clarity. It helps solving the puzzle too. The procedure of cutting and stocking squares corresponds to mapping the plane to the factor-space with points which differ by a given shift n. This procedure is often included in textbooks to explain the notion of a factor group. Through the transparent paper, we can see all points by looking only at a single square (the fundamental domain), which represents the factor group. The experiment links the concept of set with the concept of area: if the fundamental domain is fully covered, the area is at least n^2.

This mathematical thought experiment is based on the visual metaphor of an ink blot, and the previous examples are based on visual representations. These are what Brown compares to picture proofs: "...[I]n mathematics picture proofs are the analogs to thought experiments" (Brown 2007, p. 3). However, the following examples will demonstrate that mathematical thought experiments do not reduce to diagrammatic proofs or picture proofs.

3.2 Mathematical Thought Experiments, Illustrated Arguments and Picture Proofs

As in all the cases above, a picture or a diagram is just the basis for mathematical thought experiments. They come with a flexibility of imagination which is unavailable in static pictures. At the same time, some mathematical thought experiments extend inference to the experimental search for an invariant. For example, the rotation of a symmetric graph provides the evidence that the graph is homogeneous (i.e., invariant under variation of vertices). The following example plays an important role both in mathematics and in philosophical discussions about formal and informal proofs (Starikova and Van Bendegem 2021). It has been presented as a

[8] Bensimon (2009, p. 2) draws attention to the important shift of thinking due to this theorem: "In 1891, mathematician Hermann Minkowski (1864–1909) gave a lecture in Halle, Germany, where he introduced the lattice as the collection of points with integer coordinates in the coordinate system with perpendicular axes. This talk indicated his shift in focus from solving problems in Number Theory with geometric intuition towards "Geometrie der Zahlen," or, "the Geometry of Numbers." He defined this term to mean geometrical investigations of the lattice and its associated bodies. In an 1893 paper, Minkowski presents a theorem that defines parameters for the volume of a certain body, in order for that body to contain a lattice point in the rectangular Euclidean coordinate system. He begins his paper, "In Number Theory, as in all other fields of analysis, the inspiration often comes from geometrical considerations even though at the end maybe only the analytical verification is shown." Indeed, from Minkowski's "geometrical considerations" a new generation of mathematical knowledge was derived. In essence, Minkowski laid the foundation for the modern theory of convexity."

picture proof (Brown 1991, p. 50). There is also a view that it is an illustrated argument, and the picture is an auxiliary (Norton 2004). However, it can be seen as a genuine mathematical thought experiment.

3.2.1 The Mutilated Chessboard Problem

A chessboard has 8 × 8 or 64 squares. If you remove two opposite corner squares, 62 are left. Is it possible to tile the board with 31 non-overlapping dominoes, where a domino covers two adjacent squares? The answer is "No," because both of the absent corners are white, and since each domino covers black and white adjacent squares, we are left with two black squares uncovered. Could this reasoning constitute a thought experiment, and thereby exceed an argument and a picture proof? (Fig. 10)

According to Brown's realist view, we grasp the solution immediately thanks to the special capacity of intuition: we just look at the picture and "see" the answer through the mind's eye. This is how a picture proof works (Brown 1997). However, this view provokes some buts and doubts.

John Norton, contrary to Brown, claims that it cannot be immediate, and many agree that there is some reasoning leading us to our conclusion. What could that be? Norton's view is extreme: such picture proofs and thought experiments are in fact "decorated" arguments, and decorations play no role in the argument, so a specialist could simply write out the argument omitting the picture. With respect to a similar example, Norton says: "This may take more or less time according to our mathematical abilities but will be rapid in the case of someone with a mathematical background" (Norton 1996, p. 352).

Interestingly, different cognitive approaches to solving the mutilated chessboard problem have been investigated by psychologists Kaplan and Simon (1990). The researchers report that although some deductive and counterfactual reasoning has been registered in read-out loud protocols, all participants "noticed parity first, and later made an inference that dominos must cover one square of each type" (Ibid, p. 390). The parity invariant (that each domino always covers or *matches* one white and one black square) is the key to the informal argument. This key does not follow

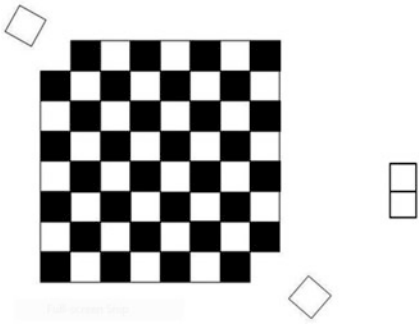

Fig. 10 Is it possible to tile the 8 × 8 board by 1 × 2 rectangles? Imagine that this is a 8 × 8 chessboard with two diagonal corners deleted. The chessboard representation gives a crucial hint for solving this problem, namely the parity of the black and white cells. Each domino must cover two adjacent cells in both colors, but our mutilated board is missing two cells of the same color

from the "hidden in the decorations" inference, but from the sensory experience.[9] Also, contrary to Norton's prediction, attempts to approach this problem mathematically have significantly slowed down performance. Only 12 out of 25 science students found the solution without some sort of a hint. The skill of recognizing invariants turned out to be crucial, whether they come from mathematical expertise or not: "Every single fast subject generated one or more perceptual invariants within the first 10 min, while none of the slow subjects did so!" (Ibid, p. 409–410) Moreover Kaplan and Simon report that *perceptual* invariants (related to color and the position of removed corners) turned out to be more effective than non-perceptual invariants (i.e., related to strategies such as decomposition, mathematical properties etc): "[F]ast subjects possess a heuristic that the slow subjects do not – of paying attention to the perceptual features of the problem." Another experiment by Bilalić et al. (2019) showed that chess players were faster than non-chess players in solving the problem. This is explained by the chess players' easier retrieval of the required color information (figuratively speaking, chess players know every corner of the chessboard). This suggests that sensory experience can play a crucial role in noticing invariants. As soon as the key invariant is found, the deductive part does not take much time.

On the other hand, immediate intuition of the parity invariant, due to just seeing the picture as Brown suggests, also seems to be a rare case. Indeed, it would mean seeing the mismatch of the board and the dominos. The same picture alone however can equally lead us to a clever solution, or to an exhaustive search (i.e., a simulation of a mathematical experiment).[10] To discover the clever argument, we must change from tiling to matching mode of thinking. Presumably we must start trying to tile, then stop it and notice that each white square matches a black one. What could motivate this conceptual shift? Some experimentation in imagination should take place, and here are reasons for that.[11]

According to Kaplan and Simon "fast subjects are noticing not only more things, but a wider variety of things" (p. 412) and that the principal difficulty for slow participants was to *distract* them from the tiling mind set: "Subjects are blocked from exploring parity by their preoccupation with other cues and representations" (Ibid, 392). This suggests that a counterfactual situation where the tiling is already done could free our attention for other (namely set-theoretic) features. This is what Kuhn (1981 [1963]) called a *conceptual change*, and he recognized it as one of the principal goals of thought experiments.

[9] Starikova and Van Bendegem (2021) argue that although formalization is possible and there are even many of them, in order to improve such a formalization and connect the problem to a broader context, e.g., solving related problems, one constantly returns to the image.

[10] Kaplan and Simon (1990) investigated performance on this problem with 25 graduate science students. The think-aloud protocols produced by the participants indicated that initially *all* began by placing the dominos on the board, and eventually *all* tried to find a solution based on the recognition that each domino always covered black and white neighboring squares.

[11] For example, in contrast to immediate intuition, Kant thought that it is thanks to the construction of the concept in our imagination that we come to a correct judgment.

The conceptual change can be done by a thought experiment, which can go as follows. Looking at the picture, we imagine that the truncated board has been mostly tiled from the middle, and we are on our way to the absent corners. *Before* imagining an almost fully-covered board, one may not even pay attention to their colors, which is normal, because coloring plays no role in exhaustive tiling. As soon as we are left with only a few squares, our attention shifts from the global task, i.e., tiling the board, to the local one of fitting individual tiles. At this moment the parity stands out and we see it as matching, i.e., in a set-theoretic mind set.

What is the condition for discovering invariants? They become visible in the background of some *variations*, often present in *experiments*. Mach and Herbert (1976, p 139) characterized experimentation as "the method of variation." In particular, he points out: "By varying the conditions (continuously if possible), the scope of ideas (expectations) tied to them is extended: by modifying and specializing the conditions where we modify and specialize the ideas, making them more determinate, and the two processes alternate." Pictures do present the information, but sometimes one has to experiment with them in order to recognize invariants. For example Cayley graphs alone do not speak about their coarse geometry, but by changing the zoom we notice that some properties do not change with distance.

In the mutilated chessboard problem, one can experiment with laying down the dominos, the size of the board and the labeling of the board's squares. Max Black (1946), who first posed the problem, did not present a diagram (he left it to the reader's imagination); and Claude Berge (1958) gave it a most difficult appearance as a monochromatic grid, which would be a canonical diagram in the tiling theory. This theory studies the coverings of two-dimensional regions with various shapes, so that there are no gaps or overlaps (like floor tilings). The mutilated chessboard problem is one of many such problems. It asks whether it is possible to cover the $n \times n$ region with 1×2 rectangles. The brilliant analogy of the chessboard and dominos problem is the thought experiment. It introduces perceptual parameters (i.e., the colors) unavailable to the standard formulation of the mathematical problem. Finally, Kaplan and Simon, searching for a better prompt for their subjects, were experimenting with the boards using the words "pink" and "black," and boards with "bread" and "butter" in the place of black and white cells. Also variations of tiling attempts and especially on a smaller board, e.g., 4×4, eventually lead to isolated black squares and prompt the color (parity) invariant.

The flexibility of our imagination is an important advantage of mathematical thought experiments. Often a physical image cannot represent features *simultaneously*, whereas imagination can. In the mutilated chessboard example, imagining an almost covered chessboard, we can "see" the colors "through" the dominoes and collate them with the colors of the missing corners. Similarly, a receding physical image of a Cayley graph would simply collapse into a point. Zooming out from it in the thought experiment, we can purposely let the plane grow and the horizontal lines extend, while the graph details are becoming smaller. This can hardly be done by changes in the physical picture, but it can be by harnessing the power of the

imagination.[12] Crucially, in most cases we can modify our imaginations, even if our experience is always of concrete particulars. According to Berkeley's *Principles*, we can imagine a triangle only of one determinate shape, namely an equilateral triangle, but in our imaginations we can exchange it for any other type of triangle in accordance with our aims.

This leads us to an interesting observation: in the mutilated chessboard problem and especially the knot diagrammatic sequences, picture proofs can be seen as resulting *freeze frames* or a visual synopsis of mathematical thought experiments. Perhaps for this reason, although picture proofs are more universally recognized, it is less well understood that they are shortcuts to the latter. Picture proofs and thought experiments are similar in the sense that they are not just inferences, yet they can provide evidence for a mathematical hypothesis. They differ in that in a picture proof, visual transformations are limited by the layout, whereas in a thought experiment, imaginary transformations would go beyond the media in which the diagram is realized, e.g., (a) the paper becomes transparent or rigid, or perhaps it grows as long as we are zooming out, or (b) we can embed a chessboard on a torus, or (c) we can add or remove dimensions and physical properties. A good example is doubling a square from Plato's *Meno*, in which we can distinguish three options (although in other examples the difference may be small):

1. A diagrammatic proof – e.g., solving problems with the use of diagrams in accordance with the given practice;
2. A picture proof – (immediate) grasping the idea of the proof from a picture,
3. A thought experiment, based on a diagram or picture and involving changes which lead to some sort of invariant.

The left figure below can represent a diagrammatic proof in Euclidean geometry (of the proposition that the areas are doubled), namely by looking at the correspondent triangles using propositions, definitions and axioms. The second figure, with geometrically atypical red arrows, is a picture proof; but both proofs can be preceded by a thought experiment, i.e., imagining the square as a napkin and bending its corners to meet the center (Fig. 11).

Besides, diagrams and pictures are only visuals, whereas thought experiments allow for multiple types of stimuli apart from the visual, e.g., motor-sensory as in the necklace example. In fact, thought experiments can motivate access to the whole

[12] There can be cases when mathematical thought experiments do not have enough demonstrative power, because of imaginary limits. For example, in order to grasp symmetries in group theory, it may be more effective to use physical models. Thus Klein advised us: "Turning now to the configuration of the dihedron, I beg the reader, here and in the similar developments in the paragraphs which follow, to make the corresponding diagrams, or to think out for himself directly by aid a model–which is easily constructed–the properties under consideration. For we are treating of concrete matters, which may easily be conceived with the assistance of the suggested aids, but which may occasionally offer difficulties if these are neglected." Klein (1888, Chap. 1, Sect. 4 to 12).

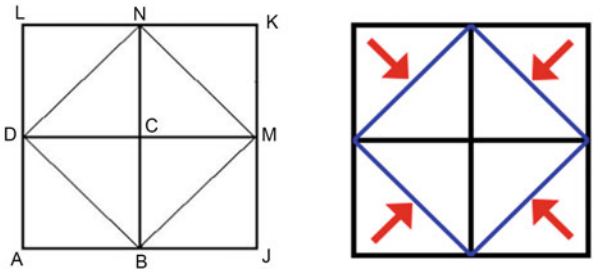

Fig. 11 The first figure is a part of a diagrammatic proof. Four adjacent copies of a given square ABCD give four times bigger square AJKL. Drawing diagonals splits it into eight equal triangles and gives us the inner square BMND. Since the ABCD contains two such triangles and BMND contains four, the latter is double the former. The second figure is a picture proof, which helps one grasp that the blue square is twice as big as any of the small black squares. In fact, both proofs can be based on the following thought experiment. Imagine a square napkin, folded in four (corresponding to the size of ABCD). Unfold the napkin (now corresponding to AJKL), and then fold the corners to coincide in the center. The result is the required doubled square (BMND)

personal experience, and this will be discussed later in this chapter. Diagrams and pictures are the most common basis for mathematical thought experiments, but the latter can easily incorporate artwork elements such as those in the *ink blot problem* or in the *dividing of 17 camels*, coming up next. To sum up, the mathematical thought experiments above extend both our deductive and visual intuition. In particular, they involve experimental variations of the settings that help us to find invariance.

3.3 Fiction in Mathematical Thought Experiments

What makes a big difference between a thought experiment and mere thinking about a real experiment is such a peculiar attribute as fiction. The former can involve a narrative and impossible elements. Indeed, when planning a proper scientific experiment, one usually does not create a story about killing a cat or riding a light beam, but rather uses theoretic terms describing settings such as "a body moving at the speed of light." Thought experiments have a selective, local and momental character, namely they have "evidential significance only historically and locally [. . .]" (McAllister 1996, p. 248). Each thought experiment is unique as a particular story, and many have a name, e.g., the *Balls and Vase Problem,* or *Hilbert's Paradox of the Grand Hotel*. This makes thought experiments closer to literature, theater, cinema and arts. The design of a thought experiment depends upon the creator's personal experience, professional background, and style of thinking. The art of thought experiments is then to tailor a scenario and choose whatever details make them effective, explanatory and revelational.

The fiction-style thought experiments exist in mathematics, and make it more engaging and accessible for non-mathematicians. But crucially, they evoke a broad

range of our tacit knowledge and experience, and direct our thinking to non-standard solutions or questions. Below are two examples.

3.3.1 The Art of Dividing 17 Camels

A father left 17 camels to his three sons, and according to the will the eldest son should be given half of all the camels, the middle son one third, and the youngest son one ninth. This is hard to do, but a wise man helped the sons: he *added* his own camel, so the eldest son took 18/2 or 9 camels, the second son took 18/3 or 6 camels, the third son 18/9 or 2 camels, while the wise man took back his own camel and went away.[13] To approach this problem, we first try to divide 17 by 2, which fails, as does dividing by 3 and by 9. So instead we try a mathematical thought experiment, which leads to a solution. The formal way to put it is $1/2 + 1/3 + 1/9 = 9/18 + 6/18 + 2/18 = 17/18$.

Again, someone like Norton would say that the story is an unnecessary illustration, since the problem implies that it should be solved in integers (representing camels). However, solving the problem without this thought experiment would require at least some mathematical skill and knowledge of the smallest common divisor, whereas the thought experiment requires none of these. The advantage of the story-narrative is that it points clearly to the key condition that the problem has to be solved in integers, as the division of living camels is unacceptable (for this problem). Therefore, the narrative guides us towards experimenting with recombining sets, rather than performing a standard algorithm.[14]

3.3.2 Flatland

Another well-known example of a story-narrative is *Flatland*, a satirical novella by Edwin Abbott (2009), where we are invited to imagine a 2D world inhabited by planimetric figures.[15] What mathematics would they have? How could we explain our 3D world to 2D inhabitants? How can they possibly understand that a space is curved or that the universe is finite but has no boundary? *Flatland* challenges the reader to imagine particular 2D life situations in detail. It also helps us to revise our default intuitions about geometry, and understand how to relate to different dimensions. The details of fiction-based mathematical thought experiments may not play a direct role in the argument, but they are not mere decorations either. Rather they are purposefully tuned to guide us towards what needs to be looked at.

[13] The oldest written version of this problem found by Ageron (2013) was written in Persian by the Iranian mathematician Muhammad Mahdi al-Naraqi (1716–1795).

[14] This popular mathematical parable became an iconic example of the method of adding and removing structure. For example, a mathematician refers to this strategy in a proof of an important lemma from graph theory and in the apportionment of procedures called divisor methods. https://mathoverflow.net/questions/271608/17-camels-trick

[15] Carl Sagan (2009) in his YouTube video discusses the possibilities of higher dimensions to the physical universe based on the *Flatland* concept, and proposes his thought experiment solutions.

3.4 Impossible Elements in Mathematical Thought Experiments

For thought experiments in general, McGinnis (2018) distinguishes *idealized* and *fictional* thought experiments on the basis "that the former at least give the appearance that they are physically possible." For him, examples of fictional thought experiments are zombie worlds or persons splitting and recombining, but Einstein riding the light beam is an idealization. But what about Abbot's 2D persons in 3D worlds? And what about heavy graphs, 0-thin triangles and hyperbolic groups? In what sense are they fictional or impossible?

In mathematics, "physically possible" is not a criterion to distinguish between *idealized* and *fictional* thought experiments, and moreover it is not a purpose. For example, Glas (2009, p. 60), discussing the ingenious thought experiment of Archimedes, says: "Archimedes 'thought of' line segments and areas as possessing weight, but this is not essentially different from normal geometrical practice, in which lines are 'thought of' as possessing length but not breadth, etc." Glas used this analogy to rightly argue that the thought experiment is as rigorous as any other geometric construction: "Archimedes also based his statics proper (the theory of the lever) on postulates – not empirical laws – in exactly the same way as Euclid had axiomatized plane geometry." However, "de-idealization," as Sorensen (1992, p 100) calls it, is not a one-to-one but a one-to-many relation: e.g., an "ideal" mathematical line may return its breadth, but it can also have weight, color or conductivity. So this phenomenon is rather a "re-idealization." While in Euclid's geometry, a geometric line is a simplification by ignoring properties, namely breadth, Archimedes is on the opposite end: *adding* properties. Besides, not all lines in the same diagram consistently hold weight (the parabola in Archimedes' example itself does not). This kind of selective and creative idealization is non-standard, applying neither to geometry nor to statics. Also, a breadthless line is (and already was before Euclid) a common geometric concept, in contrast to a heavy line.

So, there is a difference, but it is irrelevant to its physical actuality. To remind the reader, usually the goal of thought experiments is to challenge standard thinking and to introduce a conceptual change. Fiction is a good way to do this by pushing idealization beyond reality, and here is how it works. For example, in Thompson's thought experiment, "Imagine you woke up bodily, attached to a famous unconscious violinist. . ." can be modified from "Imagine you got pregnant, and it has been statistically calculated that your future child will be a famous violinist." The latter is not as effective as the former, because it does not provide a necessary conceptual change (from "the right to life" to "the right to use another person's body"), which makes an epistemic difference. Similarly, the conceptual change in Archimedes' experiment is thanks to the addition of physical properties. As mathematical concepts are already idealized in a particular way, a conceptual change requires a different type of idealization. In mathematics, "reality" is a given realm or practice with its own type of idealization. Fiction is "impossible" in respect to the current mathematical practice of using (visual) representations.

3.5 *Thick* Concepts

The fictional or "re-idealized" concepts in mathematical thought experiments can also be characterized as "thick," as suggested by Brown (2019) in the sense that they are concepts simultaneously combining both physical and mathematical aspects. As he explains further on, "[...] thick mathematical concepts are drawn (typically) from the physical realm and the pure mathematical realm" (Ibid, p. 12). To give us a flavor of what he means, Brown quotes Michael Spivak: "[Y]ou can feel the second derivative when you sit in an accelerating car" (Ibid). The concept of the second derivative itself is a *thick* concept, thanks to intuitions coming from physics and mathematics. Brown argues that thick concepts may encourage us to make progress with difficult problems, e.g. the continuum hypothesis. What is relevant is that thick concepts are drawn from two realms, and thought experiments are a way to combine them fruitfully. A *derivative* is a thick concept too in the sense that it can be defined analytically (as a limit of *df/dt*) and also geometrically (as the slope of a line tangent to a function's graph). A *hyperbolic group* considered above is another example of a thick concept because it combines geometry and algebra). A combinatorial *group*, if enriched by geometric intuitions such as 0-thin triangles, gives rise to a *hyperbolic group*.

Can we find thick concepts elsewhere in mathematics, say within number theory? We can definitely make them richer by discovering new facts about them. For example, 4 is the area of a square with the side 2 and also $4 = 2 + 2 = 2 \times 2 = 1 + 3$ (*sum of primes*) $= 2! + 2!$ Analogously, $2023 = 7 \times 17 \times 17 = 7^7$ *mod* $7!$ expresses two different facts about the number 2023 in terms of different arithmetical practices, where the latter is mostly used in computing. These are different operational practices, yet remain within pure mathematics: addition, multiplication, factorization, etc. Combining them enriches the concept of the number. In this respect, fiction in mathematical thought experiments can be understood as a different type of idealization borrowed from a different realm, whether it be physics, geometry or another related practice. Euler's proof of the Basel problem will demonstrate this next, just after some considerations about the reliability of imagination.

3.6 A Veridical Fictional Imagination

Use of imagination obviously raises doubts about the reliability of (mathematical) thought experiments. For example, Norton (2018, p. 454) points out that "We give the thought experimenter extensive latitude in introducing idealizations" and considers it as one of the sources of error. Can we really make discoveries that rely heavily on visual imagination which is fictional? Are we not simply replacing proper experiments with "fantasies of the imagination"?

In scientific experiments, the instruments and experimental settings are selected by a methodology which must take into account possible biases and risks. In thought experiments, the selection of relevant properties is an art, and at the same time a task-oriented veridical thinking. Structured and controlled imaginary transformations are

widely recognized as an epistemically valuable component of thought experiments (Kujundzic 1998). This places mathematical thought experiments among other mathematical procedures, all liable to error. Fictional imagination for veridical mathematical reasoning is a very special feature of mathematical thought experiments. Importantly, in the mathematical context, the fictional element is one of the ways that allows us to stretch prescribed procedures, and find insights in another practice or past experience. This feature of thought experiments has been discussed in Balcerak Jackson (2016), Brown (2017), Buzzoni (2011) and Starikova and Giaquinto (2018) among others. The thing is that there is an important distinction between veridical imagining and fantastical imagining. Veridical imagining is aimed at finding out the true answer to certain questions, and is ruled by the accumulated effects of past perceptual experience. This does not make veridical imagining infallible; the adjective "veridical" is intended to describe the aim, not the result, of imagining. Fantastical imagining is not constrained in that way however, as it is not aimed at answering a question, as it serves psychological ends such as wish-fulfillment, horror thrill, sensory fascination and so on. Veridical imagining is widespread and useful. Wanting a desk for a particular room for example, you visit a furniture showroom; there you see an attractive desk, somewhat bigger than what you had in mind. Would it fit reasonably well into the stated room with its other furniture? In such a situation, it is reasonable to visualize the room to reach a judgment – this is veridical imagining. We do in fact rely on sensory imagination to answer such questions, and we get correct answers frequently enough for this practice to persist.

4 Experiment

So far we have discussed how *mathematics* can be experimental, and how the *thought* can be rich in respect to the narratives and cognitive instruments used in mathematical thought experiments. Finally, *experiment* as a scientific method is essentially understood as an *empirical validation or a refutation of a hypothesis*. As previously mentioned, according to the received view, empirical validation is not considered to be a method in pure mathematics. On this basis, mathematical thought experiments, as valued by Manin and Szabó, were reduced to illustrated proofs or "decorated arguments" in Norton's words.[16] However, there is another meaning of *experiment*, which comes from the Latin *experi*, which is "trying" a new method as opposed to those accepted, established and indisputable. This sort of experimenting

[16] As a reminder, Norton (1996, 2004) holds a 'strong argument view' about thought experiments in general. Buzzoni (2008) states that since no empirical evidence can disprove a mathematical fact, mathematical thought experiments, at least as far as validation is concerned, do not exist. Similarly Van Bendegem (2003) claims that mathematical thought experiments are "anything but proofs," meaning that since mathematics aims at proofs, any reasoning towards an insight of a possible proof can be seen as a mathematical thought experiment.

does not have to result in validating a hypothesis. It may however result in discovery, a better understanding of the problem and making the hypothesis plausible.[17]

Trying out something *new* (in respect to the given domain) is a key feature of mathematical thought experiments. For example, Glas (2009) characterizes thought experiments as "relying on information which is... *not assimilated by the traditional* mode of dealing with the world" (p. 57). Starikova and Giaquinto (2018) identify the type of mathematical thought experiment that is closest to the classical thought experiments, and characterized it by two features:

(a) the *experimental* thinking goes beyond application of mathematically prescribed rules, and (b) by using sensory imagination as a way of eliciting the benefits of past perceptual experience.

While the first condition can be taken as necessary, the second is to pinpoint reasoning with imaginary physical objects and properties. Therefore, this can be taken as a good marker for thought experiments. Heinzmann (2022), talking about mathematical thought experiments as "deviation tools," relates them to a sort of sensory intuition: "These deviations involve, generally, an appeal to vision, which is supposed to provide a form of intuition." This implies that the second condition is not purely subsidiary, and sensory experience does play an epistemic role in mathematical thought experiments. Therefore the concept of *experiment* in mathematics can refer to the observation of sensory data, as in counting a cube's edges. It can also refer to the observation of variations in a diagram when we search for invariants, as in the mutilated chessboard problem.

4.1 Mathematical Thought Experiments and Mathematical Experiments

Both mathematical thought experiments and mathematical experiments can help in searching numerical patterns and structures. The former however give us freedom to extend the prescribed numeric rules and use resources from another practice, as the following example will demonstrate.

4.1.1 Basel Problem and Infinite Polynomials

The famous Basel problem asks us to find the value of the following infinite sum:

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{1}{1} + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \ldots \frac{1}{n^2} + \ldots$$

[17] Brown (2017) gives a list of such roles for thought experiments; for the various roles assigned to *mathematical* thought experiments, see also Starikova and Giaquinto (2018), Van Bendegem (this volume), and Buzzoni (2011).

Drawing from history, see Ayoub R (1974), in 1731 Euler calculated the sum of the first terms, and recognized that the sum should be $\pi^2/6$. Earlier approximations already supported his guesswork. Motivated by this evidence, in 1734 Euler published a proof conceived as the approximation of the given sum by *sin (x)/x* and treating it as a polynomial. Applying a factorization by roots, he then compared the coefficients of x^2 terms with the Taylor series of expansion. At that time, such factorization could not be applied to infinite polynomials, so Euler's bold experiment went beyond the legitimate practice. Is it a thought experiment?

Lacking a typical imaginary scenario, this can still be considered as a mathematical thought experiment. The inductive approximations of the sum suggest a hypothetical number, but are insufficient for a general proof. In order to test the hypothesis in its full generality, Euler supposes infinite polynomials and then observes how the problem "behaves'' under the new conditions. For Heinzmann, "If, in its inferences, the demonstration uses deviant tools, it is called a mathematical thought experiment, which later may become an experiment with respect to the standard formalism of the time" (Ibid). The calculative approximations therefore are mathematical experiments, and Euler's approach is a mathematical *thought* experiment due to the non-standard move of taking infinite polynomials for granted.

A similar mathematical thought experiment is described in Glas (2009). Bombelli in 1572 found a way to circumvent the appearance of $\sqrt{-1}$ in solving cubic equations. He applied algebraic procedures, which cancel "impossible numbers" on the way to solutions. According to Glas, the thought experiment is used to hypothesize this outcome and by ignoring the obstacle, to pursue the calculation. Glas describes it "as *post hoc* reasoning from the required result to the argumentative steps that were necessary to attain it" (Ibid, p. 62). In both Bombelli's and Euler's approaches, as in the examples with visualizations, the hypothesis is made plausible first on the level of observation (i.e., of a formula or an image), and next on the level of formalization.

4.2 Variety of Experience

It is important to emphasize that the whole wealth of our experience and knowledge becomes available in mathematical thought experiments. A recent peculiar proof of the Basel problem, published by the Swedish mathematician Johan Wästlund (2010) will help to demonstrate this point.[18] In contrast to Euler's proof, this one is based on a law of physics and involves visualizations. It starts with an important observation: "Inverse squares occur in physics... The apparent brightness of a light is proportional to the inverse square of its distance" (Ibid, p. 2).

[18] The proof is also nicely explained under the link https://mattbaker.blog/2018/03/14/circles-the-basel-problem-and-the-apparent-brightness-of-stars/

4.2.1 Basel Problem and the Lights Proof

The proof involves the following thought experiment: imagine standing at the origin of the number line where each integer is a light. It is like standing on a road between two villages. There are streetlight to the left and to the right of you. At a unit time, your eye is receiving a quantity of light from all the streetlights. According to the law of light distribution, the sum of brightness from all the streetlights amounts to 1 from the first star, 1/4 from the second, 1/9 from the third, 1/16 from the fourth and so on. How could this help us to test the hypothesis that the total brightness is $\pi^2/6$? It may seem that we have not moved on from the problem statement, but in fact, the physical representation opens up a new path. Roughly speaking, the law implies that the closer streetlights give out the most light – but the distant ones give out less light and can emit it from another position at approximately the same distance. How could we rearrange them to preserve the same total quantity of light? Now imagine that the same lights make a circle around a huge lake. The light from the straight line is approximately the same as that from the big circle. The lights from the other side of the lake emit roughly the same amount of light as the lights next to the villages.[19] Putting it differently, a linear distribution of lights can be seen as an approximation of a very large arc, as in Fig. 8 below. Importantly, the circumference "constellation" is where the number π naturally emerges (Fig. 12).

Also note that if we split a light into two and place them in the corners of a right triangle, then the initial light brightness can be expressed as $1/c^2 = 1/b^2 + 1/b^2$, which is the reverse of the Pythagoras theorem. A sequence of Euclidean constructions with circles and triangles can eventually lead to the desired result (Fig. 13).

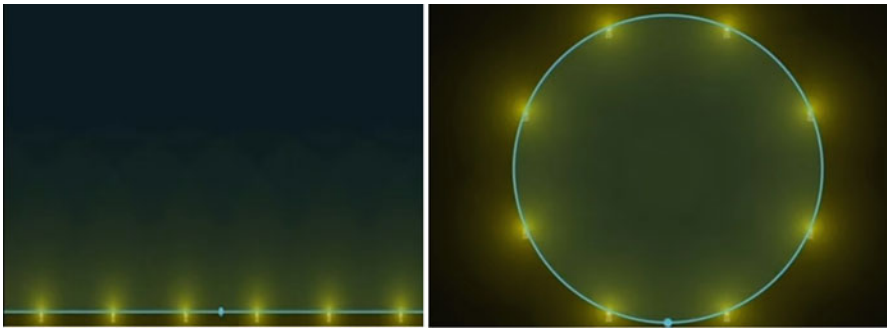

Fig. 12 The law of light distribution suggests the idea that the total amount of light received by an observer at point zero from lights arranged in a straight line and the total amount of light received from lights arranged in a circle are approximately the same

[19] Wästlund mentioned in his blog that he heard a little girl asking what would happen if the universe was finite, and the stars were all in a circle. (http://wastlund.blogspot.com/2018/03/infinite-lake-surrounded-by-lighthouses.html)

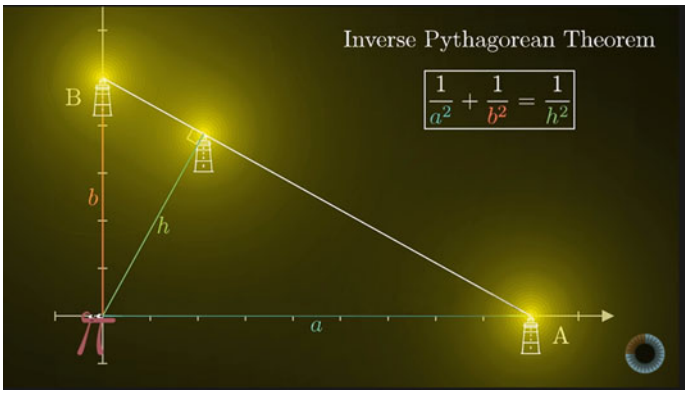

Fig. 13 This screenshot from Sanderson (2018) YouTube video *Why is pi here? And why is it squared? A geometric answer to the Basel problem* demonstrates the use of the inverse Pythagorean theorem

One can object to the conclusion that this constitutes a thought experiment. In the necklace example (in 3.1.1), we do not use knowledge of a physical fact as a premise, or lemma in a mathematical deduction about a physical situation. Instead, we simply suppose that the graph is like a necklace, with beads of equal weight spread along a string at equidistant intervals. Then we imagine what would happen to the necklace if we held on to one bead and let the rest of it drop. Finally, we attend to the resulting imagery for a clue to help us find the diameter. Therefore, we conduct an experiment in visual imagination. We get the facts merely from imagery, that we eventually use to get a mathematical answer.

In contrast it seems that in the light proof we rely on physics, but do we actually? No. In this proof, the number series of inverted squares is treated in a similar way as it is in Euler's proof. As in the necklace example, the physical representation – i.e., a heavy necklace – helps to rearrange the studied structure of the cyclic graph. In the light example too, the physical representation helps us to notice the useful rearrangement of the number line into a circle, but the proof is technically geometric and consists of geometric calculations. As Wästlund describes his proof, "What is new in our presentation is the physical interpretation which allows us to replace all trigonometric identities by classical geometry. . ." (2010, p. 10).

All the physics of light emission and reflection are reduced to Euclidean geometry.

The thought experiment consists of picking up the invariant (the inverted square), and observing what happens if it is placed in another context. A reversed square $1/n^2$ is used as an icon or a *sensed pattern*: it is a visual pattern of symbols, which is identified in the context of number theory and can be recognized outside it – i.e., in the context of polynomials as in Euler's proof, or in physics as in Wästlund's proof. In the latter, physics connects the series to a circle, and this explains the presence of π in the famous formula.

Formula-based mathematical thought experiments (Euler's proof of the Basel problem and Bombelli's approach to complex numbers) are mathematical thought experiments, because they go beyond the given calculation algorithms. They do not extend the domain of mathematics, but extend the given practice (e.g., number theory to polynomials, or real numbers calculus to complex numbers). Mathematically, the light argument is outstanding not so much due to its link with physics, but more importantly, with geometry and explaining the presence of π. In both types of mathematical thought experiment, formula-based and image-based, we use either *sensed* patterns or *thick* concepts (e.g., hyperbolic groups, or heavy graphs). The distinctive feature of mathematical thought experiments in comparison to *calculative* experiments is the scope and range of knowledge, experience and creativity that becomes available to the mathematician. The discussed examples demonstrate that mathematical thought experiments play a crucial role in discovery. They are used primarily when other methods do not help. Often, the most valuable mathematical thought experiments are exactly those that produce an *insight* such as zooming out to get the idea of large scale geometry. Zooming out per se is not so much of an extraordinary idea, but as part of a thought experiment it can lead to an extraordinary discovery, i.e., the large-scale geometry of groups. This makes thought experiments strikingly different from experimental calculations.

5 Conclusions

It is common practice for mathematicians to reason with diagrams, but it is rarely mentioned that they also reason with physical objects that for them have a somewhat abstract character. This is possible thanks to mathematical thought experiments that often go unnoticed.

Mathematical thought experiments can be based on diagrams, models, metaphors, fictions and formulas, and can combine counterfactual, deductive and visual/sensory reasonings, but they also open up even more possibilities:

1. Enriching mathematical concepts by associating them with physical properties, as well as with the properties of objects from different practices (namely *thick* concepts).
2. Extending the current algorithmic practice by fictional, but at the same time veridical, imagination.
3. Providing epistemic resources from the different mathematical practices, and the entire personal experience of the experimenter.

They are *mathematical* because they provide a deeper insight into mathematical problems. They are *thought* experiments, not for planning arguments and algorithms in mind, but for extensively exploiting the richness of our cognition and experience. They are *experiments* not necessarily for testing a hypothesis, but also for making a hypothesis plausible, revealing the new invariants and developing concepts.

Abstract

We understand experimental mathematics as the systematic experimental investigation of concrete examples of a mathematical structure in the search for conjectures about its properties. Experiments might be done by pencil-and-paper work, building physical models, and, of course, by using available computer programs for doing time-consuming calculations, geometric constructions, and other types of visualizations. The guiding intention of the chapter is the study of the interplay of experimentation and deduction (proof) in the context of the teaching of mathematics at lower and upper secondary schools as well as the education of teachers of mathematics.

The didactical intentions of the chapter make it necessary to take a special philosophical perspective, which might be characterized as a combination of Lakatosian and non-Lakatosian viewpoints (Sect. 2).

In Sect. 3 we shortly discuss three historical examples (Euler, Fourier series, Chinese Remainder Theorem) to give a more realistic image of the interplay between experimentation and deduction in contrast to the somewhat artificial character which didactical examples necessarily involve.

In the following Sects. 4, 5, 6, 7, and 8, we discuss a few classroom examples of mathematical experimentation. Section 4 is on checking, guessing, and finding a proof, and in Sect. 5 we put a particular emphasis on finding and handling counterexamples. These two sections can be characterized as the classical domain of Lakatosian ideas transferred to the classroom. Section 6 explores the potential of viewing elementary Euclidean geometry from the point of view of statics. This approach has had a long tradition in mathematics since ancient times and represents a transition to discussing experimentation with hypotheses in Sect. 7 on modelling. The latter is definitely a non-Lakatosian viewpoint.

Lastly, in Sect. 8 it is concluded that the interplay between experimentation and deduction needs to be incorporated in primary education and extended throughout for the long-term development of sound mathematical thinking and understanding of students.

Keywords

Experimentation · Deduction · Proof · Checking · Guessing · Refutation · Modelling · Lakatosian and non-Lakatosian points of view

1 Introduction

In a recent textbook for early graduate and advanced undergraduate students, Eilers and Johansen (2017, p. 1) define experimental mathematics to be: "*the systematic investigation of concrete examples of a mathematical structure in the search for conjectures about its properties*." For the aims of the present chapter, this seems to be a sufficiently simple definition which on a concrete level covers the following important functions of experimentation giving an idea of the large scale of possible activities (see De Villiers (2010, p. 206) and Jonathan Borwein (2012, pp. 73–74):

- Discovering new relationships and conjecturing (looking for inductive patterns, generalizations, etc.)
- Visualizing math principles (viewing graphical or other visual representations of analytically derived results)
- Verification (obtaining certainty about the truth or validity of a statement or conjecture)
- Computing replacing lengthy hand derivations (use of computer algebra, data handling, and/or graphical representations)
- Global and heuristic refutation (disproving a false statement by generating a counterexample, as well as reformulating, refining, or polishing a true statement by means of local counterexamples)

- Understanding (gaining insight/intuition, and grasping the meaning of a proposition, concept, or definition or assisting in the discovery of a proof)

The book from which the above definition is taken associates "experimentation" exclusively with the use of computers for doing time-consuming numerical calculations. In the programmatic editorial of the Journal *Experimental Mathematics*, however, the editors write (Epstein et al. 1992, p. 1; see also De Villiers 2021):

> *The word 'experimental' is conceived broadly: many mathematical experiments these days are carried out on computers, but others are still the result of pencil-and-paper work, and there are other experimental techniques, like building physical models.*

The present chapter has the teaching of mathematics at lower and upper secondary schools as well as the education of teachers of mathematics in mind and, consequently, follows this broader outlook. It includes quite a number of examples from geometry comprising the use of dynamic geometry software and above all the modelling of real-world phenomena.

The inevitable companions of experimentation in mathematics are proof and deduction. Like with experimentation, we suppose a sufficiently broad concept and do not precisely distinguish between "proof" and "deduction." For the moment, we refer to the discussion document of the ICMI Study 19 which says that proof is based on the principle

> *to specify clearly the assumptions made and to provide an appropriate argument supported by valid reasoning so as to draw necessary conclusions*. (Hanna et al. 2012, p. 443)

For a more detailed discussion, the reader should consult the next section.

Proving and experimentation are different sides of the same coin, inseparably connected and, yet, to be clearly distinguished. A conjecture which might be suggested by a mathematical experiment has to be proved, and, conversely, there must be some sort of a theoretical idea behind any experiment as already the very first words "systematic investigation" of the above definition show. Indeed, there is no experiment without a question, neither in science nor in mathematics. The guiding idea of the present chapter can be expressed by saying that *there is no deduction without experimentation and no experimentation without deduction*.

Experimental mathematics in the educational context can be considered as a component of "Inquiry-based learning" (IBL) (for a survey, see Artigue and Blomhøj 2013). As Bruder and Prescott (2013, p. 820) sum up in an overview of empirical studies, IBL is not per se superior to other more traditional approaches to teaching. Rather, IBL proves to be superior only when the teacher finds a right way to guide the work of the students, and positive effects are also dependent on the type of knowledge taught.

Seen from a pedagogical point of view, the relation between experimentation and proof in mathematics is among others a problem of finding a balance. When a mathematics course at university proceeds in a purely axiomatic-deductive style

without sufficiently discussing examples and counterexamples and without giving opportunities for mathematical experimentation, the image of mathematics which might arise from such "anti-didactical inversion" (Freudenthal 1973) are grossly misleading. With a high probability, the teacher trained in this way will convey the respective bad practices also to his/her students. This means:

(1) Learners are not given the opportunity to explore and to experiment but are given the conjecture as fait accompli in the form "Prove that . . ." Instead of that, there should be enough room to explore, experiment, and make conjectures on patterns or invariances. Such situations should be open-ended and divergent.
(2) Learners are exclusively provided with well-formulated conditional statements "Prove that p implies q." Instead of that, learners should themselves have the opportunity to transform conjectures into conditional statements.
(3) The instruction "Prove that . . ." implies beforehand that the result is true and learners develop the habit to accept the truth of statements on the authority of the teacher and the textbook. Instead of that, they should be given the experience to explore the truth of a statement by themselves searching for examples/counterexamples or any other kind of argument to support it.

To arrive at a good balance between proof and experimentation is a difficult and never-ending task of education. It requires looking at one and the same topic of teaching from different perspectives, and this multiperspectivity much too often meets the limitations of overloaded curricula and available time, external examinations, class size, limited facilities such as basic experimental artifacts (such as compass & ruler, calculators, computers, etc.), the philosophical perspectives of teachers and textbook authors, appropriate past pedagogical experiences of teachers, etc.

At present, in the curricula of many countries mathematical topics are implemented which strengthen the role of experimentation without lowering the role of proof and deduction and thus point in the direction which is elaborated in the present chapter. We think here of:

(a) Pattern recognition and arguing with patterns (see the chapter on proof in the NCTM standards 2000 and, for example, Wittmann and Müller 1990)
(b) Problem solving with a vast amount of didactical literature (see f. e. Schoenfeld 1985)
(c) Modelling (For the state of the art in this field, see the ICMI study 14 (Blum et al. 2007))

In what follows, we concentrate on exploring the *interface of proof and experimentation* and on *studying by means of historical and educational examples how they interrelate*. Concerning the educational examples, most of them are based without any claim of originality on experiences of the authors as educators of mathematics teachers at lower and upper secondary levels and on teaching experiments at schools. Some of them might be found directly helpful. But since any

teaching example is bound to special situational conditions and in the light of the abovementioned empirical studies on IBL, such a direct transfer will be possible only in rare cases. We aim more at encouraging the reader to develop their own experiments. It is in support of this more indirect transfer that in the next section we attempt at clarifying our general views on the topic by some philosophical considerations.

2 Philosophical Issues

Somehow as a counterpoint to the formalistic trends promoted by the New Math movement, Imre Lakatos (1922–1974) published in 1963/1964 an essay on the philosophy of mathematics an extended version of which appeared in 1976 as a book under the title "Proofs and refutations." In it, he substantially and famously criticized the traditional neglect of the experimental, inductive, and heuristic processes that have historically accompanied mathematical developments:

> *Mathematics is presented as an ever-increasing set of eternal, immutable truths. Counter examples, refutations, criticism cannot possibly enter. An authoritarian air is secured for the subject by beginning with disguised monster-barring and proof-generated definitions and with the fully-fledged theorem, and by suppressing the primitive conjecture, the refutations, and the criticism of the proof. The deductivist style hides the struggle, hides the adventure. The whole story vanishes, the successive tentative formulations of the theorem in the course of the proof-procedure are doomed to oblivion while the end result is exalted into sacred infallibility.* Lakatos (1976, p. 142)

On the other hand, he rightly rejected the position that mathematical discovery "is a completely nonrational affair" (l.c., 143). In fact, it was exactly his analysis of the intimate interplay of experimentation and deduction which made his case-study on the history of Euler's polyhedron formula so philosophically innovative and attractive to many readers. To this contributed also the terminology Lakatos invented for describing this interplay: proof-generated definition, proof-generated theorem, global and local counterexamples, etc.

In this general sense, Lakatos' philosophy of mathematics serves as a background to the following analysis of examples of teaching. We use also part of Lakatos' terminology but do not relate his views on mathematics to other approaches to the philosophy of science in the 1960s (see Lakatos and Musgrave 1970).

However, we find it necessary to extend Lakatos' approach in another regard, and this is connected with our broad view on proof and our only vague distinction between proof and deduction at the beginning of this chapter. It was Árpád Szabó, himself a teacher and close friend of Lakatos, who in his seminal study on the genesis of the axiomatic method in ancient Greece (Szabó 1960) pointed at another sense of "experimentation" Lakatos had in mind. One can call this "experimenting with hypotheses." Szabó showed in his study how the axiomatic approach originated from pre-Euclidean and pre-Platonic dialectics that is the art of exchanging arguments and counterarguments in a dialogue debating a controversial subject. In any

debate, be it philosophical, political, or scientific, it is a frequent procedure to agree for a moment to a certain proposition in order to critically examine its consequences. Participants take the proposition as given, derive consequences, and accept or reject the proposition depending on whether the consequences are plausible (desired) or implausible (not desired). On a general level, this is the procedure of theory-building in science, and today we call this "modelling," and one can find many instances of this already in ancient Greek science (Jahnke 2010). In Sect. 7, we discuss some concrete examples providing a more detailed and sophisticated view on modelling.

Even though some philosophers might feel uneasy with such a postulational perspective of mathematics, the inclusion of modelling in our understanding of mathematical experimentation seems inescapable for pedagogical reasons. There is a variety of (teaching) situations which require the introduction of assumptions which later on might be revised (Bruder and Müller 1983; Jahnke and Ufer 2015, p. 6). Such assumptions could be:

(1) Evident statements in order to convince other persons of something. The evidence might be drawn from visual impressions or from a number of special cases or from shared knowledge in the classroom.
(2) A preliminary assumption needed for the completion of an argument. Later on, one might find a backing for this assumption.
(3) Stating an assumption in order to refute it. When one arrives at a logical contradiction, one has devised an indirect proof.
(4) Stating an assumption of whose truth one is convinced but which one cannot prove yet. This case is similar to (3), but this time the intention is to see whether the consequences are plausible. Classic case: Riemann's hypothesis.
(5) Thought experiments, especially in physics. Famous example: Galileo's thought experiment for refuting Aristotle's theory of free fall. Also similar to case (3).
(6) A statement from physics in the context of a mathematical theory. Famous examples: Archimedes' application of the law of lever (see below), Dirichlet's principle, etc.

This list could of course be extended and refined. In all cases, the assumptions made have the status of a hypothesis which means it is a statement whose evaluation as true or false is insecure. Nevertheless, they function as a condition of a deductive argument which can be qualified as proof. Thus, experimenting with hypotheses is an essential tool for furthering the awareness and consciousness of a learner for the conditions of mathematical theorems. Boero et al. (2010) rightly speak of the "conditionality" of mathematical statements. It would be a pedagogical sin not to use the potential inherent in this variety of deductive argumentations.

To sum up, we think that from the first beginnings of primary education, experimentation should be a central concern of mathematics teaching guided by the question "why." Inherent in this, there is also the question "what if when things were different," i.e., what if we start with a different hypothesis? There is a natural

curiosity even of small children to imagine a world different from the one we live in. We should further encourage this curiosity also in mathematics teaching.

3 Historical Examples

As a prelude to our teaching examples, we present in this section three historical cases where the interaction of deduction and experimentation shows up in a remarkable and instructive way. There is an important and fundamental difference, however, to the situation in teaching: time. In general, we cannot expect that the interaction of deduction and experimentation takes place in short periods of time. There are such cases, but they are not the rule. The Lakatos example of the polyhedron formula, for instance, which he compressed in a fictitious dialogue, covered in real history a time span of about 150 years.

Our examples refer to.

(1) The mathematical work of Leonhard Euler
(2) The history of Fourier series
(3) The Chinese remainder theorem

(1) One of the most prolific mathematicians of all times, Leonhard Euler (1707–1783) has been characterized by Calinger (2016, p. 93) as an "experimental" mathematician who carried out numerous calculations in the process of his mathematical research (see also Ferraro's contribution in this handbook). In many of his research papers, he was frequently not above writing down numerical examples for the general formulae he had derived. As a specially gifted person, he used innovative transformations and clever substitutions to develop many new methods to solve problems from both mathematics and physics, which in some cases took up more than a century for other scientists and mathematicians to properly grasp or to fully justify. Sometimes Euler would set aside a problem if he was making no progress, allowing for what has been called the *incubation* period by Hadamard (1945), until eventually *illumination* would allow him to return and finally solve it. Several of Euler's discoveries were left to future generations to establish rigorous foundations. Perhaps one of the most famous of these is Euler's zeta function, which was extended further by Bernard Riemann (1826–1866), and is the basis of one of the greatest, still outstanding unresolved problems of mathematics, namely, the Riemann's Hypothesis (Derbyshire 2003).
(2) The second example is that of the historical development of Fourier series. Jean-Baptiste Joseph Fourier (1768–1830) (on his biography, see Grattan-Guinness and Ravetz 1970–1990) derived a Partial Differential Equation (PDE) for describing the diffusion of heat in a metal plate and broadly discussed its solution. He arrived at most of his results in a paper which he submitted to the French Academy of Science in 1807 and which was rejected on account of a negative evaluation by

J. L. Lagrange. Only in modern times has the paper been edited by Grattan-Guinness and Ravetz (1972). Nevertheless, Fourier won a prize of the French Academy in 1811 with a paper on heat diffusion, though also this time the jury made some objections in regard to "rigor and generality" probably again under the influence of Lagrange. Finally, Fourier published a comprehensive account of his results in a book in 1822, nine years after Lagrange's death.

As with most PDEs, the solution of the heat equation is dependent on an "arbitrary" function and Fourier established the remarkable result that any "arbitrary" function could be represented by a trigonometric series of sine waves. However, as pointed out by Davis and Hersh (1983, pp. 262–263), Fourier used mathematically problematic reasoning which also at his times would not have been accepted by many mathematicians. Fourier's argument implied two inconsistent assumptions and employed division by a divergent infinite product. Nevertheless, under the guidance of his physical insight, experimental background, and intuition he arrived at a correct result.

Langer (1947, p. 33) has suggested that it was probably Fourier's disregard of rigor and his calculations of many examples (l.c., p. 45) that enabled him to make the huge conceptual leap necessary to arrive at his remarkable conclusion.

But of course it was not simply by intuition and calculations of examples that Fourier found his results. There was a long and impressive prehistory in the eighteenth century comprising substantial theorizing as well as one of the most famous controversies in the history of mathematics. This concerned the PDE for the vibrating string derived by d'Alembert in 1747 (for details and access to the vast literature, see Luetzen 1983; Jahnke 2003). Again this PDE involved "arbitrary" functions, and d'Alembert argued that these functions should be analytic (that is developable in a power series), even, and periodic.

A year later, Euler protested against the restriction to analytic functions saying that for physical reasons one has to include any function which can be drawn by "free hand" and hence interpreted d'Alembert's solution as a rule to construct the solution geometrically starting from a curve drawn by free hand. Euler considered also as a special case functions defined by series of sine waves. For good mathematical reasons, d'Alembert did not accept Euler's idea of curves drawn by free hand since such curves may not have a first or second derivative, a necessary condition for applying the PDE. Then, in 1753 Daniel Bernoulli, son of Johann Bernoulli, entered the scene with the argument that any sound physically consists of a superposition of sine (or cosine) waves, and therefore Euler's special case can be generalized to comprising any function whatsoever. The controversy was never solved in the eighteenth century and received a new and decisive push by Fourier's work.

A first rigorous proof of Fourier's result was given by J. P. G. Dirichlet (1805–1859) who during his stay in Paris 1822–1826 was in close contact with Fourier. In 1829, he proved that any piecewise continuous and piecewise monotonous function can be represented by a Fourier series (Luetzen 2003, 158). Of course, this class of functions was far from arbitrary functions but for the first time included functions whose graph showed finitely many jumps.

It took about another century of effort for mathematicians and two generalizations of the notion of integral by Riemann (1826–1866) and Lebesgue (1875–1941) (see Hawkins 1980; Hochkirchen 2003) to substantially generalize the class of admissible functions and to establish firm foundations for Fourier series analysis. However, few physicists and engineers ever felt the need for a justification of Fourier analysis as its functionality in modelling experimental evidence was what counted for them.

(3) A third example shows that formal generalization and incorporation of intuitive ideas into more and more advanced rigorous structures may eventually obscure or completely hide the primitive, computational origins from which these ideas arose. Take, for example, the Chinese Remainder theorem, which states that if one knows the remainders of the Euclidean division of an integer n by several integers, then one can determine uniquely the remainder of the division of n by the product of these integers, under the condition that the divisors are pairwise coprime. The Chinese Remainder Theorem is best explained by the following party trick. A "magician" asks a participant to choose an arbitrary number less than say 60. The participant is then asked to divide the number, respectively, by 3, 4, and 5, and mention the remainder in each case. With only the knowledge of these three remainders, call them, respectively a, b, and c, the magician is then able to determine the number chosen by the participant. How is the magician able to do that?

The solution is simply that the magician has to divide $40a + 45b + 36c$[1] by 60, and the remainder of that division will be the original number selected by the participant. Suppose, for example, the number 43 was selected. The respective remainders would then be 1, 3, and 3. Therefore, $40 \times 1 + 45 \times 3 + 36 \times 3 = 283$ has to be divided by 60. Since $60 \times 4 = 240$, it follows that the remainder is equal to 43, which is the original number selected.

The Chinese Remainder theorem today has important applications, among others, in Fast Fourier Transforms and RSA secure data transfers, and in the proof of mathematical results like Gödel's incompleteness theorems.

The earliest known formulation of the theorem is that of Sun Tzu in the third century, but no proof or general algorithm was provided. Later in 1202, Leonardo of Pisa (Fibonacci) revisited the result in a slightly more general way, but also describing it in a computational algorithmic way with a specific set of integers. Like Sun Tzu, Fibonacci ignored the possibility of nonuniqueness and provides no proof of why it works. In 1734, Euler was probably the first to formulate a complete algebraic generalization and prove the generalization. However, by comparison, Shockley's 1967 and Prather's 1976 version of the Chinese Remainder theorem, based on

[1] To fully understand the choice of the arbitrary seeming numbers 40, 45, and 36 requires some modular arithmetic and of congruence relations between integers. More information can be found in abstract algebra and/or number theoretic texts.

Gauss' work on congruences and the abstract algebraic concepts of groups and fields, are hardly recognizable (to the novice) in relation to its original form.

As pointed out by Davis and Hersh (1981, p. 194), the modern version of the Chinese Remainder theorem focuses on structure at the expense of the algorithm and ignores the historically motivating question of how, given the remainders, the original number can be determined.

From an educational point of view, this illustrates how it might sometimes be necessary for the benefit of the student in order to develop conceptual understanding to retrace, at least in part, the gradual evolution of the mathematical ideas behind the Chinese Remainder theorem from its primitive, often experimental origins to its eventual abstract formulation.

In the following Sects. 4, 5, 6, 7 and 8, we discuss a few classroom examples of mathematical experimentation. Section 4 is on checking, guessing, finding a proof, and in Sect. 5 we put a particular emphasis on finding and handling counterexamples. These two sections can be characterized as the classical domain of Lakatosian ideas transferred to the classroom. Section 6 explores the potential of viewing elementary Euclidean geometry from the point of view of statics. This approach has had a long tradition in mathematics since ancient times and represents a transition to discussing experimentation with hypotheses in Sect. 7 on modelling. This is definitely a non-Lakatosian viewpoint.

4 Checking, Guessing, Finding a Proof

As should be done with students on all levels, we begin with the simple. Guessing and checking is probably one of the most basic, elementary methods of experimentation in mathematics.

For many years, one of the authors would ask the following simple question (among others) at the start of a course on Differential Equations for 3rd and 4th year university students: Solve for x if $x^2 = 2^x$. Without fail, the students would eagerly start tackling the problem by taking logarithms both sides, but then getting stuck and not knowing what to do next. Attacking the problem by algebraic manipulations is probably a natural approach given their past learning experience. It is, however, restrictive when they do not see or consider alternative approaches.

Only after letting them stew for a little while, it would be suggested that they use "trial-and-error," the most basic numerical method, upon which they then quickly find the two positive roots of $x = 2$ or $x = 4$. Since $0^2 = 0$ and $2^0 = 1$ whereas $-1^2 = 1$ and $2^{-1} = ½$, the curves of x^2 and 2^x cut each other between 0 and -1 telling us that there is a third root between -1 and 0. This third root then can be determined by, for example, computer graphing or other numerical methods. Students at this level should know that for sufficiently large x exponential functions surpass any polynomial function, and thus, they can be fairly sure that, in fact, the above equation has only these three roots. These results are reached by mental calculations within a few minutes. Students should again and again be encouraged to do simple substitutions for getting a first orientation about or intuitive understanding of a mathematical

situation. In this case, the introductory activity is intended as an "advance organizer" (Ausubel et al. 1978) for the later introduction of students to numerical methods for solving differential equations that cannot be solved algebraically.

When we imagine the same situation in an upper secondary classroom, students might do the same substitutions and mental calculations but not know how exponential functions behave for large x. Then the simple idea to organize the results of their calculations, which they might have scribbled on a sheet of paper, into a table will lead to a rigorous proof that in fact they have found all roots of the equation (Table 1).

Between any change of sign from + to – and vice versa, the two curves x^2 and 2^x cut each other and the equation has a root there. For negative numbers -3, -4, -5, etc., x^2 gives the positive squares 9, 16, 25, etc. whereas 2^x produces 1/9, 1/16, 1/25, etc. Another change of signs cannot occur and, thus, no further root. For positive integers, the table teaches us that the differences between successive squares form the sequence of odd integers whereas the value of 2^x is doubled from each integer to the next one. Therefore, x^2 will be smaller than 2^x for every integer >4 and no further root can occur.

Iteration in mathematics, doing the same procedure over and over, with each successive step using the results of the previous step, is a very fundamental concept and procedure in mathematics dating back to ancient times.

The famous method of Hero (who lived in Alexandria, North Africa, round about 100 BC) for finding the square root of a number r is a classic example. One starts the process by guessing a square root x. Therefore $r = x \cdot \frac{r}{x}$ is then a factorization of r into two factors x and $\frac{r}{x}$, one of them being larger, the other smaller than $\sqrt{r}$. Thus, taking the average of x and $\frac{r}{x}$ will give a new and better guess. Repeating this process, one will find the square root of r to whatever level of accuracy is required. In modern notation, Hero's method can be very simply expressed in the following recursive formula where x_{n+1} represents the improved guess from each iteration: $x_{n+1} = \frac{1}{2}\left(x_n + \frac{r}{x_n}\right)$.

Although carrying out repetitive calculations or constructions like these is tedious if done by hand, this has completely changed with the advent of the computational age of electronic calculators and computers. Apart from specialized mathematical software like *Mathematica* and DGS, one can now use ordinary scientific calculators, programmable graphing calculators, and/or spreadsheets to investigate many different kinds of iterations at school level.

Iterative numerical methods like these are indispensable for mathematicians, scientists, and engineers as many problems within mathematics, as well as in the application of mathematics to the real world, cannot be solved algebraically and can

Table 1 Function values for different x

x	-2	-1	0	1	2	3	4	5
x^2	4	1	0	1	4	9	16	25
2^x	1/4	1/2	1	2	4	8	16	32
$x^2 - 2^x$	+	+	–	–	0	+	0	–

only be solved numerically. In general, for example, polynomial equations of order 5 and higher cannot be solved algebraically, and the proof of this by Abel in the nineteenth century is one of the great triumphs of abstract algebra (Derbyshire 2006). And even in the cases of third- and fourth-degree equations, it is often easier to use an iterative algorithm.

As a core example of the fact that "trial and error" is a royal road in mathematics, we discuss an example of a traditional calculus problem that even Grade 8 or 9 learners can and should solve experimentally by only using a calculator and completing a table of values (or using a spreadsheet on computer to speed up the calculations):

A railroad has to be built between two towns A and B as in Fig. 1. The ground to the east of line PQ is marshy, and as a result it costs R20 000 per km to build there, as opposed to the R12 000 per km to the west of this line. If PQ is 80 km, where should X be chosen so that the construction of the railroad is as cheap as possible?

Posing problems like this with students at both school and university, the immediate response is usually to think of minimizing the most expensive cost (building in the marshy terrain), and therefore initially choosing the route AQB. However, after letting them calculate the cost of the route AQB, one could suggest to them to check the minimality of their proposed solution and to repeat the same calculation with other points X between P and Q. Much to their surprise, it will turn out that, for example, for $PX = 5$ km the Total Cost in thousands of rand is $= 20\sqrt{5^2 + 60^2} + 12\sqrt{(80-5)^2 + 60^2} = 2356$, and this is lower than the cost of the route AQB, namely, R2400. Continuing calculating in this manner, as shown in Table 2, leads

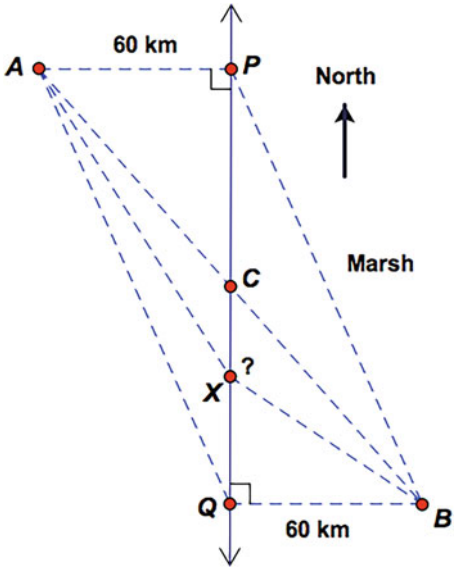

Fig. 1 Railroad building

Table 2 Total cost for different x

PX	5	10	15	20	25	30	35
Total	2356.72	2322.90	2298.44	2283.14	2276.73	2278.87	2289.24

them to eventually conclude that the minimum lies between $QX = 25$ and 30 km, and that they can continue searching within that interval for better and better solutions.

While such an approach may seem very tedious, it pedagogically emphasizes that $PX = x$ is a *numerical variable* that can assume different values and shows how the output varies as the input changes. The substitution and calculation of many values such as this could therefore help to combat the still pervasive "fruit-salad algebra" misconception among high school (and even university) students that letter symbols in algebra represent concrete objects such as apples and oranges (Küchemann 1981; MacGregor 1986).

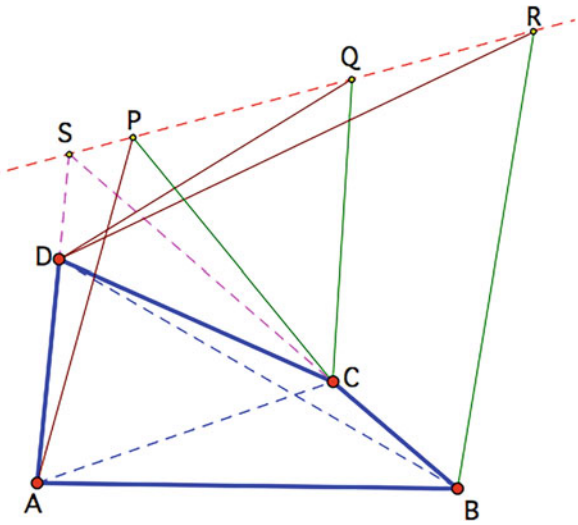
After completion of such a table, it is then more natural and meaningful to introduce an algebraic representation of all those calculations, namely, Cost $(x) = 20\sqrt{x^2 + 60^2} + 12\sqrt{(80 - x)^2 + 60^2}$. Not only is this algebraic representation more economical, but also it now enables one to use the graphing capability of a DGS, or other graphing application, to more quickly and efficiently, graphically, find a minimum. In later grades, one could even differentiate this Total Cost function within a DGS or other symbolic algebra software, draw a graph of the differential function, and then find the minimum more accurately where it cuts the x-axis.

On a higher level, numerical methods can be seen as experimental strategies or algorithms designed to solve mathematical, scientific, or engineering problems in a systematic way, and include error analyses, convergence, and the comparison of different approaches. Though many applications are readily available, numerical analyses may also involve some computer programming. Given the practical importance of numerical methods in modern-day society, it is unfortunate that few elementary methods like decimal search, half-interval or bisection method, iterative formulae, Gaussian elimination, Newton-Raphson, Euler method, etc. have been incorporated into school curricula or undergraduate programs around the world (Shirali 2012).

Experimentation in mathematics not only is useful as a method of discovering new results, but also can sometimes contribute to finding a proof. Here is an example from De Villiers (1997) relating to the following result that had been discovered through experimental investigation with dynamic geometry: If similar triangles APC, DQC, and DRB are constructed on AC, DC, and DB of any quadrilateral $ABCD$ so that $\angle APC = \angle ASB$, where S is the intersection of AD and BC extended, then P, Q, R, and S are collinear (see Fig. 2).

After some unsuccessful attempts at proving this result, the author visually noticed, while manipulating and dragging various points in the configuration, that $\angle ACB$ appeared to be equal to $\angle APQ$. Measuring these two angles confirmed that they were indeed equal, and shortly afterward, a proof of that observed fact followed,

Fig. 2 Collinearity result



which quickly cascaded into a complete proof of the collinearity result. So the empirical observation of the two equal angles was the critical tipping point in this case.

Lew (2006) also gives examples of how the interaction between analysis and dynamic experimental constructions can enable students to arrive at solutions to problems.

5 Refutation in the Classroom

Perhaps one of the most neglected areas in traditional classroom teaching is the involvement of students in the refutation of conjectures and (false) proofs. Most national or provincial mathematics curricula tend to only provide a list of content that needs to be covered in different grades, and invariably such lists are of true results and correct algorithms. When these are translated into textbooks, little opportunity is therefore often given for teachers to deal with false, but plausible conjectures, or with conjectures with restricted domains.

With the exception maybe of a few examples in the junior secondary school of patterns like $6n - 1$ giving a prime number for all n, breaking after a while (e.g., for $n = 6$ it's false), little consistent attention is given to this important aspect of mathematical thinking. In geometry also, one of the few examples that are usually dealt with is the ambiguous case of two triangles with two sides and a "non-included" angle correspondingly equal, which therefore does not guarantee congruency between them.

It is encouraging, however, that the research community in mathematics education appears to be starting to investigate this issue as exemplified by the recent work

of Komatsu (2017), Komatsu et al. (2017), and Komatsu and Jones (2019). In Komatsu and Jones (2019), for example, some task design principles for developing students' heuristic refutation (revising conjectures/proofs through addressing counterexamples) within DGEs are theoretically developed and empirically tested. Using two sets of tasks that were purposefully designed so that with a DGE possible counterexamples could easily emerge, it was found through task-based interviews that these tasks aided students' recognition of contradictions, and assisted them in reformulating their original conjectures.

It is also important to engage students in activities where they are required to produce global counterexamples to false conjectures. Ideally, this might happen when students are encouraged to make their own conjectures, which would give them a greater sense of personal ownership to either disprove or prove their findings. However, the educator may also choose appropriate pedagogical examples, and mixing them in randomly with true conjectures can be quite effective to keep students on their toes.

A particularly instructive example from De Villiers (2010, p. 218) that demonstrates not only the importance of global refutation but also the danger of relying on only experimental evidence is the following investigation. It is adapted from Rotman (1998, p. 3) and can be fruitfully used with mathematics and mathematics education students at school and university:

Investigate whether $S(n) = 991n^2 + 1$ is a perfect square or not. What do you notice? Can you prove your observations?

Since systematic or random calculator or computer investigation for several n strongly suggests that $991n^2 + 1$ is never a perfect square, students are usually easily convinced about the truth of this conjecture, particularly after random testing of the conjecture with a wide range of suggested numbers, including some very large ones on the WolframAlpha site using their prime factorization app at: https://www.wolframalpha.com/input/?i=factor+70560.

After giving them some time to attempt to prove the conjecture, it therefore comes as a great surprise (and therefore an excellent learning experience!) when it is later pointed out to them that the statement is true only for all n until[2]:

$$n = 12\,055\,735\,790\,331\,359\,447\,442\,538\,767$$

For example, as shown in Fig. 3 using the WolframAlpha app above with this input of n, we obtain a number that is a perfect square (as can be seen by the fact that

[2] This is a specific case of a Pell equation, for which solutions were discovered as an offshoot of theoretical work rather than quasi-empirical testing. For example, one can see with a modest amount of experimentation that $x^2 - dy^2 = 1$ is solvable in positive integers when d is a small, positive nonsquare integer and infer (as Indian mathematicians did in the twelfth century) that it is probably solvable for more general d. This led to ad hoc algorithms that worked pretty well (Bhaskara managed the case $d = 61$), and finally, to a theory that produced the present continued-fraction treatment, which is guaranteed to churn out a solution (and will do so with $d = 991$ in fairly short order).

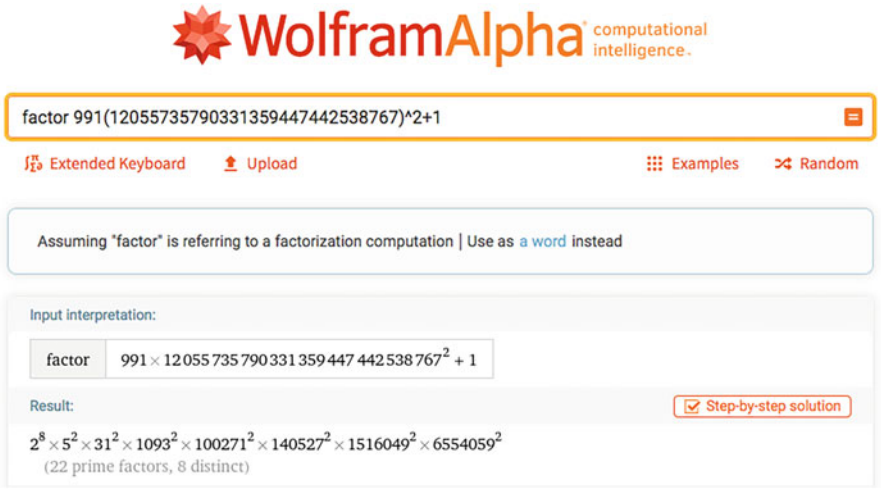


Fig. 3 Refutation with WolframAlpha

all the powers of the prime factors are even), and therefore refutes the original conjecture.

Experimental testing is also useful for identifying incorrect assumptions in otherwise completely valid reasoning. Dynamic geometry software is particularly useful in this regard, as a configuration can be easily and quickly dragged into many different variations in order to check the general validity of one's assumptions. A well-known geometric paradox, namely, "all triangles are isosceles," arises by virtue of construction errors or mistaken assumptions in diagrams (Movshovitz-Hadar and Webb 1998).

A less well-known, yet highly instructive example is the following plausible statement and its "proof" from De Villiers (2009, pp. 25, 112–113, 128–129): "A quadrilateral with one pair of opposite sides equal and one pair of opposite angles equal is a parallelogram."

Proof: Consider Fig. 4. Draw $BX \perp AD$, $DY \perp BC$ and join B and D. Then it is easy to first prove triangles AXB and CYD congruent ($\angle$, $\angle$, s), and then triangles BXD and DYB congruent (90°, s, s). Therefore, $AX = CY$ and $XD = YB$ from which we have $AD = AX + XD = CY + YB = CB$. In other words, $ABCD$ is a parallelogram, since both pairs of opposite sides are equal. QED.

To unsuspecting students, this statement and proof appear quite convincing, and it is usually with great reluctance that they embark on experimentally testing it through a dynamic construction[3] when encouraged to do so. Much to their surprise, as it then turns out, the statement and its proof are false since they are based on the faulty assumption that X and Y will always fall on (the interiors of) AD and CB. This is

[3] Although ideally students ought to do such a dynamic construction for themselves, the instructor could provide them with a ready-made dynamic sketch to save time.

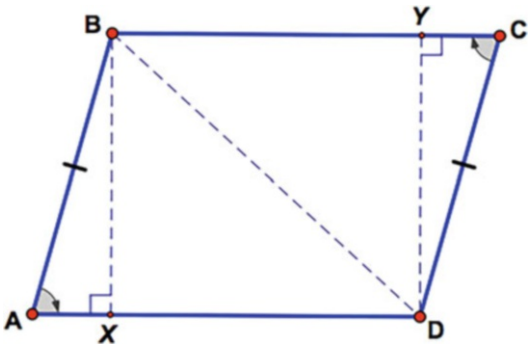

Fig. 4 Plausible conjecture

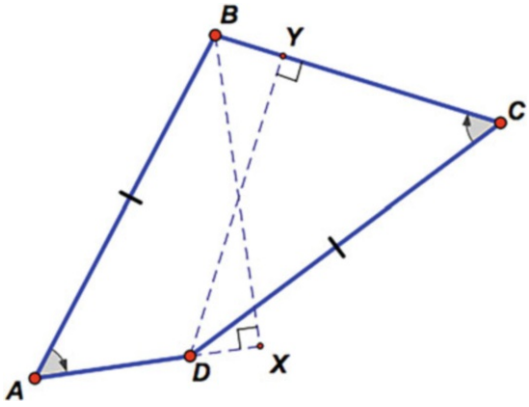

Fig. 5 Counterexample by experimental testing

unfortunately not the case as shown by the counterexample in Fig. 5 where *X* falls outside, on the extension of *AD*, and the above argument is no longer valid. This example therefore illustrates the value of experimentally testing not only one's conjecture, but also one's deductive arguments. It also demonstrates the refutation function of experimentation mentioned at the beginning of the chapter.

One could also propose to students that in order to correct the theorem we would need to add the condition that there must exist at least two opposite vertices with orthogonals to an opposite side falling inside the quadrilateral. Thus, out of a false theorem emerges a correct theorem by the addition of a further condition. Even though this improved theorem is "a bit clumsy," it would give the opportunity for discussing in the classroom that not any true statement is worth becoming a theorem. For example, whether it is worth is a matter of judgment based on criteria such as simplicity, practicability, range of possible applications, etc.

Another example that could be used in class to illustrate the importance of testing one's deductive arguments for faulty assumptions is the following generalization of Viviani's theorem: "the sum of the distances from a point to the sides of an equilateral pentagon is constant." While the result is valid for all convex cases, it

is generally not true for concave equilateral pentagons and is left to the reader to verify at this dynamic sketch online: http://dynamicmathematicslearning.com/viviani-general.html.

An authentic illustration of a heuristic counterexample in the spirit of Lakatos is to have students in class measure and sum a pair of opposite angles of a convex cyclic quadrilateral using dynamic geometry. Then by asking them to drag one of the vertices along the circumference of the circle until a crossed quadrilateral is obtained as shown on the right in Fig. 6, one can create productive cognitive conflict for a fruitful classroom discussion. What is at stake here, of course, is what we choose to understand by the concepts of "quadrilateral" and "interior angle." Such an example therefore naturally stimulates the need to more precisely, and in a more consistent manner, define these concepts (compare Lakatos 1976, p. 16).

Though the easiest way out of the dilemma would be to "monster-bar" the second example as not being a quadrilateral, it is possible to guide students to a mathematically more sophisticated alternative where interior angles are defined more precisely as "directed" angles, and to the following revised formulation of the traditional theorem: "The two sums of the opposite angles of a cyclic quadrilateral are equal (to 180° if it is convex or to 360° when it is crossed)" (compare De Villiers 2015).

Eilers and Johansen (2017, p. 6) have similarly pointed out as follows that "even if a hypotheses is disproved by a counter-example, it may not be necessary to abandon it completely. The common features of a collection of counter-examples will often supply the input to refine the hypothesis into a new form . . . the experimental process can be seen as a stepwise refinement of the initial hypothesis . . ."

Providing students with such simple, accessible Lakatosian learning experiences of modifying, adapting, and reformulating definitions and theorems can potentially

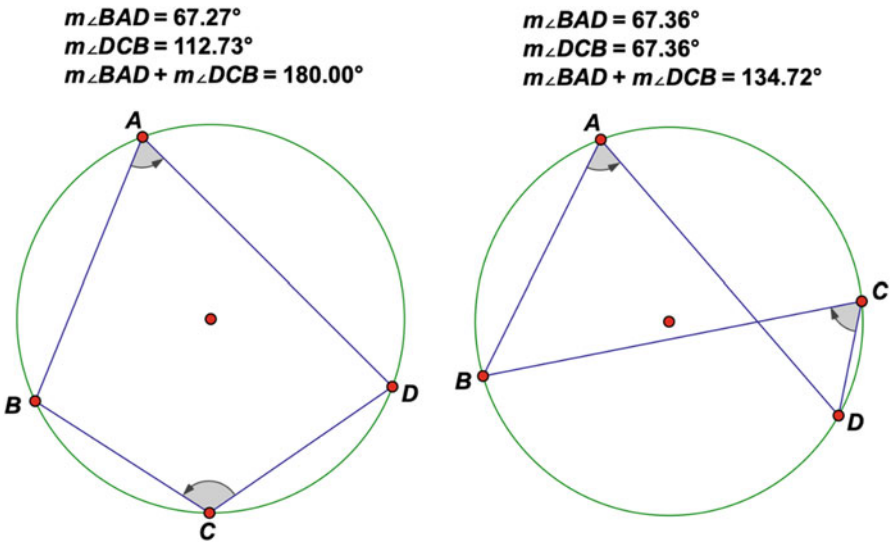

Fig. 6 Counter-example or monster?

help to combat the pervasive myth that definitions and theorems are always static and fixed (Ernest 1991).

Sometimes finding a counterexample with dynamic geometry requires an enlargement (dilation) of the figure by quite a large-scale factor. In 2014, for example, the following conjecture was investigated by De Villiers and Heideman (2014): Start with any triangle ABC and its incircle and incentre *I*. Label the points where the circle touches the sides *BC*, *CA,* and *AB* respectively as A_1, B_1, and C_1 as shown in Fig. 7. Repeat the process with the new triangle $A_1B_1C_1$ and determine its incentre I_1. Then repeating the process twice, it appeared that the four incentres *I*, I_1, I_2, and I_3 were collinear.

Despite the conjecture passing the so-called "drag-test" of dynamic geometry, and initially convincing the authors that it was true, it was only later after some failed attempts at proving it that the authors considered enlarging the diagram by a large factor of 100:1. This conclusively showed that the points were actually not collinear. The reader is invited to dynamically view the enlargement with the interactive sketch using the available slider at: http://www.sineofthetimes.org/refutation-in-a-dynamic-geometry-context/.

As argued and extensively illustrated by Klymchuk (2005, 2007) with many useful classroom examples for introductory calculus, the production of

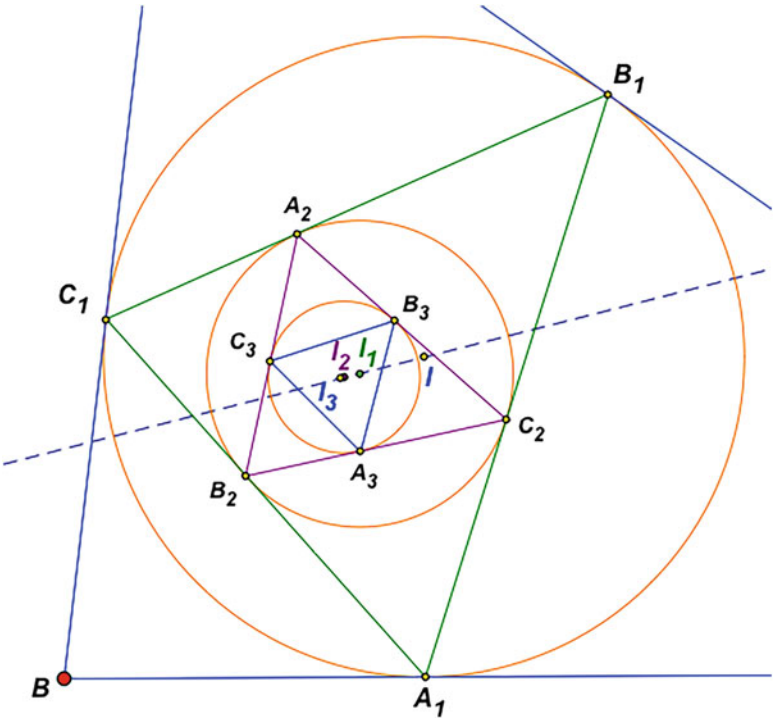

Fig. 7 Iteration of tangent points of incircle

counterexamples by the instructor or students can also deepen understanding, help combat resistant misconceptions, and potentially enhance generic critical thinking.

In the next section, we will briefly examine the use of scientific principles and results within mathematics. In particular, we will focus on the value and use of balancing points (centroids) in the discovery and explaining of some geometric theorems.

6 Using Scientific Principles in Mathematics

The implementation of the principles of physics has since ancient times been a productive approach in many areas of mathematics for not only discovering new results, but also logically explaining (proving) them. Introducing principles of physics into a mathematical theory amounts to adding new axioms/hypotheses to the set of axioms so far accepted. Of course, when a new result is found and proved by such additional principles it still remains an important question to investigate whether it can also be proved in the established axiomatic domain of mathematics proper.

In the following, we restrict ourselves to the application of principles of statics to geometry since these seem to provide the only examples accessible to school teaching.

One of the most famous mathematicians and scientists of antiquity was undoubtedly Archimedes (c.287 – c.212 BC) of Syracuse.

Archimedes used the centroids (centres of gravity) of figures, and the law of the lever, to deduce the volumes of spheres, cones, and pyramids (Heath 1897; Polya 1954; Hawking 2006). Another important figure was the Italian engineer Giovanni Ceva (1647–1734 AD) who in 1678 published a book "De lineis rectis se invicem secantibus statica constructio" exposing a comprehensive approach to elementary geometry by means of static considerations.

The law of the lever can be stated as follows: "Magnitudes are in equilibrium at distances reciprocally proportional to their weights" and is illustrated in Fig. 8. Algebraically, when in balance (equilibrium), it can be formulated as $W_1 \times L_1 = W_2 \times L_2$, where W_i and L_i are, respectively, the weights and distances to the fulcrum. In practice, it is a familiar occurrence to children playing on a seesaw where, for example, a heavy adult would need to be balanced by two or more smaller kids on the other side.

Over the years, the authors have used the experimental and theoretical exploration of balancing points (centroids/centres of gravity) of triangles, quadrilaterals, and other polygons with undergraduate and postgraduate students as well as in

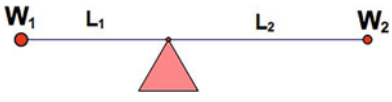

Fig. 8 Law of the balanced lever

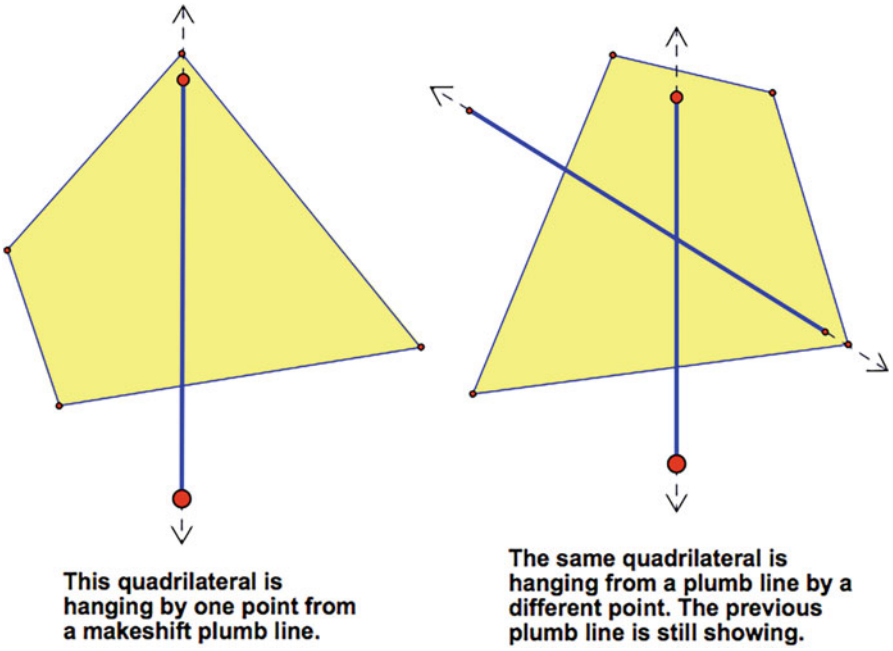

Fig. 9 Finding a centre of gravity with a plumb line

workshops with in-service teachers. The balancing point of a two- or three-dimensional object is called its centre of gravity. In architecture and engineering, accurately locating balancing points is extremely important for designing stable structures that do not collapse (Gordon 1978). The centre of gravity of a two-dimensional object can easily be found through experimentation. For example, in order to locate the approximate centre of gravity of the polygon, students can be asked to balance a cardboard polygon on the tip of a pencil or an eraser.

Another way of experimentally locating the centre of gravity of a cardboard polygon is shown in Fig. 9. The polygon is hanging on a string that is attached near its edge. The string is acting as a carpenter's plumb line, which provides the carpenter with a line perpendicular to the ground. The balancing point or centre of gravity is then located where these two lines cross. When doing experiments like these to locate centres of gravity, the results are obviously subject to some experimental error.

After dealing with the following theoretical method of finding the centroid of a cardboard (lamina[4]) quadrilateral *ABCD* (see Fig. 10), students can be encouraged to carry out the geometric construction on their physical models, and to compare the experimental finding with the theoretical location:

[4] In physics, a lamina is a two-dimensional object with uniform density and negligible thickness.

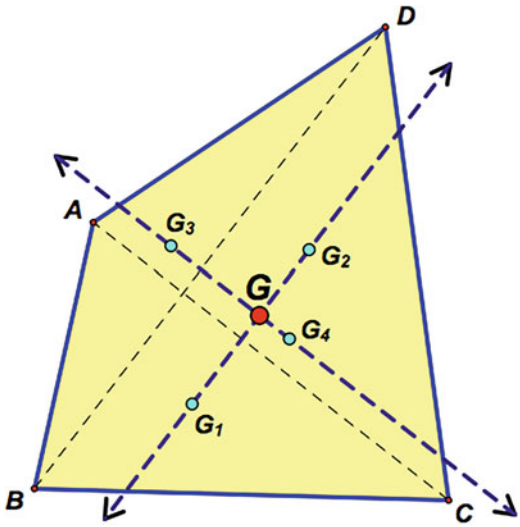

Fig. 10 Finding the centroid of a cardboard quadrilateral

1) Find G_1 and G_2, the respective centroids of triangles *ABC* and *ACD*, then the balancing point of the whole quadrilateral must lie somewhere on the line connecting these two centroids.
2) Find G_3 and G_4, the respective centroids of triangles *ABD* and *BCD*, then the balancing point of the whole quadrilateral must lie somewhere on the line connecting these two centroids.
3) Hence, the balancing point of *ABCD* must lie at the intersection of the two lines in 1) and 2).

Generally, the results of comparing the experimentally found balancing point and the theoretical location agree fairly well, unless of course major experimental or construction errors were made. Of some pedagogical interest too is to have students drag a dynamic quadrilateral with its constructed lamina centroid so that it becomes concave. Much to their surprise, and some cases even with some mild bewilderment, students will find that the balancing point could actually move outside of the quadrilateral as shown in Fig. 11. In order to balance a concave cardboard quadrilateral like that, one would have to attach a thin (comparatively weightless) wire to the centroid in order to balance it. While the balancing point moving outside of a figure is not something uncommon – for example, the rim of a wheel also has its centroid "outside" the rim, which is why it needs to be connected with spokes to its balancing point, i.e., the centre of the circle forming the rim – students nonetheless find this quite a surprising revelation.

From a sporting perspective this observation also provides a scientific explanation why the so-called Fosbury flop is so much more efficient for high jumping than the old-fashioned straddle technique. By bending their bodies in an arc as shown in Fig. 12, high jumpers are able to move their centres of gravity slightly outside their

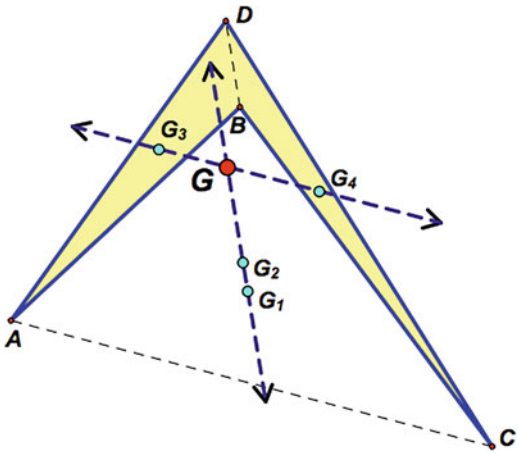

Fig. 11 Balancing point outside concave quadrilateral

Fig. 12 Fosbury flop in high jumping

body as they go over the cross bar, hence saving a few centimeters, which could be the difference between winning or not.

One can also demonstrate the theoretical solution for finding the balancing point of a cardboard quadrilateral quite nicely in another way with dynamic geometry. Since the relative weights of the cardboard triangles ABD and BCD are determined by their areas, we can determine the relative weights, respectively, concentrated at the centroids G_3 and G_4 by measuring the areas of triangles ABD and BCD as shown in Fig. 13. Now using the lever law of Archimedes, we can easily determine the balancing point (centroid) of the weights at G_3 and G_4. In particular, dilating G_3 from G_4 as centre and a scale factor of $\frac{areaABD}{(areaABD+areaBCD)}$ gives us the required balancing point G_3'. And doing this construction on the same sketch as the earlier one in Fig. 10 will show students that it is the same balancing point G as before.

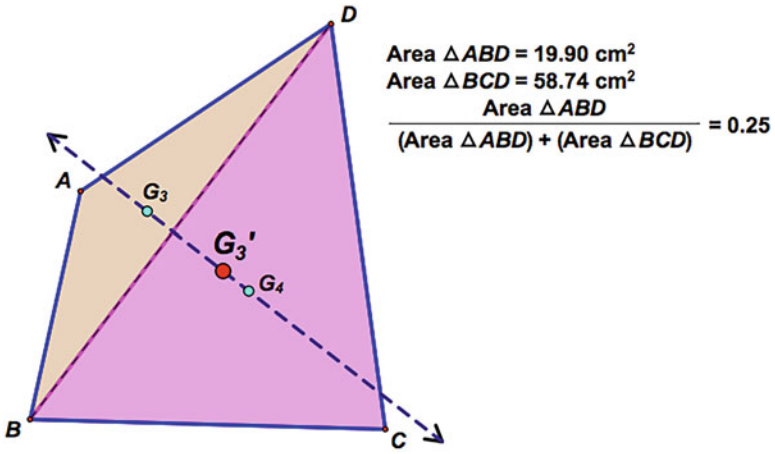

Fig. 13 Using areas as measure of cardboard weight

Saving the theoretical construction of the balancing point of a cardboard quadrilateral centroid as a tool in dynamic geometry also enables us to easily find the balancing point of a cardboard pentagon by dividing it in two different ways into a quadrilateral and a triangle, drawing the two lines between the respective centroids and finding their intersection. Alternatively, one can again use the law of the lever on a division of a pentagon into a quadrilateral and a triangle and determining their respective centroids and areas. This approach is easily extended to hexagons, etc.

A different physical way of analyzing balancing points (centroids) of polygons is to imagine equal point masses located at the vertices, and connected with thin wire of negligible weight to make it a stable structure. Where would such a structure balance? In the case of the triangle, the point mass balancing point is the same as that of the cardboard triangle, lying at the point of concurrency of the medians, but except for a parallelogram, it is not generally the case for a quadrilateral that the point mass centroid coincides with its lamina (cardboard) centroid.

As demonstrated by the French mathematician Pierre Varignon (1654–1722), the point mass centroid of a quadrilateral with equal weights at the vertices is located at the centre of the Varignon parallelogram formed by the midpoints of the sides (e.g., Hanna and Jahnke 2002). As shown in the first figure in Fig. 14, the point mass centroid does not coincide with the lamina centroid. The second figure in Fig. 14 also shows another interesting geometric property that is easy to explain (prove) using arguments from physics. For example, given equal point masses at the vertices of $ABCD$ it follows that the two weights at A and C would balance at the midpoint K of the diagonal AC. Since the same applies to the two weights at B and D, balancing at the midpoint L of the diagonal BD, it follows that altogether as a system, the four weights would balance at the midpoint of KL, which implies that it coincides with the point mass centroid (the Varignon centre of the Varigon parallelogram).

Similarly, by considering different weights at the vertices of a triangle, just like Giovanni Ceva did (see above), we can also deduce, from the principles of mechanics, the celebrated concurrency theorem of Ceva (compare Hanna and Jahnke 2002).

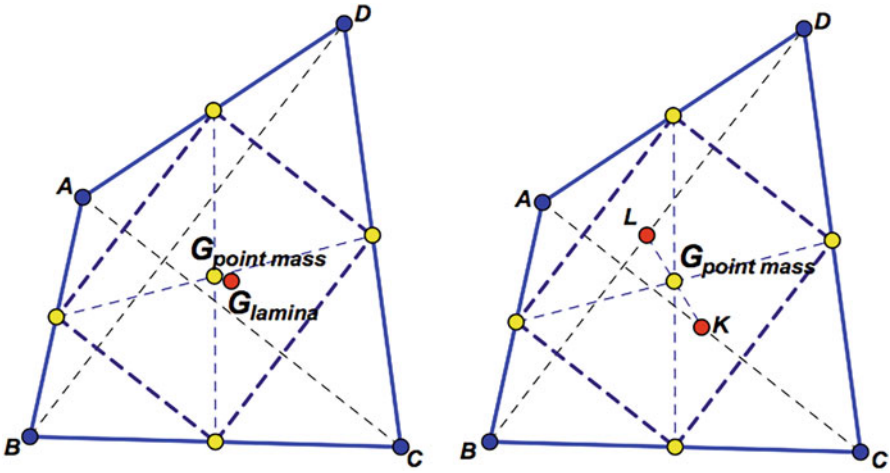

Fig. 14 Point mass centroid and lamina centroid

Fig. 15 Mechanical demonstration of Fermat point

Lastly, it is not hard to design a dynamic geometry exploration for students, and a guided worksheet to prove from coordinate geometry, that the coordinates of the centroid of a triangle can be found from the average of the coordinates of its vertices. This can be further extended by using a weighted average to find the coordinates for the Ceva point for different point mass weights located at the vertices, and easily extended further to higher polygons.

For a short outlook on other ways of using means from physics to understand mathematical relations, we hint at applying physical models and phenomena to illustrate mathematical problems and theorems. This can potentially contribute to making mathematics more meaningful to a lot of students that are not destined to further pursue "pure" mathematics. The Fermat point of a scalene triangle, i.e., the point that minimizes the sum of the distances to the vertices can easily be modeled by weights hanging in balance as shown in Fig. 15. Soap bubble geometry can also be

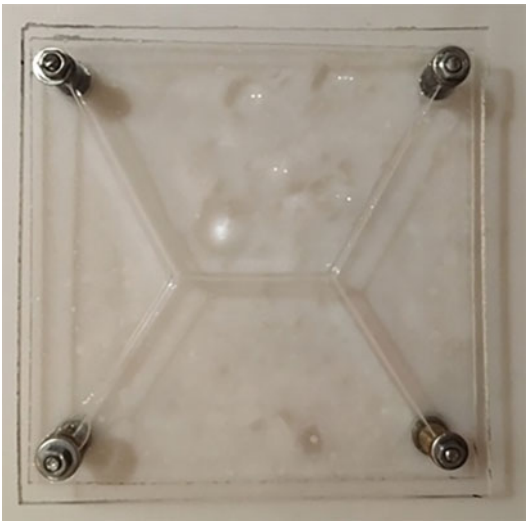

Fig. 16 Soap bubble demonstration of Steiner tree network for a square

used in class and workshops with teachers to quite dramatically illustrate the Fermat point of a scalene triangle, and as shown in Fig. 16, the similar Steiner shortest path network for a square.

7 Modelling the Real World

The inclusion of mathematical modelling as part of the mathematics curricula of many countries provides an excellent opportunity to include more experimentation into the classroom. As explained in Sect. 2, this is an important step beyond the Lakatosian point of view since, with modelling, experimenting with different hypotheses also comes into play.

There exist quite a lot of diagrammatic representations of the circular process of modelling (f. e. Blomhøj and Jensen 2003, p. 125; Kaiser and Stender 2013, p. 279). We use a very simplified diagram which consists of three important steps or stages as illustrated in Fig. 17, namely,

1) Construction of the mathematical model
2) Processing the model
3) Interpretation and evaluation of the results

Out of a practical problem, a mathematical model is constructed comprising a set of data and a set of hypotheses. The latter can be a geometric representation, a number of algebraic formulae or functions or differential equations, respectively, or a mixture of them. In the next step, the mathematical model is processed. This might mean different activities: to insert data into the equations, to manipulate formulae,

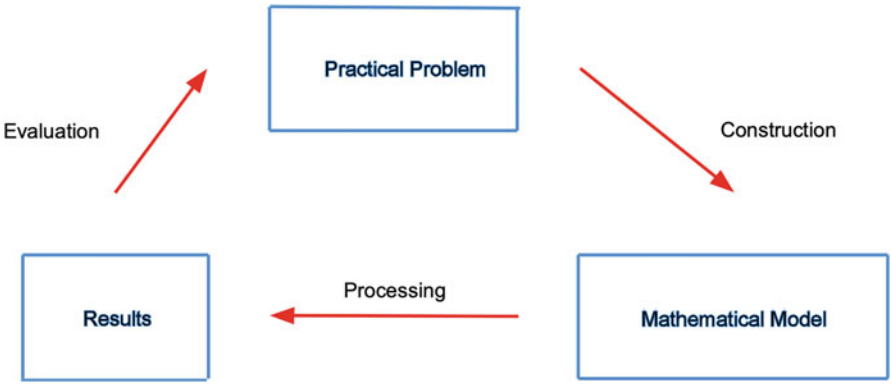

Fig. 17 Modelling stages

and/or to derive logical consequences from the hypotheses of the model which amounts to proving. Then the results of the processing are evaluated in regard to the practical problem, and if necessary, the hypotheses are modified thus starting a run through a new cycle (Fig. 17).

Today, for processing a model many tools such as Dynamic Geometry Systems (DGS) are available for introducing concepts like the derivative in a dynamic way which was not possible before (Ndlovu et al. 2011). Traditionally, much of schooling in the past has consisted of teaching learners Stage 2, namely, how to process given mathematical models by solving equations comprising linear, quadratic, trigonometric, exponential, hyperbolic, etc. functions, but hardly involving them at all in the Stage 1 construction and development of these models from real-world contexts, and much less on Stage 3, i.e., evaluating the solutions and how well they fit "reality." In short, in some countries, it consists of teaching mathematics largely disconnected from the real world, though fortunately in many countries mathematical modelling is now demanded by the official curricula (see Sect. 1 above).

Moreover, the first stage of "model developing" as well as the last "evaluation" stage can provide ample opportunity for including some experimental work. At the first stage, for example, students may simulate Galileo Galilei's experiments of rolling balls down inclined planes and gather data to determine the relationship between distance covered and time. Of course, after the derivation of a model, students could experimentally test how well it fits reality.

Here is a simple example of how "testing" a theoretical solution to a geometry problem against a real-world background led to a new modified solution under certain conditions. In De Villiers (2003, pp. 27–33) as in some other books, the concepts of "circumcentre" and "perpendicular bisector" (as "a locus of equidistant points from the endpoints of a line-segment") are introduced in order to find suitable equidistant points, respectively, from three rural villages A, B, and C (Fig. 18) to build a water reservoir. It was stated at the outset that the villages were all of equal size, while students were expected to identify other implicit assumptions such as that the villages were on the same plane, that the surface was flat, that there were no

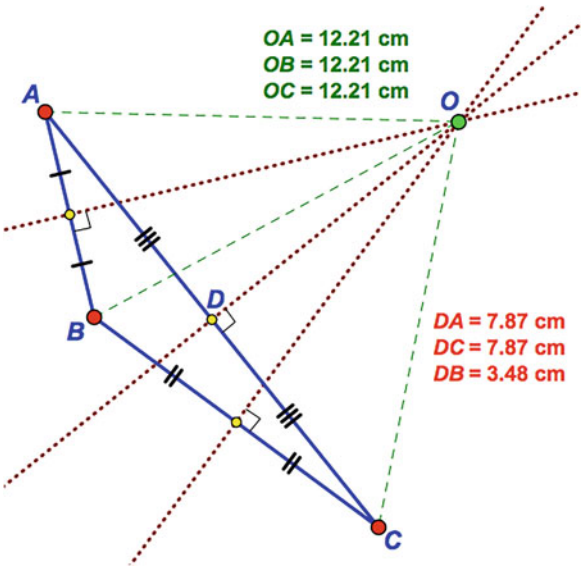

Fig. 18 Modified, improved solution

natural obstacles such as dense forest or rivers, and that the distances were sufficiently large in comparison to the sizes of the villages and the water reservoir that they could geometrically be represented by points.

During 2011, in a class with prospective mathematics teachers, author 1 was discussing with the whole class the results of their investigations that the students had completed during the previous session in the computer lab. Projected on to the screen with the data projector was a triangle with its circumcentre constructed with dynamic geometry as the required equidistant point for the reservoir. To discuss a question on the worksheet, the triangle was dragged into a right triangle, and dragging continued until it became obtuse, so that the circumcentre moved far outside the triangle formed by the three villages as shown in Fig. 18.

Immediately, one of the students objected strongly, saying that position would not be a good solution in the real world as the reservoir would then be too far away from the rural villages. Eventually only after a whole class discussion (compare De Villiers 2013), it was agreed that in an obtuse triangle case such as shown in Fig. 18, a better solution than the circumcentre would be to build the reservoir at the midpoint of the longest side. This makes sense, since in the case of Fig. 18, the midpoint D of the longest side AC is much closer to all three villages (yet still equidistant from villages A and C).

Another example of a theoretical solution in geometry having a restricted domain when interpreted within the real world is the following problem from De Villiers (2003, p. 6): Given an island (approximately) in the shape of a parallelogram, find a point on the island to build a holiday cabin that minimizes the sum of the distances to each of the beaches. It is quite easy to discover and prove by students that

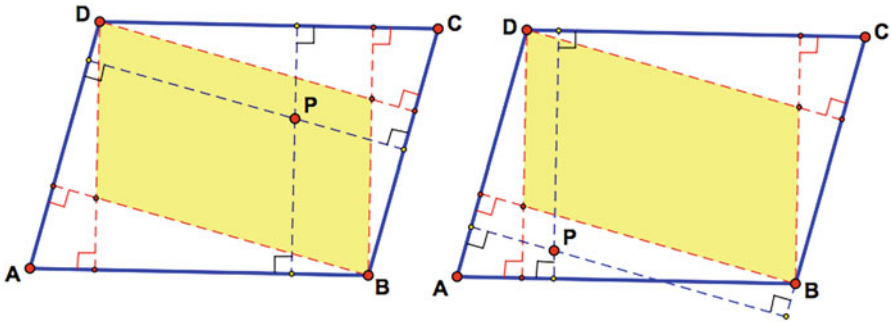

Fig. 19 Restricted solution domain

theoretically the cabin can be built anywhere inside since the sum of the distances from a point *P* to the sides of the parallelogram is constant.

However, in an actual real-world context the solution domain as shown in Fig. 19 would be restricted by the enclosed area formed by the perpendiculars from *B* to the sides *AD* and *CD*, and from *D* to the sides *AB* and *BC*. As shown in the second figure in Fig. 19, if *P* is moved outside the solution domain, one of the distances would fall on an extension of one of the sides outside and would therefore be in the sea and the "distance" would no longer be a distance to a beach. Also note that if the adjacent sides of the parallelogram "island" become extremely tilted toward each other, no feasible domain is possible, in which case one may need to choose a different criterion for building a cabin.

Ignoring the practical, real-world aspects of the problem, students may also be encouraged to drag the point outside the parallelogram to note that according to the DGE software the sum of the distances would no longer be constant. This can then also be used as an opportunity of a local or heuristic counterexample by introducing students to the concept of "directed" distances in order to make the theorem valid outside the parallelogram as well.

Though the two geometry problems above are rather artificial approximations to real-world problems, such problems can still serve an important educational purpose, if teachers point out to students similar constraints may arise when interpreting and testing general theoretical solutions against the real world. This contributes important insights to develop a more adequate understanding of modelling. In performing experiments in school, students should realize that their results are probably crude, and that, due to the limitations of measuring techniques and measuring instruments, "real" scientists in research laboratories also do not obtain "perfect" results (i.e., experimental data that fit a mathematical relationship exactly, for example, lying exactly on a straight line).

Unfortunately, textbooks often convey a distorted perspective in this regard by supplying "typical data" that fit the desired model precisely. They are giving the impression that the data were obtained in an actual experiment, while probably they were generated by substitution in the relationship they are supposedly seeking. Furthermore, by reporting only "perfect" data, the very important scientific activity

of processing and drawing appropriate conclusions from imperfect data seldom, if ever, arises.

By carefully running through modelling cycles from the earliest beginning, students should better and better understand that, since it is not possible to always include all variables in a real-world situation or to accurately quantify them, mathematics can never provide an exact, precise model of the real world. What should have become clear from the simple examples above is also true for science in general. In most cases, simplifying assumptions have to be made, and usually the simplest available mathematical model is preferred as long as it provides a useful, accurate enough approximation for description, prediction, engineering design, etc.

Quite often more than one possible mathematical model can be used to describe the same physical phenomenon from the real world. We can just think here of the complex Ptolemaic system of planetary motion (approx. 150 AD) involving epicycles, yet it was so accurate that it was in use for well over a 1000 years until the arrival of the Copernican system (1543) that was not only much simpler to use, but also growing experimental evidence substantiated it. A neat, illustrative video clip comparing the planetary systems of Ptolemy, Copernicus, and Tycho Brahe is available for students at https://youtu.be/aL_k7NwZ-2Y, but a Google search will produce many more videos that an instructor could use in this regard.

Even in ancient astronomy, the situation arose of two competing models explaining equally well the same set of data. One of the models is mathematically available to interested students of the lower secondary level. In 2010, a respective teaching experiment was performed in two classrooms (see Jahnke 2010; Jahnke and Wambach 2013). It concerns the so-called "anomaly of the sun" which was discovered for the first time by the great astronomer and mathematician Hipparchos (second century BC). Roughly speaking, the term refers to the observation that the half year of summer (spring + summer) is about 1 week longer than the half year of winter. This contradicted the basic conviction of Greek astronomers that all heavenly bodies move with constant velocity in circles around the centre of the earth (see Fig. 20). Therefore, Hipparchos invented a new hypothesis to "save the phenomena" which can be found in Ptolemy's Almagest, book III, section 2 (Toomer 2020, p. 141). In the pre-Hipparchos period, the Greeks assumed that during a year the sun moves with constant velocity on a circle, the so-called ecliptic passing vernal equinox (VE), summer solstice (SS), autumnal equinox (AE), and winter solstice (WS). Since in this model the arcs between these four points which define the four seasons spring, summer, autumn, and winter are equally long, it follows that the seasons last equally long. Hipparchos was the first to explicitly discuss the deviation of astronomical data from this simple model and to propose a new hypothesis. He kept to the assumption that the sun moves on a circular path with constant velocity. His new hypothesis was the assumption that the centre of this circle is not situated in the centre of the earth, but a bit outside (see Fig. 21). Consequently, Ptolemy called this the eccentric hypothesis.

Hipparchos' new hypothesis not only allowed a much more precise calculation of the daily position of the sun, but also implied two remarkable theorems. One of them

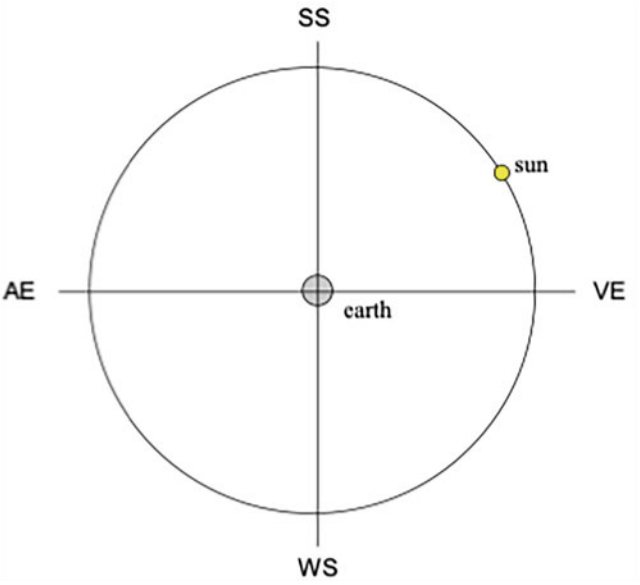

Fig. 20 Path of the sun

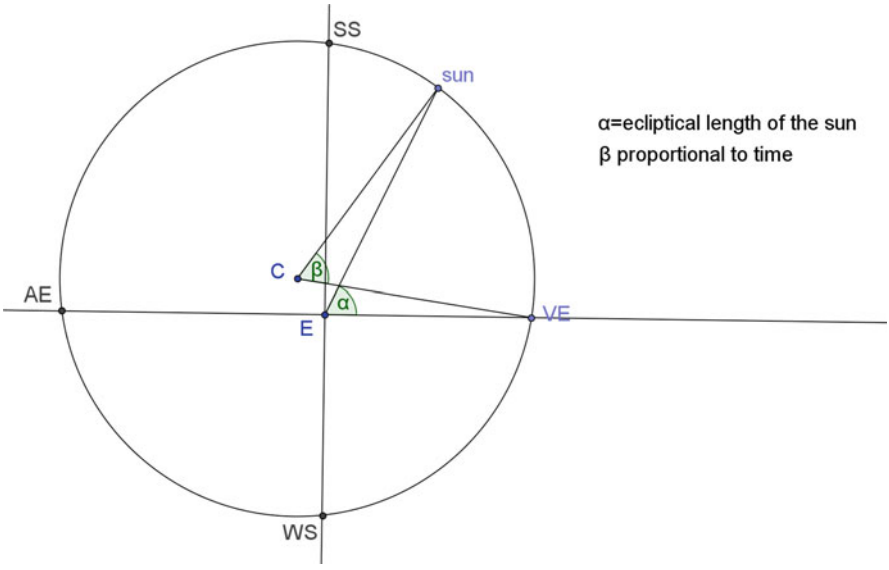

Fig. 21 Hipparchos' eccentric hypothesis. E is the centre of the earth, C the centre of the sun's circular path

says that the distance of the sun from the earth varies over the year and that there is one point where it is nearest to earth (perigee) and one where it is most distant (apogee). The second theorem says that the velocity of the sun also varies with a maximum in perigee and a minimum in apogee.

Hipparchos' model predicts not only the lengths of the seasons, but also the positions of the sun at any point in time. This position can be measured by its so-called "ecliptical length,"which is the angular distance between the vernal equinox and the position of the sun at a certain moment in time observed from the earth (angle α in Fig. 21). Since the sun travels with constant velocity on its circular path, angle β (Fig. 21) measures the time elapsed since the vernal equinox. The model predicts the position of the sun with astonishing precision.

The students constructed, using modern data of the lengths of the seasons, Hipparchos' eccentric model by means of Geogebra. They found that the maximal deviation from modern data is less than 3 angular minutes, by far below observability for the Greeks.

The historical setting of this teaching experiment enabled the students in a special way to reflect on the process of experimenting with hypotheses. The students were aware of the fact that Hipparchos' hypothesis is quite different from the modern theory. Nevertheless, it provided very precise predictions of the yearly path of the sun. They were told that Ptolemy applied also another hypothesis, the epicycle hypothesis, stemming from Appolonios of Perge (third century BC). Since both hypotheses provided the same data, Ptolemy felt free to choose the simpler hypothesis for his practical calculations. Thus, this episode in the history of astronomy uncovers in a particular manner the relativistic and experimental nature of all modelling, in general alien to Greek and European thinking until the twentieth century.

8 Conclusion

In conclusion, here are quotes from two highly respected mathematicians that emphasize the importance of experimentation in mathematics and mathematical research:

> *The mathematician at work makes vague guesses, visualizes broad generalizations, and jumps to unwarranted conclusions. He (*sic*) arranges and rearranges his (*sic*) ideas and becomes convinced of their truth long before he (*sic*) can write down a logical proof. The conviction is not likely to come early – it usually comes after many attempts, many failures, many discouragements, many false starts … experimental work is needed … thought-experiments*. – Paul Halmos (1984:2)

> *… we … practice unashamedly and in broad daylight, certain customs in which we indulge only in the privacy of our offices, and which we never admitted to students: experimentation. To a degree which never appears in the courses we teach, mathematics is an experimental science* … – Henry Pollak (1984:12).

What these professional mathematicians say about the role of experimentation in doing mathematics is true but cannot immediately be applied to situations of

teaching. The mathematicians devote their professional time exclusively to doing mathematics striving for new results. This is of course not the case for students at schools and only in a rather limited manner even for students at the tertiary level. Thus, for developing and keeping alive a balance between experimentation and deduction is an educational task sui generis.

Seen from the point of view of a long-term development of mathematical thinking, experimentation in the primary and lower secondary grades (c. 1 to 8) would be characterized by informal arguments and mostly amount to pattern recognition and arguing with patterns. One could call this a phase of informal thought experiments (Jahnke 2007, 84 pp). From grade 8 onward until the end of upper secondary, students work in small networks of deductively connected mathematical relations. Freudenthal (1973, p.458) speaks of local organization, and if modelling and small physical theories are also considered one could call this the phase of hypothetico-deductive thinking. The concept of proof should explicitly be made a theme, and real measuring should be included which leads to building small networks of theorems based on empirical evidence. At the end of attending school, students should have an idea of what a theory is. Only in a third phase, students (of tertiary level) would work in autonomous mathematical theories, and only then proof would mean what an educated mathematician would understand by proof.

In the present chapter, we have concentrated on examples of the second phase. These included topics of pure mathematics (i.e., number theory, geometry, and calculus). Geometry has a double face. It can be considered as a purely mathematical theory, when, however, seen as a theory of the real space around us, it gets the character of a theory of physics.

These phases are also more or less described by other authors. Wittmann (1981) and Skemp (1976, pp. 54–67) describe a transitional phase from intuitive to reflective thinking and view the latter as a more critical extension of the former. In the Van Hiele model of learning, this corresponds to a transition from the two lower levels of recognition and learning of properties to the third level of logical implications, and beyond (Van Hiele 1973).

Arzarello et al. (2012, pp. 97, 132) have similarly referred to the dynamic tension between the empirical nature of explorations with tools and the deductive nature of the discipline. They also illustrate with several examples the role of experimentation in proving activities in class and discuss some theoretical frameworks for better understanding the cognitive processes of students when involved in such activities. Boero et al. (2010) also distinguish several levels of development in the continuity of student levels of thinking until "cognitive unity" is ultimately achieved.

After exploring the historical interplay between the inductive and deductive, experimental and theoretical, Armella and Sriraman (2005) have proposed the notion of *situated proofs*, which can be defined as the result of a systematic exploration within an (computational) environment. The idea is that situated proofs can span a bridge between situated and formalized knowledge.

Nonetheless, however one conceives of the long-term development of mathematical thinking, experimentation and deductive reasoning should intimately interact. Frequently, it is said that experimentation leads to guessing a theorem and the matter

is finished when we are able to prove it. But this is only half the truth. We do not experiment without an aim or a question, and this requires deductions and considerations before the experiment has started. And the historical examples in Sect. 3 as well as the examples in Sect. 5 (on refutation) and in Sect. 7 (on modelling) show that the story is not finished with a proof. It is often necessary and fruitful to look for examples and possibly counterexamples for the theorem proved.

Also, the intellectual journey from handling concrete matters evolving into abstract theories requires that teachers stimulate their students again and again to think about what would happen when things or conditions were different. Not only the question "why is it as it is," but also the question "what would be if this and that would be different" should be guiding principles of any math teaching. To say it with a metaphor from grammar as another principle of teaching: "more subjunctive in the mathematics classroom!"

In conclusion, experimentation and deductive reasoning each have important, indispensable roles to play in mathematics and its teaching and should complement each other rather than seen to be in opposition to one another.

Introduction to Views from Other Domains

Andrew Aberdein

Abstract

The study of mathematical practice has always been an interdisciplinary enterprise and is not confined to history and philosophy. Important contributions have been made by scholars from many domains, including sociology, education, argumentation theory, rhetoric, formal epistemology, and theology. The chapters in this section provide overviews and introductions into the insights that scholars of mathematical practice may glean from these disciplines.

Keywords

Argumentation theory · Education · Formal epistemology · Rhetoric · Sociology · Theology

One of the closest allied disciplines to the history and philosophy of mathematical practice is the sociology of mathematics. Indeed, many of the conferences and collections that helped to define the study of mathematical practice as a field explicitly included sociology within their scope (for example, Van Kerkhove and Van Bendegem 2007; Löwe and Müller 2010). Classic works by sociologists of mathematics have also long attracted significant attention from scholars of mathematical practice (notable examples include Restivo 1992; Heintz 2000; MacKenzie 2001; and Rosental 2008). In their chapter, "Inverting Hierarchies: The Sociology of Mathematical Practice," Michael J. Barany and Milena Kremakova provide a wide-ranging historical survey of the different research traditions in sociology that have been applied to mathematical practice, including positivist, constructivist, Marxist, ethnomethodological, and institutional approaches. They also look forward to some of the ways the sociology of mathematics may develop in the future by way of

intersections with the study of other social practices, such as work, gender, education, and technology.

Historiography is another domain of inquiry that is closely allied to the core disciplines of the history and philosophy of mathematical practice. The historiography of mathematics presents distinctive questions, perhaps most conspicuously concerning the proper status of histories of mathematics (and other accounts of mathematical practice) written by professional mathematicians. Many such works have been deservedly influential in the study of mathematical practice, despite occasional departures from methodological orthodoxy. In his chapter, "Practice Makes Perfectoid: Pasts, Futures, and the Historiography of Contemporary Mathematics," Michael J. Barany teases out many of the ways the professional mathematician and the professional historian can diverge. By way of illustration, he reflects on some of his interactions with the number theorist Michael Harris, a doyen of the internal approach (notably in his book, Harris 2015). In particular, Barany contrasts his own historical study of Laurent Schwartz's theory of distributions with Harris' insider account of the much more recent emergence of Peter Scholze's perfectoid spaces, thereby highlighting the strengths and weaknesses of these two perspectives. Barany's chapter itself contrasts with Viktor Blåsjö's chapter in a different section of this *Handbook*, which makes the case for a revival of internalist historiography of mathematics (Blåsjö 2024). For yet further perspectives, a useful recent collection is (Remmert et al. 2016).

Perhaps the most prolific of other domains bearing on the study of mathematical practice is education. There are many more mathematics educationists than historians or philosophers of mathematics; while not all of their research is necessarily of interest to scholars of mathematical practice, there is much that is or should be. Crucially, many mathematics teachers and scholars of mathematics education agree that what goes on in mathematics classrooms should reflect the actual practices of working mathematicians. If this goal is to be met, it is essential for mathematics education to work out what those practices are. In their chapter, "Mathematics Education Research on Mathematical Practice," Keith Weber and Matthew Inglis provide an overview of some of the research mathematics educationists have conducted in this spirit. They focus on two particular research questions: What does the understanding of mathematical concepts comprise and what do mathematicians do when they read proofs? These questions (and others) have inspired significant empirical research from which scholars of mathematical practice may profit. There are many collections with contributions that address the relationship between mathematical practice and mathematics education research (for example, Ernest 2018; Stylianides and Harel 2018; and Kaiser and Presmeg 2019). In particular, Weber is also the coeditor of a recent collection with a focus converse to that of this chapter: introducing scholarship on mathematical practice to mathematics education researchers (the introduction is Weber et al. 2020).

One of the factors that makes mathematics distinctive as a practice is that it embeds a distinctive approach to reasoning. There are fields of mathematics and of traditional philosophy of mathematics that take mathematical reasoning as their subject matter, notably mathematical logic. However, mathematical reasoning also

has significant points of similarity to other forms of reasoning. Argumentation theory is an umbrella term for many approaches that focus on reasoning in nonmathematical contexts. But argumentation theory may also be brought to bear on mathematical practice. In their chapter, "Argumentation in Mathematical Practice," Andrew Aberdein and Zoe Ashton explore some key techniques of argumentation theory and investigate their application to mathematical reasoning. This chapter pays particular attention to two devices which have found widespread application to mathematics: Toulmin layouts and argumentation schemes. Toulmin layouts were first proposed by the philosopher Stephen Toulmin as an analysis of defeasible reasoning (Toulmin 1958). Many mathematics educationists have found this device particularly useful, so this chapter is in some respects complementary to that of Weber and Inglis. An argumentation scheme is a stereotypical pattern of reasoning, such as analogy or appeal to expert opinion. Argumentation schemes have ancient roots but have recently been studied extensively by Douglas N. Walton, a philosopher, and various collaborators, many from computer science (Walton et al. 2008). This chapter also examines the wider role of argumentation in mathematics beyond proof and discusses the social aspects of mathematical argumentation. For further consideration of the topics of this chapter, see (Aberdein and Dove 2013).

As the study of persuasive communication, rhetoric is closely allied to argumentation theory; indeed, it is sometimes considered a proper part of that field. Rhetoric is also related to mathematics, in at least two ways: mathematics can be put to rhetorical use as a way to persuade people of nonmathematical claims; but mathematics also has a rhetoric of its own. Much mathematical reasoning embodies rhetorical features which many treatments of mathematical practice have tended to ignore. Aberdein and Ashton briefly address these relationships between rhetoric and mathematics, but a much more extensive treatment is provided by G. Mitchell Reyes in his chapter, "Rhetorical Approaches to the Study of Mathematical Practice." Reyes pays particular attention to a work familiar to most scholars of mathematical practice, Imre Lakatos' *Proofs and Refutations* (Lakatos 1976). However, as a rhetorician, Reyes brings a novel perspective to this work. Through a close reading, he spotlights some of Lakatos' own rhetorical choices and shows how they in turn work to illuminate the rhetoric implicit in the mathematics behind the development of a proof for the Descartes–Euler conjecture. Reyes is also a coeditor of a recent collection of papers on the relationship between mathematics and rhetoric (Wynn and Reyes 2021).

Bayesian approaches to probability comprise another line of enquiry that is much more familiar in application to nonmathematical reasoning than to mathematical reasoning. This is understandable, since Bayesian epistemology is designed to accommodate uncertainty whereas mathematical proof promises the elimination of uncertainty. Nonetheless, there are important aspects of mathematical practice from which uncertainty cannot be (or, at least, has not yet been) eliminated. James Franklin, in his chapter "Bayesian Perspectives on Mathematical Practice," provides a brief introduction to Bayesian reasoning and discusses some of these aspects, including the means by which mathematical consensus can form about the likely outcome of as yet unproven conjectures, such as the Riemann hypothesis. For a more

extensive, but still accessible introduction to Bayesian epistemology, see (Schupbach 2022).

Formal epistemology is the application of formal methods derived from logic or mathematics to questions from epistemology. As such, it can be seen as incorporating Bayesian epistemology as a component of a broader enterprise. (For a collection of survey articles on formal epistemology, see Pettigrew and Weisberg 2019.) One way of distinguishing the philosophy of mathematical practice from more traditional projects in the philosophy of mathematics is that it tends to pay greater attention to the epistemology of mathematics as opposed to its ontology. Hence, it is natural that formal epistemology should itself be applied to mathematical practice. In their chapter, "Polymath as an Epistemic Community: Analyzing the Digital Traces of the Polymath Project," Patrick Allo, Bart Van Kerkhove, and Jean Paul Van Bendegem apply one such formal method, network theory, to the study of the Polymath project, a much discussed recent example of mathematical practice. The Polymath project originated in a proposal for "massively collaborative mathematics" coauthored by the prominent mathematician Tim Gowers (Gowers and Nielsen 2009). Gowers subsequently helped to orchestrate several crowd-sourced mathematical projects, which have led to genuine progress on some open problems, including papers published under the collective pseudonym "D. H. J. Polymath" (the initials standing for "density Hales-Jewett" after the theorem for which the first Polymath project provided a new elementary proof) (Polymath 2012, 2014). What makes the Polymath project particularly exciting for scholars of mathematical practice is that its collaborations are primarily mediated by publicly accessible web sites, thereby generating a searchable record of research-level mathematics in progress and granting access to a characteristically private process. Allo, Van Kerkhove, and Van Bendegem provide a broad survey of the uses to which this resource has been put by past scholars and offer a novel analysis of their own, grounded in the tools of network theory. This leads to some striking insights into the structures that have emerged within the communities of mathematicians who have participated in the 16 Polymath projects to date.

Theology may seem to be an unpromising source of insights into mathematical practice. It is certainly much less closely allied to mathematics than many of the domains discussed so far. However, Stanisław Krajewski answers the question he poses in the title of his chapter "Is Mathematics Connected to Religion?" firmly in the affirmative. Some mathematicians, from Pythagoras onward, have ascribed a sacred significance to their mathematical work; more widely, theological metaphors have been influential for many mathematicians and mathematical progress has come from theological disputes. Celebrated historical examples include George Berkeley's critique of the calculus which originated as a tu quoque response to the theological views of its early promoters (Moriarty 2018, 2023), and Georg Cantor's surprisingly extensive engagement with Catholic theologians while researching the foundations of transfinite set theory (Dauben 1977). Some philosophers have postulated a deeper connection between mathematics and religion. Silvia Jonas, for example, has argued that abstract beliefs in both contexts present parallel difficulties for rational acceptability (Jonas 2016). Several recent collections offer diverse perspectives on the

interrelation of theology and mathematics: Krajewski is himself the coeditor of a special issue for which he provided a useful introduction (Krajewski 2016); another prominent collection is (Lawrence and McCartney 2015).

There are yet more domains with valuable perspectives on mathematical practice which are not the topic of a chapter in this section. Formal epistemology is not the only recent trend in the study of knowledge that should be of interest to scholars of mathematical practice. Naturalized epistemology, the application of empirical results to epistemological questions, also offers many valuable insights. Experimental philosophy, or "x-phi," can be understood as a closely related trend. Two recent collections each contain several chapters bringing such work to bear on mathematical practice (Aberdein and Inglis 2019; Bangu 2018). Cognitive science is perhaps the empirical field from which the greatest share of the relevant empirical results are drawn. Studies of numerical cognition include classic works such as (Dehaene 1997; Lakoff and Núñez 2000), and there has been a substantial volume of subsequent research. For a recent anthology, see (Cohen Kadosh and Dowker 2015). There is also a considerable overlap between the cognitive science of mathematics and some of the domains addressed by chapters in this section, notably mathematics education.

Researchers in artificial intelligence have long taken an interest in mathematics, particularly in the context of designing theorem proving software. One perspective within such work is that in order to produce an artificial mathematician we must first improve our understanding of what it is that human mathematicians do. Conversely, an artificial mathematician would reveal what was necessary to mathematical practice and what was mere human idiosyncrasy. (That recent breakthroughs in artificial intelligence have come from large language models whose inner workings are notoriously inscrutable does not undermine the value of the work conducted from this opposed tradition, although the application of such techniques to mathematics does present significant philosophical issues of its own.) Alan Bundy, a pioneer in the application of artificial intelligence to mathematics, has long championed an approach that pays close attention to mathematical practice (Bundy 1983). The mathematician turned computer scientist Ursula Martin has also investigated mathematical practice extensively to this end (and was one of the earliest scholars to reify "mathematical practice" as an object of enquiry) (Martin 1999; Martin and Pease 2013). A recent anthology of research on the significance of theorem proving technology for the understanding of mathematics is (Hanna et al. 2019).

The relationship between mathematics and the creative arts is a large enough topic to have inspired another handbook from the same editor as the present collection (Sriraman 2021). Literature, in particular, has a multiplicity of surprisingly deep connections to mathematical practice. Close attention to formal structure is of central importance in many literary media, just as it is to much mathematics. In addition, many of the domains discussed above, such as sociology, education, argumentation, and rhetoric, are also intimately related to literature and its scholarship. Some authors, such as Lewis Carroll and Jorge Luis Borges, are particularly well known for the mathematical sophistication of their work (see Wilson and Moktefi 2019; Bloch 2008). But there are many other writers whose use of mathematical concepts reflects the currency that these ideas had for the educated public of

their era, itself a valuable insight into mathematical practice in the wide sense. In recent years, there has been increasing scholarly attention to many of these phenomena. Individual studies address the relationship between literature and mathematics from the early modern era (e.g., Jarrett 2019) to the twentieth century and beyond (e.g., Engelhardt 2018; Bamford 2020). Other scholars have surveyed a broader chronological range (e.g., Abbott 2023; Hart 2023). A valuable anthology of recent scholarship is (Tubbs et al. 2021).

In sum, interdisciplinarity is at the heart of the study of mathematical practice. Progress relies on insights not only from history and philosophy, but also from many other domains including other humanistic disciplines, as well as social sciences and other fields. While this presents its own challenges, not least in securing suitable venues for publication, it is also a great source of vitality and originality.

Abstract

Sociology originated in the mid-nineteenth century from a new confidence in the power of science to explain the world on a mathematical foundation. Both mathematics and sociology transformed over the ensuing century, inverting the hierarchical relationship from sociology as a mathematics-based science of complex human configurations to mathematics as a complex science based on social institutions. That is, where sociology began as the hard case for mathematics, it became possible to see mathematics as the hard case for sociology. In this light, we examine a number of motivations and provocations for the sociology of mathematics, from language and social cognition to Marxist and materialist skepticism of ideology, and sample the evidence and arguments brought to bear on the sociology of mathematics at a range of scales.

1 Introduction: Mathematical and Social Order

Mathematics and society are based upon two radically different but essentially identical forms of order. Where mathematics is made up of *abstract* entities and *formal* structures governed by *universal* laws of reasoning, society counts *human* entities and *social* structures governed by *particular* laws of relation. Both are made from methods and modes of intersubjective agreement and of human groups organizing themselves and their senses of reality around something that is ultimately in their heads, a shared imagination. The evidence of the working of mathematics and of society is in collective episodes of argument and validation and of proposition and correction, by which people make sense of the possibility of having something invisible, immaterial, and greater than themselves in common.

Mathematics is a very old science, arguably dating back thousands of years. Sociology is a very new one, aged just a couple of hundred. The former was integral to the origin of the latter. To give one necessarily fabular tale of beginning: sociology started as the opposite polestar to mathematics in the positive philosophy of Auguste Comte, whose ungainly coinage of *sociologie* urged the possibility of a systematic science of society built on a hierarchy of more fundamental physical and mathematical sciences with abstract mathematics at the very foundation (Comte 1842).

The ambition for a science of society, for a social physics (as Comte and many contemporaries also termed it), grew from early nineteenth-century transformations in the relationship between mathematics and society. Propounded in new scales and uses of comprehensive training in calculus-based engineering (see Belhoste 2003), this transformation instilled a new confidence among certain European elites in the engineerability, and accordingly the mathematical knowability, of the increasingly urbanized social world after the Industrial Revolution. Comte's sociology became one of many sometimes-conflicting mid-nineteenth-century sciences of society – mathematical statistics derived from perhaps an especially notable contemporary variation of "social physics" (Hacking 1990) – each with its own social and scientific legacies and relationships to mathematics.

In this light, the sociology of mathematics has a kind of *ouroboros* character: it circles back; it eats its own tail. If the apparent universality of mathematical order underwrote the promise of a scientific account of the social world, such accounts can have the paradoxical effect of localizing and particularizing socially produced mathematics. Sociologists and mathematicians, alike and in their own ways, revel in paradoxes. They show the limits and the contradictions of what may be agreed, of the terms on which people may come together.

The next section reviews some of the major areas of sociology that have had something to say about mathematics. We then sketch how the sociology of mathematics, as such, has been constructed as one such limit, or contradiction, and develop some of the consequences of that view. Our analysis dwells at some length on the sociology of David Bloor, not necessarily because his work is representative or exemplary of the sociology of mathematics but because it has been a widely shared point of reference in the field, an excellent provocation, and a fruitful illustration of many of the themes discussed here. We identify a thread of interest in collective and societal responsibility in mathematics, which we follow from early Marxist analyses of the discipline through the proposals of Sal Restivo and others motivated by the socially critical potential of sociologizing mathematics. Finally, we consider the varieties of evidence at different scales that have informed such sociologies and some of the conclusions that can be drawn from these, including understandings of small-scale practices, labor, communities, and large-scale networked knowledge and authority.

2 Sociologies of Knowledges

Ideas about the relationship between mathematical and social order are at least as old as the oldest societies that were large and complex enough to put mathematics to social purposes. As an apparatus of recording and accounting, mathematics began as an aid to memory and reconciliation, as far as the oldest surviving mathematical records appear to show. Mathematics stabilized valuable entities across time and among people. Its stabilizing uses made it useful in claims about justice, initially with measurements and resources and later in other domains of contestation and coordination, including (a very long time after the earliest mathematical records) those of civic and religious authority (Robson 2008; Desrosières 1998). These uses and expectations of mathematics constituted claims about its social conditions and implications.

Such claims can be identified in numerous traditions, many of very long standing, including traditions of philosophy as well as the practice of mathematics. They include invocations such as the famous heading to Plato's Academy, forbidding those ignorant of mathematics from entering. The idea of mathematics as a prerequisite to organized knowledge has never been unanimous or uncontested but runs from before Plato's time through to our own times. After the trivium of grammar, logic, and rhetoric, the quadrivial mathematical subjects of arithmetic, geometry, music, and astronomy made up the foundation of the medieval liberal university curriculum. Vernacular arithmetician Robert Recorde claimed in 1543 that numbers were "the ground of all men's affairs" (see Barany 2023a). The pedagogical status of mathematics supported broader claims about the relationship between the subject and the intrinsic characteristics of human thought and perception, notably significant to Kantian metaphysics among many philosophical traditions.

Sociologies of mathematics draw from these long traditions of reasoning about relationships of mathematics and society. These sociologies have come, in turn, from a variety of distinct and often mutually disconnected scholarly traditions concerned

more explicitly and systematically with such society-knowledge (including society-mathematics) relationships. There has been no single or even dominant disciplinary or methodological home for social studies of mathematics, which have ranged across and often combined social scientific, anthropological, humanistic, philosophical, pedagogical, and other modes of inquiry.

For the purposes of this chapter, such an ungainly and unruly cluster of knowledge about knowledge is drawn together by a shared attention to the conditions and labor of producing and reproducing theoretical mathematics in the context of social institutions. That is, the sociology of mathematical knowledge is distinguished by seeking the interpersonal and socially organized dimensions of the most personal and logically governed forms of knowing. This view of the field favors the elements that are closer to the mainstreams of the philosophy of mathematical practice, at the expense of social accounts of the uses of mathematics and quantification, including their social and sociological uses. These latter topics have at times crossed fruitfully with what might be called the sociology of "mathematics itself" (notably, for instance, in the work of Donald MacKenzie 2001) but have tended to distinguish between the socially manifested meanings and implications of mathematical reckoning and the situated production of those reckonings as such.

Institutional contexts of mathematics include formal organizations – educational institutions, research institutes, states, corporations, and so on – as well as the constellations of norms, expectations, and more or less formally organized ways of understanding and being in the world that mediate participation in social groups of various kinds connected to mathematical work (see Barany 2021, 2022; a summary of the main sociological uses of the term "institution" can be found in Miller 2019). Institutions can be understood at a range of scales, from how an individual experiences and navigates institutional forms to how such forms structure roles and interactions at the scale of an entire society or of interacting social groups. The sociology of mathematics has tended to focus on the smaller end of these scales, closer to the activities of intellection and communication of shared interest to the philosophy of mathematical practice. However, especially in sociological studies of methods and systems of education or on patterns of mathematical careers or funding, scales of analysis can grow and interpenetrate, linking the personal to much larger patterns of thought and action.

Sociologies of knowledge and of mathematics interpret institutions from a variety of methodologies and perspectives, reflecting these fields' decidedly mixed parentage from many different branches of sociology, anthropology, psychology, and other humanistic and scientific disciplines. Some generalize and aggregate; some particularize and individualize. Sociologies of mathematics, like philosophies of mathematics, may be unusual in the degree to which individual experiences of cognition or sense-making are taken as general or exemplary on the basis of the presumed generality of laws and principles of mathematical reasoning: many accounts of how mathematics works in general (sociologically) are based on very few social individuals or contexts.

The precise relationship of individual experiences of mathematics to the kinds of phenomena discernible on larger scales can make a great difference, analytically and methodologically. How one understands the nature of mathematical consensus and

of collective reasoning changes what it means for individuals and communities to know and share mathematics. Producers and users of mathematical knowledge manage to agree on a lot, and they often see their agreement as being special in form, character, and even logical necessity. However, the social and historical fact of mathematics is that disagreement, misunderstanding, error, and variant comprehension are regular and routinized parts of mathematical research, learning, and communication. Sociological (particularly microsociological, ethnographic, and microhistorical) approaches cast light on the process of achieving mathematical agreement before disagreements are folded into consensus and erased.

Constructivist sociologies see such variation as evidence that mathematical consensus is only ever provisional and is made in social groups from a variety of ideas, experiences, practices, and values that combine to support particular senses of what one should accept and how one should reason. Among a variety of approaches, one may study such social constructions phenomenologically, examining how mathematics manifests in the lived experience of its users and producers, or one may study these ethnographically at the level of cultural forms and norms and group dynamics of sense-making. Constructivism is often opposed to realism or Platonism, two perspectives that prioritize claims that mathematics derives ultimately and inevitably from stable underlying truths that can be temporarily missed or misunderstood but that are not meaningfully revisable. This distinguishes sociology of mathematics from its object: while being a Platonist or anti-Platonist is typically understood to make no practical difference for a mathematician's daily work, these opposing epistemological perspectives result in entirely different approaches to sociological analyses of mathematics, the study of that daily work. Whether disagreement and negotiation are part of mathematical knowledge or extrinsic matters that circumscribe mathematical knowledge alters what needs to be explained about processes of knowledge making and sharing in mathematics and how these can be explained.

The status of dissensus matters both for settled or "textbook" knowledge and for open, unresolved, dynamic, or contested mathematics in the making. Sociologies of mathematics often focus on the latter as a circumstance where assumptions and processes of reasoning are expected to be more explicit, as people try to develop their understandings and to convince each other. Settled mathematics can be approached with related methods by focusing on contexts of learning, mobilizing the fact that settled knowledge is only ever settled for those who know it, and there is a constant supply of learners who navigate the often unsteady passage from ignorance to acceptance and even comprehension of established knowledge.

3 Making a Hard Case

In Comte's hierarchical philosophy of knowledge that was one of sociology's nineteenth-century points of origin, sociology was the hard case for mathematics, the pinnacle of a system of ever-complexifying structure based on mathematics and verging toward comprehending everything. Over the twentieth century, this relationship inverted. A significant scholarly tradition came to construe mathematics as a

hard case for sociology, perhaps the quintessential hard case for the sociology of knowledge.

Comte called his philosophy Positivism, referring to the combination of empirical facts and reasoning on which he claimed rested all positive knowledge, as opposed to lesser theological or metaphysical knowledge. In the early twentieth century, a critical confluence of philosophical interest in the linguistic foundations of both empirical description and logical reasoning gave rise to a different program in the philosophy of knowledge, also sometimes called positivism. Both positivisms were projects of unification and ordering, explaining how the modern sciences related to each other and to the nature of human thought.

Of their many differences, the most significant for understanding the inversion of mathematics and sociology as hard cases may be the respective positivisms' account of where mathematics comes from. For Comte, mathematics emerged as the first positive science from the problem of indirectly measuring magnitudes, based on the empirical and rational study of magnitudes' relations. For the later positivists, the key relations were between symbols, not magnitudes, and mathematics emerged as a semiotic or representational science built from the logical order and interpretation of written signifiers. This semiotic reorientation placed an emphasis on understanding and on mathematics as an achievement of rational representation (if not necessarily communication, inasmuch as one comprehending mind sufficed).

When mathematics was a science of relations among worldly magnitudes, cognition and comprehension were importantly peripheral to the underlying stuff of the subject. As mathematics came to be located in symbolic representations, language and meaning became more central to characterizing the human production and understanding of mathematics, if not what it was exactly that was being symbolically understood. Language and meaning are social things. The scholarly possibility of sociology of mathematics (in its form as a sociology of knowledge) came from a refocusing of the epistemology of mathematics around individual and collective linguistic representation. The enduring notion of the underlying truth or reality of mathematics as existing outside of language, in worldly relations or in the basic logical forms of knowledge itself, meant that such sociologies of mathematics were founded in a paradoxical project of characterizing the social conditions of knowing something intrinsically independent of the social world.

Ludwig Wittgenstein has come to represent the centrifugal dynamic of mathematics as language in the first half of the twentieth century. It is common to divide his career into an "early" and "late" period. The former, defined by his immersion in the symbolic architectures and paradoxes of turn-of-the-century logicism and represented by his *Tractatus Logico-Philosophicus* (1922), epitomized logical mathematical knowledge as the ultimate product of an orderly propositional system. The latter, shaped by the tumult of interwar philosophy and represented in his *Philosophical Investigations* (1953) and *Remarks on the Foundations of Mathematics* (1956), emphasized the conventionality of linguistic understanding, including the linguistic understandings that underwrite knowledge and agreement in mathematics.

Wittgenstein was no sociologist and a very unconventional philosopher, but his provocative writings, mostly published posthumously, have influenced sociologists

and nucleated major debates about the linguistic and cognitive bases of foundational knowledge in social contexts. The later Wittgenstein's emphasis on contextual and informal understanding and the provisional nature of mathematical agreement was inspirational to a postwar generation of scholars approaching mathematics from a multidisciplinary critical perspective that blended psychology, anthropology, social theory, and other fields into critical reconsiderations of the foundations of knowledge. In Wittgenstein's posthumous aphorisms, read through these approaches, the most banal mathematics – counting in a sequence, multiplying numbers – pulsed with indecision and shed their veneer of inevitability.

One of the most enthusiastic and controversial such re-readers of Wittgenstein was David Bloor, one of the formulators of the strong program in the sociology of knowledge, part of a cluster of constructivist sociologies that came to be known as the Edinburgh School of the sociology of science and technology. The strong program aimed to take a naturalistic view of knowledge, studying it empirically through the terms and manifestations observable wherever knowledge claims are made and collectively challenged or respected (Bloor 1976, pp. 2–3, see also Bloor et al. 1996). Regarding mathematics, the strong program contrasted with a "weak program" of identifying a diversity of mathematical cultures and traditions, seeking sociological explanations for errors or failures in mathematics and its applications but not successes, or otherwise granting the primacy of mathematical reasoning in accounting for mathematical knowledge (Restivo 1993, p. 252). Adopting mathematics as the hard case with which to demonstrate the reach and potential of his program's claims and ambitions, Bloor latched onto Wittgenstein's illustrations of the linguistic embedding of confidence and consensus in mathematics. For Bloor, Wittgenstein demonstrated that mathematics was derived through naturalistically observable social processes of navigating and managing irreducible or undecidable conventions.

These conventions – rules and institutions, in the terms of a later (1997) Bloor book title – were not just social but *social like everything else* (see also Bloor 1983). In Bloor's heterodox interpretation, there was ultimately nothing intrinsically mathematical about the language-mediated determination of right and wrong in mathematics. That "ultimately" is important and a key source of misinterpretation of Bloor's program: this analysis focused on extremal moments of indecision in mathematics where no mathematical principle *in itself* uniquely determined the next step or inference. Asserting the continuity and primacy of social institutions in the fundamental decisions of mathematics, science, and *everything else* was Bloor's answer to postwar sociologists of science who focused on identifying the distinctive (and distinctively virtuous, rigorous, and truth-producing) features of science as a realm apart (Kaiser 1998). As Kaiser (1998) shows, this shaped Bloor's interpretations of earlier sociologies of knowledge (e.g. Bloor 1973), such as the interwar work of Karl Mannheim (e.g., 1979 [1936]), to suggest misleadingly that they assumed an intrinsic difference between science and other forms of knowledge and placed science out of scope for their sociologies.

This posture of framing sociological accounts of mathematics against a backdrop of ignorance, indifference, or presumptive impossibility is itself a long-running

tradition in sociologies of mathematics. Where most sociologies of modern societies could be said to have encountered situations of demystification, mathematics appeared to some to be becoming increasingly mystified. For François and Van Bendegem, "the more we have become dependent upon mathematics, mostly in an indirect or invisible way, the less we are actually understanding its principles" (2010, p. 122). The sociology of mathematics has been called "neglected" (Startup 1983) and "severely underrepresented" (Löwe et al. 2010), characterized by "a queer mixture of devotion and lack of interest" (Heintz 2000, p. 9; noted in Löwe et al. 2010). Mathematics as a subject is, for François (2007), "untouchable and frightening" for the general public, as well as for social scientists, as a result of an alienating technical norm in global curricula. This view of mathematics as marginal to sociology (of knowledge) comes in tandem with the construction of mathematics as a limiting form of knowledge, an extreme that tests what sociologies of knowledge can say. Restivo (1985 [1983], p. 161) called it "the ultimate arbiter of the limits of the sociology of knowledge" and noted the omission of mathematics from a popular 1970s collection on the sociology of knowledge (p. 165). For Bloor it was "the most stubborn obstacle . . . the holy of holies" (Bloor 1976, p. 73; see Barany 2017). For Heintz (2000, p. 10), the "epistemological specificities" of mathematics mean that it is not certain whether the content of mathematics can be studied through constructivist sociology.

Proposing to question the most basic and taken-for-granted elements of mathematics has put these sociologists squarely in the company of foundation-minded mathematicians themselves (see Barany 2023b, pp. 53–56). Going back to basics, revisiting axioms, and rejustifying the seemingly obvious are time-honored narrative and mathematical techniques in both pedagogy and research. At the turn of the twentieth century, Russell and Whitehead famously and at great and inscrutable length rederived the "occasionally useful" proposition that $1 + 1 = 2$. In the middle of the century, Bourbaki presented the number 1 as the product of a symbolic calculus far too tedious and complex to write out in full. The code that makes numbers work in recent computer proof systems contains multitudes, often far beneath the surface of programming interfaces that promise numerical deductions will work as expected.

This tradition is highly misleading, in similar ways, for mathematicians and sociologists alike. Most mathematics looks very little like $1 + 1 = 2$, even for elementary learners. The claim that "*even this* can be understood sociologically" or "*even this* can and must be developed from more fundamental logical principles" obscures how unrepresentative *this* is for most mathematical knowledge and practice. (Barany has argued elsewhere, 2014, that in other contexts such a focus on *the very most elementary* reckoning has derived from and contributed to scientific racism.) As a result, sociologies of mathematics have tended to share many of the biases and fixations of foundational philosophies of mathematics, albeit typically from a very different angle.

4 Hard Cases and Soft Targets

Bloor's strong program unsettled and provoked interlocutors and critics from a whole landscape of fields from anthropology and sociology to philosophy and mathematics. Most provocative was the strong program's principle of symmetry, that the same social causes should explain true and false ideas and theories in science (see esp. Bloor 1976). If truth and falsehood were the products of social processes of investigation and consensus-making, not predetermined manifestations of natural reality, there should be no sociological difference between the success of theories now believed true or now believed false: that they were respectively believed in their own times in their own social contexts made them sociologically equivalent.

The motivation for this approach was deeply empiricist, following a scientistic commitment to the process of deriving knowledge from rigorous observation undiluted, to the extent possible, by metaphysical presuppositions. Realist truth claims were, for Bloor, metaphysical distractions from the empirical question of how people came to agree about what they agreed about the natural or mathematical world. Such questions could and should only be answered by the observation and analysis of social facts. These, Bloor joined many sociologists of knowledge in supposing, should be most visible in episodes of controversy where advocates of rival knowledges had to put their reasoning and argument in the open (see, e.g., Ernest 2023).

Bloor's early articulations of the strong program included an extensive revisionist reading of Imre Lakatos's influential heuristic history of Euler's theorem about polyhedra, presented in the posthumous book *Proofs and Refutations* (1976, see Barany 2017; cf. Lakatos 1980). Lakatos's account was a prime example of the indeterminacy and revisability of less elementary mathematics in Bloor's (1976) *Knowledge and Social Imagery* and the centerpiece of a speculative and provocative 1978 article mapping Lakatos's historical examples of mathematical responses to exceptions, counterexamples, and other troubling phenomena to Mary Douglas's anthropology of purity and pollution. For Bloor, Lakatos's classification of responses to his titular refutations corresponded to Douglas's (1978) grid-group scheme for understanding how members of different social groups respond to disruptions to social order based on their degree of hierarchy and their concentration or mobility in or between social groups. This analysis exemplified the strong program's identification of classification as a central and constitutive activity of science, befitting Douglas's anthropological interest in the maintenance of categories as a central facet and manifestation of social order.

An appendix to Bloor's 1978 article took Lakatos's posthumous editors, John Worrall and Elie Zahar, to task for adding explanatory footnotes that toned down what Bloor saw as the more radical relativist implications of Lakatos's analysis. Worrall replied at length in the next issue of the journal, to which another shorter back and forth was appended (Worrall 1979). For Bloor, Lakatos's account showed the interminable revisability of mathematical concepts as well as mathematical proofs. For Worrall, Lakatos demonstrated that revisability was important in mathematics up to a point at which reasoning could be reduced to certain and rigorous

logical deduction. This, to Bloor, exemplified just the sort of response to a troubling phenomenon that had been analyzed with Douglas's scheme in Bloor's article, with Worrall answering a perceived threat to the integrity of logical deduction by reclassifying disagreements about proofs as unthreatening revisions to theorems (Bloor in Worrall 1979, p. 79).

The notion – preposterous to Bloor but dreadfully serious to a number of mathematicians, logicians, and mathematical scientists – that relativist and social constructivist accounts of mathematics were a threat to logic and mathematics itself (or at least to broader support for and trust in these) became a significant component of the so-called Science Wars of the 1990s (see Harris 1999). To a degree, social constructivist challenges to the obviousness or inevitability of extremal elementary mathematics invited the criticism that they were simply (perhaps ignorantly or perhaps malignly) attempting to deny the obvious. Mathematical physicist Alan Sokal gained notoriety by publishing a hoax article in the journal *Social Text*, which he claimed had demonstrated a willingness of cultural critics to endorse any anti-scientific nonsense. Cultural critics, including historians and sociologists of science, took the occasion to historicize and sociologize the animus of Sokal and his supporters, as well as their own disciplines, much as Bloor had done in reply to Worrall (e.g., Scharping 2001).

Bloor's commitment to controversies as stages for displaying the assumptions and stakes of scientific reasoning applied reflexively to his own scholarly practice, which featured exemplary exchanges with theorists who, unlike Worrall or Sokal, shared many of his relativist and constructivist principles and motivations. A 1992 back and forth with ethnomethodologist Mike Lynch in an edited volume dedicated in part to staging methodological debates in the sociology of science drew out the importance of social structure and authority for Bloor's understanding of agreement and closure in mathematics (Lynch 1992; Bloor 1992). The authors revisited a parable from Wittgenstein's *Philosophical Investigations* exploring the indeterminacy of rules of counting. A pupil counts successfully by twos until 1000, then continues the series 1004, 1008, and 1012, and is reprimanded for misunderstanding.

For Bloor, the pupil has shown that an infinite variety of logical rules would have been consistent with the sequence up to 1000, including an infinite number that would have the sequence continue as the pupil did. The correct interpretation was underdetermined and is settled only by an exercise of social authority over the pupil. For Lynch, by contrast, the lesson is that rules are not reducible to their formal logical representations. The pupil has indeed erred, and this shows not that the rule was underdetermined but that there was more to the rule than what Bloor's account supposed. Following a mathematical rule is not just following (or obeying) a logical dictate; it is recognizably conforming to a pattern of observable practice. Bloor returned to the problem of rule-following at several later points, including a rich 2004 debate in *Social Studies of Science* initiated by philosopher Martin Kusch that directly revisited the 1992 arguments (Kusch 2004; Bloor 2004; Kusch opens the exchange with a review of the rule-following problem in the philosophy of mathematics).

A 1999 exchange of journal articles with Bruno Latour, although not so directly concerned with mathematical knowledge, developed another dimension of Bloor's

commitment to social explanation (Bloor 1999a, b; Latour 1999). Latour had famously framed one of his most significant interventions in the sociology of agency and agreement in science as a generalization of Bloor's principle of symmetry. Where Bloor's symmetry principle emphasized the ultimate status of social causes to account for the stabilization of claims about nature, Latour argued that this principle of symmetry must be extended to account for the very opposition between social and natural causes. They thus differed over whether (per Bloor) symmetry was a matter of prioritizing human agency in the adjudication of claims about nature or (per Latour) a necessary next step to account for the constructed opposition of nature and society as part of the formation of scientific knowledge.

The stakes of symmetry weigh especially heavily in strong program interpretations of mathematics. For Worrall, for example, finite logical deductions are precisely the indubitable ground truths that cannot be denied (almost by definition) by any rational person. The formal underpinning of mathematical rigor may appear to be outside the nature-society binary that concerned both Bloor and Latour in their own ways, and little in their debate would seem to contradict this impression. Latour's intervention explicitly invoked the Science Wars context of their disagreement and the difficulty of articulating nature's role (such as it is) in a social theory of scientific knowledge. In Bloor's view, centering social explanation to the exclusion of nature was not to deny nature's relevance to scientific knowledge but to assert that, in the end, responsibility for scientific knowledge was exclusively human.

To insist on human, collective, social responsibility for the ground truths of mathematics was indeed a radical and challenging position. However, as the next section discusses, it was a position very much in keeping with a robust tradition of analysis of the social contexts and implications of mathematics, perhaps too easily missed in readings of strong program sociology outside of its formative intellectual and political contexts. Bloor built on a tradition of social study of mathematics that was based foremost in social critique rather than critique of mathematics as such, and the primacy of social responsibility was accordingly all the more visible.

5 Roots and Radicals

Restivo (1982, 1985 [1983]) identified the formative role for sociologies of mathematics of a train of Marxist interest in the social and material underpinnings of apparently idealist mathematical knowledge. These date to Boris Hessen's famous 1931 intervention as part of the exceptional Soviet delegation to that year's International Congress of the History of Science, in London, transgressively proposing a Marxist analysis of the hosts' national hero Isaac Newton and his *Principia Mathematica*. Varying forms of Marxist philosophy and politics were important commitments for Dirk Struik (e.g., 1942, 1986) and Joseph Needham (e.g., 1956, 1959), among those Restivo identifies as forerunners of the later sociology of mathematics. Restivo also includes in this list Ludwig Wittgenstein, whose later philosophy of mathematics has been argued to have been influenced by his engagement with Marxist thinkers (see Kitching and Pleasants 2002). This was not confined to the First and Second World of the Cold War; we might add Indian Marxist

mathematician and historian Damodar D. Kosambi as a contemporary deeply invested in materialist historiography.

At one level, the significance of Marxism to the social study of mathematics derives from the philosophical commitment to understand the development of ideas and production of knowledge in social, economic, and material terms, as part of the global capitalist system. But, especially for the postwar contributors to the Marxist tradition of social studies of mathematics, the dimensions of societal direction of and social responsibility for mathematics motivated inquiry into how mathematical knowledge responded to social contexts and conditions. Such "social and economic connections" and their relevance to questions of responsibility and the role of mathematics in modern society were central motivations for later work that somewhat critically recognized the influence of Marxist perspectives (e.g., Bos and Mehrtens 1977, pp. 10–12).

Restivo (1985 [1983], see also 1993, 2001) embraced the strong program as a foundation for continued materialist investigation of mathematics. Having engaged in detail with existing Marxist sociology of mathematics that he argued had been insufficiently grounded in materialism, Restivo took sociological inspiration from Spengler (1926) whom he identified as the first sociologist of knowledge to have expressed a strongly constructivist view of mathematics as a human activity inherently defined by its social, cultural, and historical milieu (1985 [1983], p. 86). Restivo recognized the "sociological imperative" to understand mathematics as a social pursuit (1993, p. 249) and responded by laying down an ambitious program for a radical sociology of mathematics "in which all talk about mathematics is social talk." This built upon the Marxist premise that all science is a collective and socially embedded activity and drawing on essential social elements of scientific activity, such as language, other "material," and the scientists' existence within multiple layers of social institutions. Restivo shifted the focus from the individual mathematician to the "math world": a collective representation of the activities and institutions inhabited by mathematicians. Restivo's key argument was that mathematics is not manufactured by individual mathematicians alone but is a product of "math worlds." These "math worlds" are embodied by mathematical objects and are inseparable from the social history of their own construction. Mathematical objects, in turn, are collective representations, sensibilities, and worldviews – and not merely symbols.

This, for Restivo, showed the necessity of "entering math ethnographically" (1993, p. 249). Restivo's later work defends the sociology of mathematics from "misguided" fears of its relativism when in his view it is in fact realist (2001). Restivo brushes aside the "unreasonable effectiveness of mathematics" conundrum as something that in fact demonstrates the realism of his sociology of mathematics: he declares the success of mathematical applications in the "real world" unsurprising, since mathematics is "'borrowed' from the real world to begin with" (1985, pp. 180–181, see also Hamming 1980). Restivo elevates mathematics, along with logics and religion, to the status of a "battleground" (2008) similar in scope to the Copernican revolution, and highlights the challenges math-fueled technological progress can bring if not accompanied by sociological understanding of mathematics as a social act and a complex of social institutions (see also 2016, 2017).

The critical and transformative potential of social accounts of mathematics has been especially visible in mathematics education and in studies motivated by that field. Restivo and Bloor both offer social constructivist foundations for philosopher of mathematics education Paul Ernest's examination of learning, language, and ethics in mathematics (e.g., Ernest 1991, 1994, 1998, 2000, 2018; see also Ernest's chapter in this handbook; cf. Pinxten 1994). Leone Burton (e.g., 1995) outlines a feminist epistemology of mathematics and mathematics education. The visible and large-scale social contexts and consequences of mathematics education, especially primary mathematics education, have motivated social studies of race and marginalization in and beyond mathematics classrooms (e.g., Gutiérrez 2013, 2018; Martin 2019). Sociological critiques have addressed institutional inequalities and injustices based on race, class, and gender, in various settings: elitism in academic journals (e.g., Chang and Fu 2021), racist political regimes (e.g., Mehrtens 1987), Hunsicker and Rittberg's discussion of the social injustices caused by unequal dissemination of mathematical ideas (2022), or the unequal effects of mathematization in different applied contexts (e.g., Ziols and Kirchgasler 2021), to name a few examples.

Critiques of school mathematics and the particular eurocentric model on which many hegemonic curricula have been based have underwritten programs of investigation into other forms of mathematical learning and activity under the rubric of ethnomathematics (e.g., d'Ambrosio 1997, 2000). Emphasizing the diversity, contextual specificity, and mathematical substance of knowledge and practice across different places and by historically underrepresented and underprivileged people, ethnomathematical research has ranged across non-Western cultures as well as examples of activity in Western settings that has not traditionally been understood to be mathematical but can be interpreted from a mathematical perspective (e.g., Lave 1988).

Gellert and Jablonka (2007) approach mathematics sociologically by locating mathematical knowledge in power relations and social inequality. They link and problematize the concurrent trends of mathematization and dematematization in contemporary society and warn of the resulting political "threat to democracy because of a widening gap of mathematical knowledge between constructors and consumers." Williams and Wake (2007), employing a microsociological and ethnographic approach to inform their analysis, similarly find that mathematical knowledge in workplace division of labor is increasingly "black-boxed, with groups of people excluded or insulated from mathematical knowledge and power" (2007). François (2007) argues that ethnomathematics has the potential to play a transformative role in Western school curricula, help undo some of the social stratification perpetuated by existing mathematics education, and demystify the "untouchable and frightening" public perception of mathematics. Drawing on Alan J. Bishop's "M-m distinction," she argues that school curricula reproduce social stratification by restricting vocational pupils' exposure to "small m mathematics" ("a purely deductive science, using a technique-oriented curriculum" and basic competencies such as counting, designing, explaining, locating, measuring), while far fewer pupils have easy access to mathematics (the Western scientific discipline, including ideas of mathematical beauty and creativity).

6 Watching and Listening to Mathematicians

Sociologists of mathematics have long struggled to catch mathematics in the act. Even when one can directly observe people at times and in places where they are doing mathematics, seeing the mathematics being done as such can be vexingly difficult. Mathematical communication combines visible, audible, and other sensory qualities with elements of invisible cognition that can be necessary to make sense of the more observable aspects of such communication. Proxies, inferences, and reconstructions can make up for some of this inaccessibility while bringing their own compromises and challenges.

At one extreme end of the scale of observation, cognitive scientists Lakoff and Núñez (2000) have contributed to materialist understandings of mathematics by correlating specific mathematical concepts and intuitions to features of embodied cognition. Their universalist conclusions about undifferentiated masses of human beings, and their corresponding generalizations about mathematical knowledge, are by design and supposition un-sociological while sharing sociologists' interest in the tangible human production of mathematics and resisting idealist notions of mathematics as entirely separate from the human condition.

Drawing on ethnomethodological approaches to scientific knowledge (e.g., Livingston 1986), Greiffenhagen (sometimes in collaboration with Sharrock) has expanded the scale of observation from that of individual cognition to small settings of interpersonal communication including university classroom lessons and supervisor-student meetings (Greiffenhagen 2014; Greiffenhagen and Sharrock 2011, 2019). Barany and MacKenzie (2014) combined ethnographic observations with interviews to characterize the material production of mathematical knowledge at the scale of small research communities, identifying the situated and dynamic roles of particular forms of writing (on blackboards, scrap paper, and other media) for mobilizing particular kinds of understanding and communication. Kremakova (2016a, b) used ethnography and autoethnography to uncover links between mathematicians' careers, professional identities, and mathematical activities such as teaching, learning, collaboration, proving, publishing, supervising graduate students, and so on, locating these in the context of ongoing marketization of higher education and the precarious scientific labor market.

Methods of institutional sociology permit indirect characterizations of mathematics and mathematicians at larger scales. Early examples can be found in Hagstrom (1965), Fischer (1973), and Startup (2021 [1979]), who investigated the composition of mathematics and other scientific university departments and the social characteristics and working lives of academic mathematicians, reflecting on (and analyzing mathematicians' own reflections of) aspects of mathematical labor and practice along the way. More recently, combining surveys, publication data, and other methods, a large international collaboration to study gender gaps in science has produced large-scale systemic findings about the contemporary mathematics profession (e.g., Mihaljević and Santamaría 2020; Steinfeldt and Mihaljević 2023).

Sociologists of mathematics have also used variations on historical methods, focusing on discursive and contextual analyses of written records to watch

mathematicians indirectly by viewing the records of their written communication with each other. Such studies have ranged in scale from Merz and Knorr Cetina's (1997) examination of the email records of a single collaboration to Rosental's (2008) analysis of usenet discussion posts about a contested theorem in mathematical logic, to Martin and Pease's (2013) study of online mathematics interactions including question and answer forums, and to Steingart's (2012) examination of the paper trail of a large-scale and long-running project in group theory. Written records can, through their references and omissions, show aspects of unwritten practice and indicate how mathematicians rely on combinations of formalized and unformalized reasoning to make sense of concepts and arguments and to establish confidence or articulate its absence whether or not these make sense.

A vital source of knowledge about mathematical knowledge has been mathematicians themselves. In the course of their mathematical practice and careers, mathematicians necessarily develop personal and shared understandings – to varying degrees of explicitness and formality – of relationships between mathematical institutions and mathematical knowledge. Many core activities of mathematical work, from evaluating research proposals and results to assessing peers and students to navigating careers and organizations, all depend on sociological knowledge. Restivo (1993, 248) calls this "[t]he everyday folk sociology of mathematicians." Beyond their personal navigation of their professional worlds, some mathematicians pursue (with varying degrees of rigor and amateurism) social and humanistic studies of their subjects. These can all be significant sources of insight and understanding in the context of social theories and more systematic sociological analyses of mathematics (e.g., Lane et al. 2019) while being susceptible to the biases and limitations of their informants (see Hanna and Larvor 2020). Socially and politically engaged mathematicians have employed sociological theories in support of both theoretical and political arguments against institutional racism and other sources of inequality and discrimination in academic mathematics departments (see, e.g., H[Harron] 2017).

Many academic mathematicians engage in sociologizing their "math worlds" and turn to insights from anthropology, sociology, history, and philosophy of mathematical practice to make sense of the mathematical experience. Mathematicians have produced social commentaries on various aspects of the mathematical existence, work, career, biography, professional identity, teaching, the nature of mathematics, and the way it is done (see, e.g., Hardy 2019 [1940]; Wilder 1981 [1950]; Davis and Hersh 1981; Hersh 1997; De Millo et al. 1979; Thurston 1994; Lockhart 2009 [2002]; Harris 2015). Mathematicians' endogenous sociologies proliferate in global public channels such as blogs and public talks, steering public discussions in the mathematics community and beyond (Terence Tao, Timothy Gowers, Edward Frenkel, Marcus du Sautoy, Günter M. Ziegler, Piper H[Harron], to name a few). These voices, often in dialogue or open disagreement with one another, serve the dual purpose of being an ongoing participatory sociology of mathematics produced by "mathematical natives" in its own right and forming a metacorpus of data for nonmathematician sociologists of mathematics to interrogate and draw upon. These "native sociologies" also provide a key point of tangency for sociologists and

mathematicians at which mutual assumptions, biases, and ignorances become exposed, helping to develop a more realistic mutual understanding of what it is that mathematicians, and sociologists, actually *do*.

Extensive conversations with mathematicians formed the basis for Bettina Heintz's (2000) study of contingency and flexibility in the "inner world of mathematics," which sets mathematicians' perceptions of their principles and practices in the context of sociological theories including those of Bloor and Restivo. Lane et al. (2019) apply Ingold's notion of crafting as wayfaring to analyze mathematical metaphors of landscape, journey, and craft to understand the way in which mathematicians' work is represented and contrast the realities of mathematicians' work with the myth of the lonely genius. In Kremakova's (unpublished) sociology of labor and career patterns of mathematicians, personal experiences and perceptions of career trajectories among mathematicians aggregate into a systemic view of patterns of research and mobility with significant social and intellectual consequences. Kremakova's approach of analyzing what mathematicians do as scientific labor reveals tight links between what happens inside mathematics as a scientific discipline (such as the content of emerging mathematics, the formation of university curricula, or the choice of research questions and methods related to available funding), on the one hand, and the workings of scientific institutions and the conditions of the scientific labor market, on the other. Analyzing the mathematician as his or her own "nomological machine," Kremakova discusses mathematicians as embodied, material, and social beings, working with material (or quasi-material) artifacts and constantly negotiating tensions and conflicts between individual career paths and constraints within mathematical institutions.

Important constraints that define and anchor the mathematical experience in socioeconomic realities include the precarity of early career work and contracts, the need to reconcile personal life and caring responsibilities with the challenges of standardized academic career trajectories tailored to an idealized atomized and disembodied rational agent, and other challenges posed by the "new spirit of academic capitalism" (Kremakova 2016b). Narratives of inspiration and passion prevalent in mathematics, as well as the challenges of quantifying and demonstrating mathematical "outputs," make mathematicians (similarly to other academics) prone to exploitation and self-exploitation as workers embedded in contemporary capitalism. The "technocratic time" of contemporary neoliberal academia allows little room for "playful exploration" and insufficient "thinking time" required to do *new* science, while the current "managerial turn" in universities (characterized, inter alia, with increased reliance on productivity metrics for research assessment) produces strategic responses by mathematicians who, in order to remain successful in their field, are led to turn more into managers and less into artists or adventurous explorers. As a result shorter-term research programs become prioritized, pragmatic publication strategies are adopted, and "safe choices" (e.g., of which open problems to pursue or of which candidates to hire in mathematics jobs) are made. The precarious conditions and increasing internationalization of the job market for early career mathematicians are hard to combine with a viable (gendered) work-life balance and also contribute to the prioritization of short, "doable" research projects – or

even projects that have already been carried out but are as yet unpublished – as mathematicians without stable positions find themselves unable to commit to and carry out ambitious long-term research agendas. The (perceived and real) lack of stability and the pressure to publish fast and move countries for work create insurmountable barriers for mathematicians with caring responsibilities (disproportionately female), disabilities, lower socioeconomic backgrounds, and results in perpetuating multiple social inequalities within the mathematics community.

At the same time, mathematics "in the making" also brings moments of joy and other intense emotions. Mathematicians experience and talk about playfulness, creativity, pure curiosity, intellectual satisfaction, the addictive reward of sudden "a-ha moments" following long periods of hard toil, the skill of making mistakes without embarrassment, the pride in developing your own mastery and seeing your students surpass you, and the joy of collaboration and belonging to a shared community of practice and of values (both in person and across space and time). Mathematics is made up of a wide variety of social roles valued by the community. Mathematicians devise, maintain, and reproduce collective institutions, roles, and myths in service of their own community: examples include the "troll on the bridge" (the head of department who craftily uses university leadership to shield department members from excessive bureaucratic demands), funding councils and journals that legitimize and uphold the importance of various strands of mathematics against the tyranny of fashionable buzzwords, or outreach programs targeting marginalized groups both within research communities (conferences such as "Women in Numbers" and organizations such as the Network of Minorities in Mathematical Sciences) and among the general public.

7 Conclusion: Making and Breaking Order

Sociologies of mathematics aim to comprehend the collective achievement of order and agreement in mathematical knowledge and mathematical institutions. The orderly production of theorems and the orderly production of mathematicians to produce, store, and share them are, in their own ways, distinctive social problems addressed by common social forms in the modern world. Sociologies of mathematics matter because these mathematical orders are never as stable as they seem, and that instability can present risks and opportunities that run through and beyond mathematics as a discipline, subject, and form of knowledge.

We note and anticipate productive scholarship in these directions at the intersections of traditional and new subfields, such as the sociology and anthropology of work and labor, of gender, of social inequality and of education, higher education and academia, feminist sociologies of care and social (re)production, and the sociology of technology and computing.

Institutional understandings of mathematics are especially important in the midst of a long era where the uses of mathematics and the processes of producing that mathematics have each grown more complex and more consequential across greater segments of the social world. Algorithmic and informatic mathematics draws a great

deal of attention in this regard, but even seemingly esoteric, isolated, or pure areas of mathematics participate in a political economy and social arrangement of making, knowing, and sharing mathematics that conditions its higher-profile manifestations. The institutions of mathematics span modern societies and involve many interconnected and hierarchical relationships of knowledge and power with profound implications for what mathematics may do in the world, how, by whom, for whom, and to whom.

It therefore bears emphasizing, to an extent not emphasized in the foregoing analysis, that mathematics in its institutions *and* as a form of knowledge is today (and long has been) in many respects a tremendous locus of inequality and injustice, a resource for the empowered, and a burden for the marginalized. What we have, rather, emphasized in the foregoing is the extent to which concern for the social ramifications of mathematics has motivated and guided investigations into its social and material foundations and the potential for such investigations to revise what is taken for granted about what may and must be in the world of mathematics and from mathematics in the world.

Abstract

Comparing my historical account of the early years of Laurent Schwartz's theory of distributions with number theorist Michael Harris's narrative of the early years of Peter Scholze's perfectoid theory, I develop a perspective on change and temporality in mathematics that emphasizes the relationships between concepts, expectations, and communities of practice. Contemporary mathematics, understood as mathematics imbued with temporality, reflects the dynamic relationship between the people, ideas, pasts, and prospects of mathematical knowledge. Studying these historically may offer critical perspectives on the social and political conditions and implications of mathematical research and the communities that practice it.

1 Prologue (with Apologies to Michael Harris)

I first met number theorist Michael Harris when I was an undergraduate student, by way of a number of essays posted to his website. I had no notion at the time that Harris was a number theorist, but the essays made clear that he was a mathematician who was also a clever writer and an insightful reader of French critical theory, all things I too hoped to be. I was particularly inspired by Harris's (1999) remarks on the Science Wars, a cultural conflict of the 1990s that continued to reverberate in the academic contexts where I aspired to study both mathematics and the cultural theories that perhaps (allegedly, controversially) misunderstood or undermined it.

I first introduced myself to Harris some years later, in 2011, at one of the famous coffee breaks at the Institute for Advanced Study in Princeton, New Jersey. I was, by then, a new graduate student in history of science at the neighboring university, part way toward abandoning my ambition to be a mathematician and somewhat less focused on the particular French cultural theories that most excited me as an undergraduate. I had no notion that at that very moment a veritable revolution was unfolding at the Princetitute, that Harris was among the number-theoretic eminences who were in the process of witnessing the spectacular arrival of the perfectoid.

The perfectoid concept was developed and introduced by Peter Scholze, a German mathematician born in the same year I was. Scholze and I began our respective life courses toward Harris in the latter part of the decade in which the precocious Harris "acquired charisma" as a recognized mathematical leader, ratified with a tenured professorship at age 27 (Harris 2015a, Chap. 2). Still a graduate student at the time of the perfectoid debut, Scholze completed his doctorate by the end of 2011 and attained a full professorship the subsequent year at age 24.

I first learned of Scholze from Harris two years after our fleeting 2011 introduction, during our first proper conversation in Harris's Paris office. I had come to Harris's mathematics institute to work with the institute's renowned historians of modern mathematics on the planned subject of my doctoral research, the theory of distributions. Introduced by French mathematician Laurent Schwartz in the latter half of the 1940s, the theory of distributions was an exciting revision to the foundations of mathematical analysis and partial differential equations, earning Schwartz one of the second ever pair of Fields Medals in 1950.

Nearing the end of my Paris research, I asked Harris for an informal meeting. As luck would have it, Harris had just two days prior read a preprint of my report of my sociological research into the material dimensions of mathematical seminars and research practices, from the year prior to my arrival in Princeton (eventually published as Barany and MacKenzie 2014). We had a lot to talk about. I do not remember how the topic came up, but (as can happen in elite mathematics institutes) the conversation turned at one point to future Fields Medalists. I offered a naive guess, which Harris disabused before sharing with great confidence that, sooner or later, the most exciting young mathematician in the world would surely win the coveted prize. The mathematician, whose work Harris was following with great interest and was seeing his students' generation engaging with infectious zeal, was, of course, Scholze.

I caught up with Harris again at a 2014 conference in London (Larvor 2016), by which time I had some thesis results to share (Barany 2016) and Harris could share intimations of his forthcoming monograph, *Mathematics Without Apologies* (Harris 2015a). I was delighted to be invited the next year to review the book for *Mathematical Reviews* (Barany 2015b), my first book review for the venerable bibliographic enterprise whose history had just recently captured my interest as a significant element of mid-twentieth-century mathematics (see Barany 2021a). This occasioned a renewed email correspondence with Harris, during which he shared a draft of an essay on the perfectoid concept, which he presented as a "test case for an absent theory."

One thing led to another, and I found myself attempting to revise Harris's draft into a joint essay that would combine Harris's perspective on the emergence of the perfectoid concept with a sociological theory taken from my own work and my interpretation of Harris's recent book. The attempted collaboration fizzled, and Harris's chapter ultimately appeared in a version close to what Harris had generously shared initially (Harris 2017a). For me, the abortive collaboration was a tremendously fruitful chance to rethink my own understanding of what it means to debut an exciting new theory. As I continued to develop my account of the dramatic entry of distributions at mid-century, Harris had primed me to notice the striking convergences in the trajectories of distribution theory and perfectoid theory.

With apologies to the mathematician without apologies, I aim to share here an elaborated account of my theory for his test case, based on Harris's (2017a) narrative of perfectoid theory and my own collaborative account of the corresponding period of Schwartz's career (Barany et al. 2017; Barany 2018b). My theory proposes a social-historical perspective on contemporary and unfolding mathematics. I draw from historical theories of the narrative construction of temporality and from sociological theories of the dynamics of confidence and evaluation in mathematical communities. This represents an alternative to the rich and provocative account of the relationship between mathematics and history presented by Blåsjö (2021) in this handbook. The concerns of mathematicians and of critical social historians of mathematics have many significant interfaces, and the perspectives of the latter have much to offer the former.

2 Making a Promising Theory

Laurent Schwartz was born in 1915 into a world divided by a Great War and was brought up in a family of scientists and scholars. He came of age and embarked on advanced mathematical training as his world divided again in the Second World War, excelling in elite settings of French mathematics under mentors connected to some of the most forward-looking and internationally oriented currents of modern mathematical research. As an unestablished researcher in Grenoble, Paris, and Nancy, as the war wound to a close and reconstruction began, he developed the initial ideas that would become his theory of distributions, derived from recent developments in the theory of topological vector spaces.

Schwartz claimed that a radical shift in theoretical perspective could resolve a long-standing foundational concern about the meaning of differential equations involving non-differentiable functions, including functions that had become central in fields such as electrical engineering and quantum physics. He focused initially on potentially intricate technical problems, such as the role of convolution and Fourier duality in his theory, pursued in an intensive French context strongly shaped by the Bourbaki collaboration of pedagogical and foundational radicals. The prestigious 1946 Prix Peccot of the Collège de France gave him a platform in Paris to pursue theoretical questions and build a case and an audience for his theory's significance to modern mathematical analysis.

His theory was based on difficult ideas from recent mathematics, but their implications could be intuited and adopted into mathematical practices in a variety of registers without demanding special expertise in the subjects underpinning Schwartz's arguments. Indeed, for the first half-decade of the theory of distributions, most of the theory's systematic justification and exposition rested in a future textbook that was little more than a promissory note. Most users of the theory could realize its conceptual promise using familiar frames of calculation such as integration by parts, a basic calculus technique whose dramatic reinterpretation in Schwartz's theory demanded very little change to the representational or intuitive dimensions of reckoning about differential equations.

Several influential senior figures of international mathematics encountered Schwartz and his theory in the first years after World War 2, including Norbert Wiener, Marshall Stone, and (most importantly) Harald Bohr. The latter connection was cemented at a 1947 colloquium on harmonic analysis sponsored by the Rockefeller Foundation and Centre National de la Recherche Scientifique as part of an international effort to rebuild outward connections in French science. Bohr was particularly excited by the possibilities he saw in the theory as a bridge between the frontiers of modern pure mathematics and its applications, and he supported Schwartz in promoting the theory on those terms. With Bohr's help, Schwartz attracted a wide international interest between 1947 and 1949, including his first international and transoceanic speaking invitations.

Bohr's final intervention, shortly before his death, was to engineer Schwartz's recognition with a Fields Medal at the 1950 International Congress of Mathematicians, decided by a committee Bohr chaired and was not shy about guiding toward his preferred outcome (Barany 2018a). Sensing that his presentation to the 1950 congress might be his last major appearance on the international stage of mathematics, Bohr presented Schwartz's theory as the future of the discipline. He argued that distributions had already transformed basic calculus through the modernizing march of generalization in a way that he predicted would be central to future mathematics curricula.

Things did not go quite as Bohr predicted, but the promise of distributions made Schwartz a sought-after international visitor and interlocutor and helped him secure a stable platform in France on which to build an influential career that did not ultimately depend on the theoretical fruitfulness of early claims about distributions. Mathematicians on multiple continents believed they could build successful careers by engaging, adapting, and teaching the theory of distributions, and they acted on

that belief to create an efflorescence of expository texts and proposals for the theory's potential uses and implications. The theory did indeed become foundational in some branches of advanced mathematics, but not necessarily in a way that drove future research programs. Building on his recognition, international travels and connections, and scientific credibility, Schwartz became a public leader in mathematical research, science and education policy, and antiwar and human rights activism (see Journoud 2013; Coeuré 2022).

3 History Repeating

Peter Scholze was born in 1987 into a world divided by a Cold War and was brought up in a family of scientists and scholars. He came of age and embarked on advanced mathematical training in a world still geopolitically defined by war and by global (financial) crisis, albeit not of the sort that surrounded Schwartz, excelling in elite settings of German mathematics under conditions that similarly prepared him for an international orientation to widely recognized mathematical challenges. As a student in Bonn, he developed his perfectoid theory based on recent developments in the field of arithmetic geometry.

Like Schwartz, Scholze debuted his theory with a claim that it resolved a decades-old problem, in his case a special case of the weight-monodromy conjecture. That claim, made without a full demonstration at the Institute for Advanced Study in Princeton in 2011, was followed by a visit and series of six lectures to the Princetitute's Paris counterpart, the Institut des Hautes Études Scientifiques. The first public demonstration took place at these lectures at the IHES, a site of historical and symbolic importance for the problems in algebra, geometry, and number theory for which Scholze's approach appeared to offer a refreshing and spectacular breakthrough. In 2012, as Schwartz had in 1946, Scholze received the Prix Peccot the year after first presenting his theory to the public of mathematical elites.

Some things move quicker in the early 2010s than in the late 1940s. News, videos, and notes of Scholze's presentations were rapidly available across much of the world of arithmetic geometry research. Scholze travelled far and wide, published rapidly, and alone and in collaboration demonstrated a striking series of further uses of his theory. His virtuoso performances of proof and exposition convinced eager audiences, primed to spot the pitfalls of algebraic intuition and ready to be inspired by their circumvention in the resolution of previously stubborn constructions and deductions. As Harris puts it, the cascade of theoretical applications, together with the way the perfectoid concept made sense of relevant antecedent theories, made it clear that this was *the right* (Harris's emphasis) concept to bring together timely combinations of concepts and research agendas from arithmetic geometry. A professorship and associated institutional responsibilities accrued to Scholze much more swiftly than they had for Schwartz.

There were more prizes to win, and Scholze won quite a few of them. He declined one such prize for which Harris had nominated him, for reasons that he did not publicize but about which Harris sympathetically speculated (Harris 2015b; see also Harris 2014). (It will be significant below that the declined prize was called New

Horizons.) He did not win a Fields Medal right away, an effect of a major shift in the medal's criteria and perception since 1966 (Barany 2015a). Under the pre-1966 criteria, Scholze would have been unlikely to win at all. His University of Bonn professorial forebear Friedrich Hirzebruch was disqualified from the 1958 medal for having risen too fast in the discipline and consequently being too well recognized to qualify under the prevailing older criteria despite his young age (Barany 2018a).

In Harris's telling, Scholze rapidly nucleated a generation shift in his field, supplying new terms, representations, styles, and methods to young researchers who saw his difficult theory as a promising highway toward the vanguard of contemporary research. Graduate students organized study groups to dissect the flood of materials coming from a burgeoning research community. Harris's account recalls the exhilarating sense of motion from supervising a Masters thesis on perfectoid theory begun shortly after Scholze's IHES lectures. By following the theory as it spread and developed in those frenetic months, the student not only rapidly outpaced Harris's own sense of competence in the field in which Scholze intervened but could chase the theory as far as new results that were unimagined even to Scholze and his collaborators at the time Harris's student had started the project. It was hard to keep up, a difficulty it seems older generations felt more acutely, but those who managed to keep pace with the community of perfectoid researchers were quickly and thrillingly rewarded with access to a fast-moving forefront of mathematical theory.

Berkeley's Mathematical Sciences Research Institute hosted a staggeringly well-attended 2014 "Hot Topics" meeting on perfectoid spaces that brought together senior figures who saw their work carried forward in perfectoid research with younger researchers keen to see where the theory could take them. By then, Harris was aware of competent and confident users of perfectoid theory who had not personally closely collaborated with Scholze. This milestone for the reproduction and sustainability of a perfectoid research community corresponded to developments in Scholze's own research trajectory toward *next* concepts and challenges that would go beyond probing the limits of his 2011 formulation.

I spotted Scholze in the queue to enter the opening ceremony of the 2018 International Congress of Mathematicians in Rio de Janeiro. He was conspicuously one of only a very few, especially among the younger attendees, to be wearing something approaching formal attire, as though prepared to be in the spotlight. His was among the least surprising Fields Medal awards in history. It was evident in Scholze's plenary address later in the Congress that the perfectoid concept as such had become just a part of a multifaceted theoretical framework and research program.

4 Time for Mathematics

Setting Schwartz next to Scholze prepares us to analyze the history of *contemporary mathematics.* By contemporary, I mean mathematics as it is being produced, shared, interrogated, and evaluated. It is mathematics understood to be "now," whenever "now" is. "Now" is a moving target, and its mathematics is therefore always

precariously poised between particular pasts and futures, which can alike be mobilized in contemporary mathematical practices. It is thus essential to understand such mathematics as being contemporary in another sense, not just *together in time* (the usual meaning of contemporary) but *imbued with time.* Contemporary mathematics is mathematics pulsing with temporality.

There are two basic ways for mathematics to be *in time*: static or dynamic. Static mathematics exists on a fixed timeline, with ideas and arguments and events each having their place on a linear continuum stretching from past to present to future. The core questions of static mathematics are ontological and epistemological: what things are, what they mean, what they signify or imply, how they relate to each other logically or conceptually or genealogically. These relations can be fixed to identifiable durations: prime numbers in the seventeenth century, epsilon and delta arguments in the 1860s, homotopy type theory pondered over breakfast last week. They can exist outside of duration: the eternal congruences of triangles, the principle of induction, the propositions on page 214 of a textbook. The stuff of static mathematics is separately defined by when it is, where it is, what it means, and so on.

Dynamic mathematics, by contrast, exists at the always-shifting join of specific pasts and futures. There is not a single timeline of dynamic mathematics, because for each person in each place at each moment there may be a different constellation of experiences, understandings, and expectations that shape what mathematical concepts and practices mean (cf. Barany 2017). In the formulation of conceptual historian Reinhart Koselleck (1985), historical time is not a fixed backdrop of human events but a constantly recreated condition generated by the interface of ever-changing experience and ever-retreating horizons of expectation. Rather than what a concept signifies, a dynamic analysis asks (with a subtle but crucial shift in perspective) what its significance is, how it brings together and makes relevant particular experiences and understandings of what the concept relates to, where it comes from, and what it suggests, inspires, or disrupts. The stuff of dynamic mathematics is always on the move, always reconfiguring a multiplicity of pasts and futures (cf. Epple 2011).

Static and dynamic perspectives give two distinct ways to explain the parallel successes of perfectoid and distribution theory. They draw attention to different facets of what matters in the foregoing narratives, with correspondingly different implications for the historical understanding of mathematical practice (cf. Barany 2020). While both kinds of accounts are retrospective, I claim that the retrospection of a static past misrepresents essential features of the contemporary development, adoption, and dispersion of new mathematical ideas identified through a dynamic conception of this history.

Historical and contemporary mathematicians, however, often frame their own conceptions of their past and present in static terms. Customs of narration and of genealogical and conceptual accounting in mathematics can directly obscure the dynamism and instability that is not just intrinsic to contemporary mathematics in the making but is necessary to explain how such mathematics moves and transforms. That is, dynamic practices produce the conditions for the epistemic closure of mathematical understanding in static terms.

5 Temporalities in Counterpoint

In homage to a narrative device from Harris (2015a), let us consider a series of oppositions posed by a fictional Number Theorist (NT) and Mathematics Historian (MH), categorically not suggested to represent the biographical number theorist and mathematics historian from this chapter's prologue. Specifically, the biographical number theorist Michael Harris deliberately avoided making the kinds of claims in his perfectoid narrative that I shall here attribute to the figure of NT, and he in fact often appears (to my reading at least) to take a perspective closer to MH where he does theorize elsewhere. The number theorist will venture static explanations of the early histories of perfectoid and distribution theory, based on a commonsense view of the sociology of mathematics articulated for optimal contrast with the ensuing counterpoint, not on an empirically grounded summary of views of any particular number theorist(s). On the importance of such commonsense endogenous sociologies among mathematicians to the ordinary practice of mathematics, see my chapter with Kremakova (forthcoming) in this handbook. The mathematics historian will then reframe NT's static explanations in dynamic terms so that we may consider their different implications for the histories in question.

Our first counterpoint concerns the relationship between mathematical concepts and mathematical communities.

NT: Communities of mathematicians develop mathematical concepts and theories.
MH: Mathematicians use concepts and theories to organize into communities.

Mathematical concepts and theories are, from either perspective, fundamentally communal, developed through exchange, contestation, interpretation, and other communicative activities. For concepts and theories in their infancy, the relationship between communities and concepts runs importantly in both directions: communities change concepts, but concepts are critical loci and resources for changing communities in turn. Concepts and theories can be exciting, inspirational, even *hot,* and these evaluations and designations matter because they transform the communities that engage those concepts and theories. I have in fact elsewhere suggested that, from a social-historical perspective, theories may be *defined* in such terms, as "social systems built around relationships of partial mutual understanding," such that the "theory of distributions" can be defined as a "social system built around relationships of partial mutual understanding of distributions" (Barany 2018b, p. 264). (The significance of the "partial mutual understanding" aspect is a major theme in the rest of this section.) The early formulations of perfectoid spaces, distributional derivatives, and other elements of Schwartz's and Scholze's theories were most historically significant, for reasons we shall explore, for how they could be used to nucleate and expand rapidly growing and highly variegated communities of interested mathematicians with the social, material, technical, and theoretical capacities and motivations to promote the respective theories in a variety of capacities.

This reorientation of the relationship between communities and concepts changes how to interpret the role of those whose names become famous alongside

their theories. Both Schwartz and Scholze gained forms of celebrity status with their theories, and their celebrity drew from *and contributed to* the success of their theoretical interventions. Major awards and prizes, likewise, responded to, reshaped, and advanced the mathematicians' theoretical agendas as well as their careers and public images.

NT: Awards and career milestones follow from, and recognize, important results.
MH: Awards and career milestones certify and reinforce the importance of existing results, making them more important for more people, thereby promoting further results and certifications of importance.

The celebrity faces of distribution and perfectoid theory had to convince people in positions to recognize their theories' potential significance, and both succeeded in doing so from early stages in their research and careers. Not only did they convince those with more social and epistemic authority in the discipline of their theories' potential, they were both strikingly successful in establishing that they were the best people to bring their theories to wider and wider mathematics communities. Generous, charismatic, persuasive, and credible, Schwartz and Scholze became recognizable as mathematical celebrities because they were easily legible as potential celebrities.

Prestigious lecture invitations, their respective Prix Peccot and later Fields Medals, and other accolades signaled that these were mathematicians not only worth watching but worth joining. Particularly with Scholze, not just awarded but anticipated recognitions added fuel to the blaze. Conversations like my early one with Harris, speculating about major prizes and future distinctions, lent excitement and momentum, a sense of a theory going somewhere. Both theories and both mathematicians began to receive formal recognitions well in advance of having definitively and widely established the results that would come to be seen as the most significant indications of their importance, and well before there could be said to be a stable consensus about what their interventions really meant for their areas of mathematics. Both mathematicians used the occasions of their honors and associated opportunities to develop their research conversations, introduce further ideas, and project toward the future directions and implications of work in progress.

I have documented how Bohr's enthusiastic and arguably mostly exaggerated impressions of the joint potential of Schwartz and distribution theory motivated Bohr to engineer invitations and recognitions to help that potential be realized (Barany 2017). The Fields Medal and Bohr's highly visible characterization of Schwartz and distributions at the 1950 International Congress of Mathematicians, in particular, decisively set a celebrity trajectory that helped Schwartz establish what I suggest is the first mathematical theory from a previously unrecognized mathematician to establish an interconnected and multi-continental research community in its first decade (Barany 2018b). Schwartz charted a path and benefited from nascent institutions that Scholze could traverse and benefit from on a much faster timescale half a century later, helping mathematicians the world over to identify their often-challenging interventions as worth knowing and pursuing.

Public fanfare combined with information infrastructures (preprints, travel, rumor mills, letters, seminars) to build research communities at a pace that far exceeded that of the kind of individual interpersonal interaction that is the usual focus of accounts of collaboration and sense-making in mathematics. To take off or break through requires a conviction of going somewhere. Prizes and careers are simultaneously indications and engines of *going somewhere*, enabling the crucial shifts in perception and scale for theories and names to become big.

NT: Inspiring leaders of mathematical research communities assume positions of influence and prestige that reflect the leadership they offer.
MH: Potential leaders exercise influence and accrue prestige by assuming and representing the roles and expectations of leadership.

The personal and prospective natures of celebrity and leadership in mathematics mean that the visible, recognizable, attributable identities of mathematicians shape their theories and their disciplinary communities. One cannot lead if nobody is there to follow, if whoever is there does not expect one at least potentially to lead. Credibility and leadership are self-reinforcing. Leaders who successfully occupy, justify, and satisfy the optimistic expectations others have of their leadership gain more opportunities and expectations to do the same. Those who do not start with such optimism or who do not fit templates or roles for expectations of leadership, conversely, can do many of the things that would otherwise be associated with innovation and leadership without provoking the loop of expectation and recognition that defines the meteoric careers of others (Rossiter 1993).

From early stages in their careers, both Schwartz and Scholze converted smaller platforms into larger platforms by stepping into and satisfying escalating expectations of mathematical charisma and leadership. Harris (2015a, p. 143) perhaps even understates the case when observing that by age 24 Scholze had become "one of the youngest elder statesmen ever" in his branch of mathematics. As articulate young men, comfortable traveling and confident in settings of academic demonstration and socialization, they launched their careers from a presumption of belonging and potential (see Barany 2021b). Their leadership asked of them qualities and actions they were prepared to exhibit. Both were inarguably exceptional communicators, theorists, and much else, but their success was critically conditioned on, in many other respects, being visibly unexceptional in elite mathematical communities.

Expectations of celebrity and leadership make a big difference to the trajectories of the careers and theories of celebrity leaders, but they also quite profoundly overstate the difference that those celebrity leaders personally make. Like Bohr before him (but thankfully without the same sense of mortal urgency), Harris and a number of comparably positioned established mathematicians followed their somewhat circumstantial encounters with perfectoid theory at its earliest comings-out with later personal and professional activities and commitments to embrace and support the theory and its leading proposer and spokesperson. These established figures, like Bohr and Bohr's generational correspondents, attended lectures, spoke in private and wrote in public, connected students and colleagues, nominated for

prizes, and otherwise treated perfectoid and distribution theory, and Scholze and Schwartz, as theories and people of which and whom to take note.

In public and in private, Harris has expressed quite strongly that he was marginal to the early trajectory and success of the theory and mathematician he found so exciting. He makes a repeated point in his essay (Harris 2017a) and elsewhere (e.g., Harris undated) to disclaim any deep understanding or expertise in perfectoid theory, emphasizing that he has watched and appreciated the rise of perfectoid theory to a significant extent as an outsider. Without wishing to suggest an equivalence in their respective historical roles relative to their theories of interest, I quite suspect Bohr would have felt something similar. Bohr, for his part, was never a recognized mathematical contributor to the theory of distributions as such and was perceived by Schwartz as a somewhat peripheral (though valued) early supporter. Though their roles and situations have many important differences, I think Harris and Bohr each challenge us to reconsider what role such (sometimes self-consciously) theoretically marginal disciplinary elites have in the pivotal formative stages of a fast-rising theory or career.

Bohr's more-than-circumstantial centrality to the history of distributions was a somewhat surprising finding for my collaborators and me based on detailed archival research across many countries and languages (Barany et al. 2017). Without having done the same investigation of perfectoid theory, it is clear enough to me that there are significant differences in precisely how mathematicians in positions of established authority encouraged the latter theory's success. To the extent the comparison is informative here, Harris should be understood as an avatar for the subset of mathematicians who, in parallel to Bohr, recognized and encouraged Scholze's early theory from positions of established professional authority while being peripheral to the core perfectoid research community. In particular, within that community Harris did not appear to play the most Bohr-like role, which might instead be speculatively assigned to Harris's collaborator, the highly decorated number theorist Richard Taylor (an impression Harris has shared with me in more recent correspondence). It was Taylor, for example, who as Distinguished Visiting Professor at the Institute for Advanced Study in 2011 facilitated Scholze's spectacular IAS perfectoid debut. To what extent and to whom further comparisons may apply is a question that may await and surprise future historians.

NT: Mathematical theories and concepts start with those who best understand them and take hold as more people come to understand them better. Informal and imprecise understandings help motivate and support mathematicians' acquisition of more rigorous understandings.

MH: Mathematical theories and concepts are always simultaneously understood in a variety of ways, and those with middling understanding can be crucial for the theory's early success. Informal understandings, even arguable misunderstandings, often quite adequately replace apparently rigorous understandings, and can be more effective than normatively rigorous accounts at producing and promoting meaningful mathematical knowledge.

The experience of core users and active researchers of a concept and theory only begins to explain its significance and success. Theories and concepts and associated careers necessarily depend on convincing non-experts at different degrees' remove from the active research community. These non-experts must act on partial, provisional, approximate, or proxy understandings to form their evaluations and shape their advocacy.

The unmistakable lesson of the histories of perfectoid and distribution theory is that these non-expert understandings work for the social and intellectual purposes they serve. Among other purposes, such understandings supply a means of organizing and evaluating mathematicians' labor, histories, and values, and these uses are not in general reducible to the technical details that supply the concepts' notional content. It takes an extraordinary amount of work to understand the ideas and methods that have come to be associated with perfectoid spaces and still more work to adopt those ideas and methods in one's own research. One need not, however, be a perfectoid researcher to be a perfectoid advocate, mentor, sponsor, and (in some settings at least) expositor. Nor need one be a perfectoid expert to appreciate the kinds and extent of difficulty it takes to become such an expert and to support and reward it accordingly.

Some distance from the active research community can in fact better position an advocate for the social and intellectual roles they play in a theory's success. That distance demands and poises mediating elites to find terms and perspectives that bridge the central ideas and insights of a theory to those who are not (yet or ever) active researchers or experts but who may become experts, interact with them, celebrate or support them, or otherwise be in positions of finding meaning and value in the theory. A small remove from the day-to-day difficulties and frustrations of research with a theory also usefully obscures a sense of its shortcomings, a general phenomenon in the sociology of technical systems that Donald MacKenzie (e.g., 1990, pp. 370–372) has called the certainty trough. Those with the most confidence in a technical system, whether a mathematical research program or a nuclear missile guidance device, are not those with the most or the least expertise. Rather, they tend to be those who know enough to appreciate and be excited by such systems without knowing enough to mitigate that optimistic picture with the quotidian grind of subtle limitations and promises not yet fulfilled.

Even closer to the beating thrum of active research, the multiplicity of meanings matters. Mathematical concepts and theories are always polysemic, always understood in a variety of ways by people attempting to comprehend, use, teach, apply, and reimagine them for mathematical and other purposes. Indeed, many mathematical environments, technologies, and practices appear to be maintained specifically for the purpose of mobilizing unstable and polysemic representations (Barany and MacKenzie 2014). This gives a sociological explanation for the importance of multiple forms and modalities of communication for theories in the making, including venues for localizing and particularizing activities and habits of "reading down" mathematics as a converse to the formalizing work of "writing up" statements and conclusions in stable and circulable forms. I have argued (Barany 2018b) that the proliferation of sometimes mutually conflicting theoretical understandings of the

theory of distributions in different research contexts and communities was necessary for its rapid intercontinental trajectory. No one mathematician, Schwartz (or Scholze) included, is ever the comprehensive and exclusive master of everything that makes their theories meaningful, suggestive, useful, valid, or otherwise meritorious. The imagined future uses of a theory, the features that are most important for its adoption and adaptation in growing communities of research and practice, are perhaps most susceptible to and dependent on the constitutive polysemy of dynamic mathematics.

NT: A theory's antecedents culminate in a new theory, and that culmination is evidence of the theory's promising future. Together, the antecedents and expected future explain (or at least support) its successful adoption. Citations acknowledge the dependence of new mathematics on the past.

MH: A theory's antecedents and futures are negotiated (and continually renegotiated) as part of the theory's formation and successful adoption, supporting and shaping what the theory means to those developing and embracing it. Citations identify instrumental pasts that situate new mathematics for the future.

In Harris's and Bohr's respective accountings, there is a striking resemblance in the extent to which Scholze and Schwartz established the promise of their theoretical interventions by successfully mobilizing relevant and suggestive pasts for their theories. In both stories, the most significant antecedents emerge and become canonical as part of processes of explaining and developing a new theory. This frequently happens, and did happen for both of these theories, in dialogue and with the active participation of experts and practitioners in the traditions and theories that become adopted as canonical forerunners and underpinnings of the new theory. While these can be understood in the moment as processes of *recognizing* and *appreciating* those relevant pasts, in a vital dynamic sense, the pasts are re-narrated and created as part of the stories and trajectories of the theories for which they become crucial justifications and resources. The pasts link theories to communities of users, suggest conceptual and social affinities, and promise theoretical futures in the form of projections along a train of development. They show current and potential users and appreciators that the theory is (in Harris's term) *the right* one for them, for their goals, values, and interests. Thus canonized, antecedents establish that the theory brings together the pasts that matter to its audiences and shows them a viable way forward.

For Schwartz, and amplified in Bohr's telling, the most significant pasts and antecedents for the theory of distributions could be quite indirectly related to the genealogical configuration of theories and problems from which the theory of distributions first emerged. The theory's early meanings and audiences were thus created in significant part by the addition of temporal and conceptual antecedents that made the new theory meaningful to early interlocutors. In particular, Schwartz grafted distributions onto a conceptual and temporal trajectory of symbolic calculi reaching back through the Dirac calculus of formal derivatives in mathematical

physics to the Heaviside calculus in electrical engineering. In this framing, distributions were a culmination of a half-century of symbolic reckoning that motivated the utility and possibility of generalizing the process of differentiation to discontinuous or otherwise non-differentiable functions. Bohr, for his part, enrolled Schwartz in an even longer history of generalization and conceptual closure that included the development and algebraic stabilization of number systems.

These arrangements of pasts for distributions and their associated implicit (and sometimes, especially for Bohr, explicit) futures directly shaped early audiences for distributions and their understandings of the theory. In France, Denmark, and Canada, Schwartz met with crucial early audiences who proved willing to recognize distributions as an ideal solution to a foundational problem about the use of partial differential equations at the interface of pure and applied mathematics. Important advocates following Bohr, such as George Temple in England, domesticated the early framing of the theory as part of a progression of symbolic calculi associated with English theorists. Temple presented his version of Schwartz's theory as an import that reconnected the essential insights and essential utility of distributions to a local tradition of analysis and practical generalization.

The communal and programmatic orientation of the work of establishing canonical antecedents to new theories can be seen in the historical uses of abstracting, bibliography, and citation in modern and recent mathematics (Barany 2021a), as well as in mathematicians' historiographical practice (Paumier and Aubin 2016). Schwartz actively used reviews and citations to establish conceptual and programmatic relationships between his distribution-theoretic work and other bodies of research that may or may not otherwise have had much of anything to do with distributions. The history of citing and acknowledging prior work and of using those citations in ongoing work is thick with the ongoing labor of establishing research communities, reconciling understandings, and demonstrating significance by drawing the past through present projects toward a promising future.

When Scholze introduced perfectoid spaces, he could call upon the skills, techniques, terminologies, and intuitions of the fields at whose crossroads he situated his concept. He could expect researchers in those fields to be prepared to take notice of his intervention, if only he could interest them. These fields gave Scholze a ready means of establishing his work's significance and calling attention to his concept, by providing both a vocabulary for asserting relevance and a stable of open problems that could prove his concept's worth. Importantly, Scholze's early interlocutors saw themselves in the antecedents brought to bear on perfectoid theory and wrote the history of their own work, priorities, and engagements into the methodological and conceptual trajectories Scholze proposed.

By situating perfectoid spaces both genealogically and analogically in Grothendieck's algebraic geometry and Fontaine's constructions, Scholze supplied a ready basis for affirming their optimality (by analogy to affine and general schemes) and their fruitfulness (by extension of the fruitful genealogy of a tradition in arithmetic geometry). This promise of fruitful applications, based on successfully framing perfectoid spaces as the conceptually appropriate and most practically promising concept for a number of programs of research, helped Scholze recruit

(both directly and indirectly) a community of researchers who would begin to fulfill that promise and thereby reinforce the validity of the initial assessments. Despite the difficulty of perfectoid reckoning, its novelty meant that an enthusiastic young researcher could hope to study up to a meaningful research competency after a relatively short period of intensive study. With the goal of perfectoid geometry in view, such a student could take a short cut (if not a royal road) through only those aspects of the theory's background as seemed most relevant to a desired line of inquiry. Thus, Harris's Masters student could race in the space of a short project from ignorance of the theory almost directly into the community of perfectoid researchers.

Mathematics is, as Harris (2015a) put it, a problematic vocation. That is (in part), mathematics is organized around posing and solving problems (see Barany 2015b). Since fields of study are effectively defined by the programs of active research within them, by frameworks for articulating workable problems and meaningful solutions, the growing programmatic orientation of mathematical researchers toward perfectoid spaces as a unifying concept had the effect of embedding perfectoid geometry as a fundamental framework for a growing body of scholars. Above all, this reflected the self-fulfilling character of being *right*, worthwhile, or fruitful. Scholze's concept had to appear *right* long before its promise for arithmetic geometry began to be realized in great measure and in a wider community of scholars. He set this realization in motion by situating perfectoid spaces in a technical and communal framework that assured his audience of the ability to follow and appreciate his maneuvers and supplied a ready-made basis for establishing their significance. Casting backward to Hodge through Fontaine, Tate, and Grothendieck made it possible to cast forward to a perfectoid-theoretical future.

6 History and Contemporary Mathematics

I continue to treasure my sporadic exchanges with Harris, who continues to offer a distinctive and invaluable perspective on the contemporary discipline of mathematics. He was one of the first to see a draft of this essay. A recent theme of our conversations on which Harris has also had much to say in public[1] is the political economy of mathematical scholarship and its implications for the social and political responsibilities of mathematicians. Harris is a member of the Azat Miftakhov committee, a group modeled on Schwartz's Committee of Mathematicians to challenge human rights abuses and political imprisonment of mathematicians in our own time, focusing on Miftakhov's political imprisonment (ongoing as of this writing) in Russia. Scholze participated in the group's 2021 conference to raise awareness and show solidarity following Miftakhov's sentencing, an effort to convert some mathematical celebrity into political consciousness.

Harris has made a point of drawing attention to historical analyses, including some of my own, out of a conviction that mathematicians stand to benefit from

[1] See esp. Chap. 3 of Harris (2015a). See also Harris (2017b) and Harris and Jackson (2014).

awareness of the fruits of scholarly research on the social and political history of their field. Part of his exercise of professional and social responsibility is to use his standing as a mathematician and his profile as a cultural critic of mathematics to promote research that helps mathematicians critically interrogate their present and consider the implications of possible futures for the discipline. This kind of engagement and its political and intellectual motivations have a long tradition (see Barany and Kremakova forthcoming).

They are not, however, what Viktor Blåsjö (2021) refers to in this handbook with "Mathematicians used to be highly invested in the study of the history of their own field." Examining the purposes and uses of history "from the mathematician's point of view," Blåsjö advocates for the mathematical value of what he calls "critical internalist" histories of mathematics as a creative fount of mathematical understanding. Blåsjö sees a virtue in mathematicians' endeavor to use the values and methods of conceptual mathematical thinking to make sense of historical mathematics as a form of research experience, one that might build intuition or perspective on the conceptual dimensions of mathematics as a field.

I have suggested here that there are ways of thinking about the power of mathematical ideas that are good for producing mathematical ideas but bad for understanding mathematical communities and the different sorts of power that runs through them. In contrast to Blåsjö's critical internalist historiography, I think this is where a critical social historiography can and should speak to mathematics and mathematicians. An understanding of the inauguration and development of mathematical theories that focuses on static conceptual relations will necessarily miss the most significant dimensions of mathematical creativity and community. These dimensions, of a necessarily dynamic temporality, challenge familiar distinctions between internalist and externalist historiography. Community dynamics have tremendous conceptual consequences, and vice versa. Is hope internal? Is excitement? Is credibility? Is conviction?

From the perspective of the history of contemporary mathematics, of mathematics emphatically temporally in the making, theories and concepts must be understood as both products and tools of social organization, based on the temporalized production and mobilization of relevant pasts and promising horizons. Truth alone does not make a theory successful or even correct (at least in the broader sense I associate with Harris's invocation of being *right*) and is only a small part of its context. Insightfulness, significance, and value are negotiated in communities of practice.

These, in turn, give purchase on the critical potential and importance of the political economies and social contexts of contemporary research. A dynamic temporality of mathematics trains attention on the facets of mathematical knowledge work where privilege and inequality relate to the central features of mathematics as a system of knowledge and practice, and vice versa. Critical social histories can obscure or rationalize as well as identify or challenge the communal-conceptual dynamics of mathematical practice – we might signal the ambivalence of sociohistorical analyses by reference to the indecision of history narrated in the *past imperfectoid*, with apologies to Tony Judt's (1992) critical history of the political rationalizations and recriminations of Schwartz's generation. Critical potential is no

guarantee of critical purchase, but it is at least a way of interrupting the critical vacuity of static mathematical conceptions of mathematical change.

In his 1543 arithmetic primer, a long distant forerunner to the kind of arithmetic that made Scholze famous, Robert Recorde exhorted that "rules without practice, is but a light knowledge, and practice it is, that maketh men perfect and prompt in all things" (quoted and discussed in Barany 2023). The study of static mathematical rules without dynamic mathematical practice is indeed but a light knowledge. There is, rather, much to be gained from a historiography of contemporary mathematics in the sense sketched here, one in which practice makes not just perfect but also perfectoid.

Abstract

In the mathematics education research literature, there is a growing body of scholarship on how mathematicians practice their craft. The purpose of this chapter is to survey some of this literature and explain how it can contribute to the philosophy of mathematical practice. We first describe how mathematics educators use empirical methodologies to investigate the behaviors of mathematicians and argue that findings from these studies can inform the philosophy of mathematical practice. We then illustrate this by summarizing research on mathematicians' understandings and mathematicians' proof reading.

Keywords

Mathematics education · Philosophy of mathematical practice · Proof · Proof-reading · Understanding

1 Introduction: The Relationship Between Mathematical Practice and Mathematics Education

Many mathematics educators believe that mathematicians' practices can and should inform the way that mathematics is taught to students. For this reason, mathematics educators regard empirical research into the psychology and sociology of professional mathematics as a legitimate topic for mathematics education research. In the last two decades, a number of research reports on mathematicians' practices have appeared in highly prestigious journals, on topics as diverse as the genre of writing in mathematics journals (Burton and Morgan 2000), how mathematicians choose research questions (Misfeldt and Johansen 2015), and whether mathematicians skim proofs before reading them closely (Inglis and Alcock 2013; Weber and Mejía-Ramos 2013). The purpose of this chapter is to survey some of the educational research on mathematical practice and to describe how this research can inform the wider literature on the philosophy of mathematical practice (from hereon, PMP).

1.1 Authentic Mathematical Activity in the Mathematics Classroom

A central reason that mathematics educators are interested in mathematical practice is because many believe that mathematics classroom communities should behave similarly to professional mathematical communities and that students should be engaged in activities that are reflective of professional mathematicians' activities.

The calls for classrooms to be reflective of disciplinary practices date back to Bruner (1960) who claimed that there should be "a continuity between what a scholar does on the forefront and what a child does in approaching it for the first time" (pp. 27–28) and Schwab (1978), who argued for a school curriculum "in which there is, from the start, a representation of the discipline" (p. 269). Applying this general theme to the specific subject of mathematics, Lampert (1992) wrote that "classroom discourse in authentic mathematics has to bounce back and forth between being authentic (that is, meaningful and important) to the immediate participants and being authentic in its reflection of a wider mathematical culture" (p. 310). In concert with Lampert, Schoenfeld (1992), Sfard (1998), and Rasmussen, Zandieh, Teppo, and King (2005) all argued that having students engage in authentic mathematical activity is a central goal of mathematics education.

Satisfying the calls from the previous paragraph requires an understanding of what it is that mathematicians do at the forefront of their discipline and what it would mean for a classroom community to be authentic in its reflection of mathematical practice. Following Stylianides et al. (in press), the situation can be framed as follows. Professional mathematicians engage in goal-directed activities. That is, mathematicians have goals (e.g., deciding whether a conjecture is true) and they engage in activities with the aim of satisfying those goals (e.g., seeing if the conjecture holds for particular examples or trying to prove the conjecture) (There can be a nested structure to mathematicians' goal-directed activities. For instance, they may engage in the activity of proving with the goals of demonstrating that a statement is true and understanding why it is true. But successfully engaging in proving (i.e., writing a proof) can thereby become a meaningful subgoal. They may then engage in the activity of reading the research literature to find techniques that will allow them to achieve their goal of writing a proof.). Mathematics classroom communities also engage in goal-directed activities. Activities can be said to satisfy Lampert's criterion of being "authentic in its reflection of a wider mathematical culture" if mathematicians have similar goals and engage in the same types of activities to attain them. Activities can be said to satisfy Lampert's criterion of being "authentic. . . to the immediate participants" if the students can perceive how these activities are enabling them to achieve these goals.

1.2 Mathematics Educators' Need for Understanding Mathematical Practice

If mathematics educators are to successfully engage students in authentic mathematical practice, they need to have an accurate understanding of what professional mathematical activity is. Our preceding description of authentic mathematical activity suggests three specific questions about mathematical practice that are of interest to mathematics educators:

- *What are mathematicians' activities and why do they engage in these activities?* For instance, it seems clear that mathematicians frequently read proofs.

Mathematics educators desire that students read proofs for the same reasons that mathematicians do (e.g., Hanna and Barbeau 2008). Why do mathematicians read proofs?

- *What are mathematicians' goals and how can mathematics educators decide when a goal is achieved?* For instance, it is widely accepted that a goal of mathematics education is to prepare students to solve mathematical problems and prove mathematical theorems in a way that would pass muster to a mathematician. How can a mathematics educator decide if a student has successfully resolved a problem or proven a theorem?
- *How, at the level of cognitive mechanism, do mathematicians engage in their goal-directed activities?* If we want students to successfully engage in a goal-directed activity, then we need to teach them how they should do so, which in turn requires mathematics educators to have a model of competent performance with regard to that activity. Mathematics educators frequently study mathematicians' behavior to build that model of competent performance (e.g., Schoenfeld 1985).

In short, it behooves mathematics educators to have an accurate understanding of what mathematicians do, why they do it, and how they do it. Accordingly, many mathematics educators conduct empirical studies addressing these questions.

2 The Relationship Between PMP and Mathematics Education Research on Mathematical Practice

2.1 The Different Ways That Claims About Mathematical Practice Are Used in PMP and Mathematics Education

There is an important commonality between how mathematics educators and philosophers of mathematical practice investigate mathematical practice. Both groups of scholars use empirical data to make descriptive claims as a basis for drawing implications. However, the *types of implications* each group draws are different. The implications that mathematics educators draw ultimately aim to be practical – tools for teachers and researchers to analyze student performance, and inform instruction. The implications that philosophers draw naturally pertain to philosophical matters, often concerning the epistemological and ontological status of mathematical claims. Because mathematics educators and philosophers aim to make different claims, they will seek out and value different empirical data about mathematical practice.

To mathematics education researchers, findings about mathematical practice are useful to the extent that they can inform the practical work of the teacher or researcher. This often leads to a desire for *precision* in how mathematicians' behavior in their practice is modeled. Consider, for instance, Polya's (1945) *How to solve it*. Mathematics educators want students to be able to solve challenging nonroutine problems; in the past, they have attempted to teach students the four-step problem solving process and the heuristics contained in Polya's volume. However, teaching students from Polya was not sufficient to improve students' problem-

solving performance. Schoenfeld's (1985) diagnosis was that the heuristics that Polya described were too *vague* to be useful for students. For instance, Schoenfeld considered a specific heuristic: To better understand an unfamiliar problem, exemplify the problem by considering various special cases. But identifying what serves as a suitable special case is a complex skill that depends on context. What example serves as a special case in one context may be unsuitable to another. Without being able to articulate the complex subskill of identifying a suitable special case, simply telling students to consider a special case, or illustrating how it is done for a particular problem, is not sufficient to help students solve problems. Some philosophers may find a description of the fine-grained cognitive processes needed to identify special cases to be psychological minutia that is not of philosophical interest, but this articulation is important for mathematics educators.

In the search for practicality, mathematics educators may also downplay issues that are of philosophical importance if they do not have implications for teaching or research. For instance, Dubinsky (2000) approved of Beth and Piaget's (1966) declaration that the status of platonism is an unreasonable question for the psychologist or the educator, as is the issue of whether mathematical ideas are perceived in a platonic realm or constructed by the learner as the resolution to these questions will not impact how a teacher helps students learn mathematics: "If we decide to adopt a Platonist point of view, then we still must determine the mechanism by which an individual gains access to the mathematical ideas that exist in some ideal world, and if we are thinking in constructivist terms, we still must work out the mechanisms by which the individual comes to construct these ideas" (Dubinsky 2000, p. 215). We do not present this passage to imply that Dubinsky speaks for all mathematics educators when he declared that the status of platonism is not important to mathematics education research (For instance, some mathematics educators, such as Paul Ernest (1985), explicitly call for rejecting platonism on the grounds that this philosophy will lead to problematic teaching practices.). Rather, we are illustrating how many mathematics educators can be indifferent to philosophical concerns if these concerns do not have practical implications for mathematics education research and teaching.

2.2 How Mathematics Education Research on Mathematical Practice Can Contribute to PMP

Even though mathematics educators and philosophers have different agendas, we nonetheless argue that mathematics education research on mathematical practice can contribute to PMP for three reasons. First, mathematics education research can corroborate or challenge claims about mathematical practice that philosophers have made. Second, mathematics educators' claims about mathematical practice can constrain philosophical accounts of mathematical practice. Third, surprising results from mathematics education studies about mathematical practice can give philosophers interesting puzzles to explain. We elaborate on each point further below.

Philosophers of mathematics often assert claims about how mathematicians think and behave and then use these claims to warrant philosophical conclusions. For instance, Fallis (1996) claimed that computer-assisted proofs are universally accepted by all mathematicians as unproblematic bona fide proofs; he used this claim to argue that proofs do not need to be a priori or transparent to gain mathematical acceptance and as part of an argument for why mathematicians should accept exotic proofs that use DNA evidence. In contrast, Rota (1997) averred that mathematicians are generally skeptical of computer-assisted proofs (proofs of the four-color theorem in particular), viewing such proofs as error-prone and not definitive. Rota used this observation as a basis for claiming that mathematicians find some proofs (or convincing verifications, if the mathematicians deny that computer-assisted proofs are proofs) to be inadequate. Aberdein (2009) believed that the mathematics community is split on the status of computer-assisted proofs. He cited a computer-assisted proof as an instance of proof*, accepted as a proof by some mathematicians but rejected by others. Aberdein used the existence of proof*s to highlight the role that argumentation that extends beyond pure deduction plays in mathematics discourse.

Whether mathematicians *ought* to accept computer-assisted proofs and the theoretical import of the publication of the proof of the four-color theorem are legitimate philosophical issues. However, the *actual* stance adopted by mathematicians about the status of computer-assisted proofs is an empirical question and therefore should be addressed by empirical research. Further, this empirical question has philosophical consequences. If Fallis, Rota, or Aberdein were found to be wrong about their beliefs about the status of computer-assisted proofs, the argumentative support for their philosophical positions would be undermined. The difficulty with describing an empirical question about mathematical practice is that there is rarely a single piece of evidence that definitively answers the question, especially when the claims are general in nature – that is, the claims do not concern the views of a single mathematician or the development of a particular mathematical concept, but rather pertain to the collective viewpoint of the mathematical community or general trends about how mathematical concepts develop. As Löwe and Van Kerkhove (2019) emphasized, philosophers of mathematical practice should seek *triangulation* to buttress their empirical claims about mathematical practice. Different types of evidence should be sought to support the same empirical claim.

The value that mathematics education research can provide to PMP is that mathematics educators tend to collect different data to support their claims. Philosophers often warrant their claims about mathematical practice with naturally occurring preexisting data, such as proofs that appear in journals, private correspondence between mathematicians, and memoirs and reflections from famous mathematicians. These data have the strength of mathematical authenticity; they come from real mathematicians engaging in real mathematical activity. However, these data can be limited in terms of generalizability. In contrast, if mathematics educators are interested in a particular issue, they will often create laboratory settings with multiple mathematicians in which data are *elicited* that bear on the specific phenomenon. To avoid misinterpretation, we are not claiming that mathematics educators' methods

for investigating mathematical practice are *better* than the methods employed by philosophers. To the contrary, our methods too have significant limitations, especially with regard to our data's authenticity to mathematical practice. We advance the more modest argument that our methods can complement philosophers' methods by addressing limitations inherent in philosophers' methods (and vice versa).

As an example of how findings from mathematics education research bear on mathematical practice, Weber and Czocher (2019) conducted a survey in which 94 mathematicians were shown a computer-assisted proof that had been published in the *American Mathematical Monthly* and were asked a series of questions about it, including whether they would judge the proof to be valid. The key findings were that 39% of the participants said the argument was a proof (61% said it was not), but 90% of the participants believed that at least 10% of mathematicians would disagree with their judgment. Further, 75% of participants felt their judgment of the proof's validity would depend on context, and 85% of the participants felt that the computer-assisted proof would qualify as a proof in at least some contexts. These findings thus support Aberdein's (2009) assertion that computer-assisted proofs are regarded as controversial within the mathematics community. These results also reveal that *some* mathematicians are suspicious of computer-assisted proofs and are thus consistent with Rota's claims, although the data neither corroborate nor refute Rota's claim that mathematicians never regard a computer-assisted proof as being definitive. These results challenge Fallis's (1996) claim that there is a consensus among mathematicians that computer-assisted proofs are not problematic.

A second way in which mathematics education research on mathematical practice can contribute to PMP is by offering a constraint on the accounts that philosophers provide. For instance, Weber and Czocher's (2019) results show that mathematicians' acceptance of a proof depends upon context and they will not agree on the acceptability of some proofs (We should be careful not to overstate our case about mathematicians' disagreement. Weber and Czocher also found that nearly all mathematicians accepted proofs using routine techniques from number theory and claimed their acceptance was independent of context. It may be the case that mathematicians only disagree on the correctness of a small subset of the proofs that they encounter.). Any philosophical account of how proofs guarantee the truth of assertions for mathematicians should account for the fact that the acceptability of some proofs depends on context and any account of how proofs may foster consensus on which theorems are true should account for the fact that mathematicians may disagree on the acceptability of some proofs. Finally, mathematics educators sometimes unearth surprising results about mathematical practice that are in need of philosophical explanation. The finding that mathematicians *disagree* on their judgments, including on the acceptability of inferences within a proof, has occurred often in studies on mathematical practice (see Hanna and Larvor 2020, for a survey of some of this research). It is an interesting question about how the mathematical community reaches consensus on the status of most theorems yet they disagree on the status of some types of inference (Or at least the common *perception* among mathematicians is that such a consensus exists. That itself is a perception worth verifying empirically.).

In the next two sections, we will summarize mathematics education research on what it means for mathematicians to understand a concept and on how mathematicians read mathematical proof. For each topic, we discuss how the results that mathematics educators have found might inform PMP.

3 Research on Mathematicians' Understanding

3.1 The Importance of Mathematical Understanding

There is universal agreement among mathematics educators that students should not just learn procedures. Students should also develop an *understanding* of the concepts that they are studying. Unfortunately, mathematics educators have struggled to define precisely what it means to understand a mathematical concept (see Hiebert 2013, for a review of some of this literature). Indicative of this struggle is the plethora of articles claiming that what mathematics educators lack is an understanding of understanding (Davis (1992), Goldenberg (1995), Michener (1978), and Nickerson (1985) have each written articles where the wordplay "understanding understanding" has appeared in the title, and Thompson (2013) dedicated a book chapter to the "meaning of meaning" in mathematics education.

The difficulty is especially pronounced when it comes to understanding the types of abstract concepts that occur at the university level. For instance, what does it mean for a student or mathematician to understand a group, a limit, a complex function, or a topological space? With respect to abstract algebra in particular, mathematics education researchers have proposed very different models of instruction where the differences are due, at least in part, to very different ideas about what it means to understand algebraic concepts (Burn 1996; Dubinsky et al. 1994, 1997; Larsen 2004, 2013). In summary, there is an undesirable state of affairs in mathematics education research: Teaching for understanding is accepted as a primary goal in mathematics instruction, but it is not clear what understanding is or how it should be measured, especially with the abstract mathematics taught at the university level.

Mathematical understanding is also important for PMP. For many mathematicians, their primary reason for engaging in mathematics is to understand mathematics better (e.g., Gowers 2000; Thurston 1994). As the mathematician and statistician David Blackwell once said, "I'm not interested in doing research and I never have been. I'm interested in understanding, which is quite a different thing" (as cited in Albers and Alexanderson 1985, p. 19). Because understanding is a primary motive for many mathematicians, it would seem that any adequate philosophical account on the growth of mathematical knowledge would need some account of what mathematical understanding is. Yet, perhaps surprisingly, there are few accounts in PMP of what constitutes mathematical understanding (We say "surprisingly" because there is an emerging literature in the philosophy of science on what comprises scientific understanding (e.g., Grimm, Baumberger, and Ammon 2016), but the literature on mathematical understanding is comparatively sparse (but see, e.g., Avigad 2008, in

press; Delarivière and Van Kerkhove in press; Folina 2018; Inglis and Mejía Ramos in press).)

Some mathematics education researchers have conducted empirical studies with mathematicians to provide a better account of what it means to understand advanced mathematics and how mathematical understanding develops. In this section, we review some of this literature. We then discuss some potential implications of this research for PMP.

3.2 Open-Ended Interviews with Mathematicians About Their Understanding of Abstract Concepts

Sfard (1994) and Sinclair and Tabaghi (2010) each conducted *open-ended semi-structured interviews* (Hammer and Wildavsky 1993) with mathematicians about what it means for them to understand a concept. In an open-ended interview, a small number of mathematicians meet individually with a mathematics education researcher, who asks them a series of questions about a particular phenomenon of interest. The individual mathematician's responses is typically recorded in some way, transcribed, and subjected to analysis. The "open-ended" modifier signals that at least some of the questions are designed to elicit open-ended responses that allow for the mathematician to elaborate on her viewpoints. The "semi-structured" modifier means that the interviewer has the right to use her professional judgment to ask unplanned follow-up questions, for purposes such as clarification or elaboration. The way that mathematics educators use data obtained from semi-structured interviews is in some ways similar to the ways that philosophers use the memoirs and reflections of famous mathematicians (e.g., Hardy 1940). In both cases, researchers are using mathematicians' accounts of their mathematical beliefs and activities to provide models of mathematical practice. There are several advantages that semi-structured interviews have over relying on the reflections of famous mathematicians. Because the interviewer chooses the question and steers the discussion, the interviewer can target a phenomenon of interest, rather than hoping that a mathematician will happen to write about it. Because the interviewer can ask for clarification and elaboration, this will reduce ambiguity in the mathematicians' comments about the targeted phenomenon, although ambiguity can never be eliminated entirely. Interviewing multiple mathematicians allows the researcher to compare and contrast their responses, which offers a richer and more textured perspective on the phenomenon in question (The memoirs of famous mathematicians have advantages over semi-structured interviews. For instance, these memoirs represent the most mature reflection rather than the commentary from mathematicians who are put on the spot. As always, our point is not that the data that mathematics educators typically rely on is *better* than the data that philosophers are more familiar with. Rather, it is that the data have different strengths and weaknesses.).

Sfard (1994) reported a study based on extended (3+ h each) semi-structured interviews with three mathematicians about what it meant to understand abstract mathematics. Sfard analyzed her data using Lakoff's (1987) linguistic theory based

on the premise that our understandings are based on metaphors which can ultimately be traced down to our physically embodied experience. Sfard reported data illustrating the following claims. First, the mathematicians she interviewed claimed they understood a concept only if they could view the concept metaphorically. For instance, one mathematician said, "To understand a concept, I must create an appropriate metaphor. A personification. Or a spatial metaphor. A metaphor of structure. Only then can I answer questions, solve problems" (p. 48). Second, mathematicians provided different types of metaphors, including personification metaphors where the mathematical concept is viewed as taking up physical space, performing actions, and/or having a personality. Indeed, the mathematicians claimed that they would become intimately familiar with these concepts, and this familiarity was critical for reasoning about them. Third, mathematicians' visual representations of concepts were vague frameworks for reasoning and action, rather than a concrete instantiation of the concept itself.

Sinclair and Tabaghi (2010) conducted open-ended semi-structured interviews with six mathematicians about their understanding of eigenvectors. In their analysis, the authors used a theoretical frame in which they distinguished between conceptual mathematics (CM) and ideational mathematics (IM) (as introduced by Sinclair and Schiralli 2003). CM are public representations of mathematical ideas that exist in public space and have shared meanings in the mathematical community; IM are the personal representations that individuals use to represent mathematical ideas to themselves.

Sinclair and Tabaghi's key findings were that when their participants were asked to describe eigenvectors, all used metaphors involving motion. Although the formal CM definition of the eigenvector of a matrix involved equality (i.e., $Ax = \lambda x$), participants were inclined to say that a matrix A acted on an eigenvector x by transforming it in a manner that stretched or shrank x. For instance, one mathematician described eigenvectors as follows:

> I think of a matrix I think of applying a vector to, no applying a matrix [lifts left hand] to the vector [moves left hand toward right hand and then back again] and then what you get out is another vector [moves his right hand, bended fingers], that is in the same direction but either stretched [clenches his hands and extends his arms] or shrunk [brings his clenched hands and extended arms together], but you also have to be aware of like [moves both hands up and down in an alternate fashion] flip direction [hands moving toward each other and index fingers pointed to each other] or it could just sent to zero [moves left index finger down] and that will still count as an eigenvector (p. 229).

Sinclair and Tabaghi (2010) emphasized two things from this excerpt and others (Sinclair and Tabaghi (2010) included photographs of this participant (and other participants) illustrating their gestures that we do not include here for the sake of brevity.). First, the mathematicians' descriptions of eigenvectors had a *temporal* quality that was not captured by static equality. The mathematicians treated a matrix as a transformation that you "apply" to a vector and you compare what you "get out" with the original vector. Second, in all their descriptions, participants used gesturing to illustrate their ideas, particularly how vectors were being transformed, which

suggested to Sinclair and Tabaghi that these mathematicians were using enactive metaphors based on their embodied cognition.

Sinclair and Tabaghi also observed that individual mathematician's understanding of metaphors was idiosyncratic and involved personal metaphors, such as thinking of eigenvectors in stretching or shrinking a rubber band, the motions of hands on a distorted clock, or stressors acting on a plate. Finally, participants sometimes used diagrams to describe their understanding of eigenvectors. When diagrams were introduced, the participants associated motion with the diagrams that they often represented using gestures (e.g., using a sweeping motion of the hands to describe a mapping represented in a diagram).

In another study, Soto-Johnson et al. (2016) asked five mathematicians to describe what representations or explanations might be useful to understand the continuity of complex valued functions (Soto-Johnson et al. (2016) also asked their participants to determine whether two specific complex functions, $f(x) = Re(z)/|z|$ and $g(z) = zRe(z)/|z|$, could be extended to $z = 0$ in a way that would preserve their continuity. The latter task is known as a task-based interview, which we will say more about in the next subsection.). Like Sinclair and Tabaghi (2010), Soto-Johnson et al. (2016) used Sinclair and Schiralli's (2003) constructs of conceptual and ideational mathematics (CM and IM) to analyze participants' responses. Soto-Johnson et al.'s findings were consistent with Sfard's (1994) and Sinclair and Tabaghi (2010) in that all participants used IM comprised of idiosyncratic personalized metaphors for understanding the continuity of complex functions. Soto-Johnson et al. further observed that the metaphors that participants used were often based on their previous embodied experiences in nonmathematical contexts. For instance, one mathematician who hiked as a hobby used the hiking metaphor of falling off a cliff to describe function discontinuities.

3.3 Task-Based Interviews on How Mathematicians Develop an Understanding of Advanced Mathematics

We now consider the issue of how mathematicians may develop their understanding of an advanced mathematical context. In both popular culture and mathematicians' memoirs, some mathematicians describe their process of coming to understand a piece of mathematics as comprised of small increments of local understanding followed by sudden jumps. The mathematician Andrew Wiles offered the following metaphor to explain his experience doing mathematics:

> Perhaps I could best describe my experience of doing mathematics in terms of entering a dark mansion. One goes into the first room, and it's dark, completely dark. One stumbles around bumping into the furniture, and gradually, you learn where each piece of furniture is, and finally, after six months or so, you find the light switch. You turn it on, and suddenly, it's all illuminated. You can see exactly where you were. (Andrew Wiles, as quoted by NOVA 1997)

Later, Wiles offered some elucidation on what it might mean to stumble around in a dark mansion:

> I sometimes might scribble. I do doodles. I start trying to find patterns, really, so I'm doing calculations which try to explain some little piece of mathematics, and I'm trying to fit it in with some previous broad conceptual understanding of some branch of mathematics. (Andrew Wiles, as quoted by NOVA 1997)

Poincaré also described a flash of mathematical insight as emerging after a series of more modest connections were formed:

> A host of ideas kept surging in my head; I could almost feel them jostling one another, until two of them coalesced, so to speak, to form a stable combination. When morning came, I had established the existence of one class of Fuchsian functions. . . I then only had to verify the results, which took only a few hours. (Poincaré 1952, 52–53)

For the purposes of mathematics education, we view these quotes as descriptive rather than prescriptive. While they provide important insights into how Wiles and Poincaré do mathematics, they are not specific enough to guide instruction. To gain more precision, mathematics educators sometimes conduct *semi-structured task-based interviews* (Clement 2000; Goldin 2000; Mejía-Ramos and Weber 2020). In these interviews, a modest number of mathematicians meet individually with a researcher who asks them to think aloud as they complete predetermined tasks that are meant to approximate mathematical practice. The benefits of task-based interviews are that they offer a more fine-grained account of how mathematicians complete tasks than can be gained from interviewing mathematicians or reading their reflections.

To "understand how mathematicians make sense of ideas that are unfamiliar to them" (p. 22), Wilkerson-Jerde and Wilensky (2011) conducted task-based interviews in which ten mathematicians were observed reading a paper from geometric topology about "links." The paper was outside of the participants' areas of research so they would be learning the topic for the first time. However, the paper was accessible to nonexperts. This task was meant to approximate how mathematicians might learn a new mathematical topic in their professional practice.

As Wilkerson-Jerde and Wilensky's participants read the paper, they continually engaged in two metaprocesses. In the first metaprocess, which the authors labeled as deconstruction, the mathematicians sought to understand how individual ideas fit together. In the second metaprocess, which the authors labeled as coordination, the mathematicians would fit ideas together in a coherent framework which they can use to predict mathematical relationships that they had not yet considered. In both cases, mathematicians engaged in a cycle in which they asked questions, answered their questions, and provided explanations. For instance, when the mathematicians encountered a new definition, they may ask how it applies to a particular example with which they were familiar or they may form a hypothesis about the meaning of an idea in the definition. After answering their question, they may offer a more high-level explanation about what the definition means.

Wilkerson-Jerde and Wilensky's (2011) findings are useful to mathematics educators because they offer potential prescriptive accounts of how abstract mathematics can be learned. Their work offers the hypothesis that mathematicians' understanding is based on a rich set of connections of basic ideas in a mathematical theory that are developed by mathematicians constantly questioning the meaning of certain terms and how they relate to other ideas and examples. Students can, in fact, be trained to ask similar questions when they are reading mathematical text. When students are trained to do so, their comprehension of the text improves dramatically (Alcock et al. 2015; Hodds et al. 2014).

3.4 Discussion of Mathematics Education Research on Mathematicians' Understanding and Its Implications for PMP

In this subsection, we offer several cross-cutting findings about professional mathematicians' understanding of abstract mathematics. Before doing so, we offer the following caution. Each of the studies cited above was *exploratory studies* that were used for *hypothesis generation*. These studies were exploratory in the sense that the researchers were not conducting the studies to test the viability of any prespecified theoretical claim. Rather, the researchers' aim was to put mathematicians in situations that would elicit interesting data about a phenomenon of interest from which the researchers could construct plausible models of mathematical practice that would be consistent with their data. Consequently, the findings presented here should be viewed as tentative hypotheses that are empirically grounded in the data that were collected rather than definitive claims about mathematical practice.

A first finding is that mathematicians viewed dynamic metaphors as essential to their understanding. The primary salience of dynamic metaphors in mathematicians' reports on their understanding would seem to us to put a demand on any philosophical account of mathematical understanding. A viable account should either explicate the role that dynamic metaphors play in understanding or at least explain why mathematicians hold the belief that dynamic metaphors are important for understanding.

A second finding is that mathematicians' metaphors are idiosyncratic and based on individual mathematician's personalized experience. If we view "mathematical understanding" of a concept to consist of mathematicians' productive ways of thinking about that concept that successfully guide their work, then there is no single mathematical understanding. Alternatively, if we claim that there is a specific way of thinking about a concept that constitutes true understanding, that account would need to explain why mathematicians so often deviate from that understanding in their own idiosyncratic ways.

Finally, as Sinclair and Schiralli (2003) argued, the metaphors used by mathematicians to create concepts are distinct from the metaphors that contemporary mathematicians use to understand the concepts. For instance, surely the concept of the continuity of complex functions was not created with hiking in mind, but this is how

one mathematician understood continuity. Lakoff and Núñez (2000) offered a theory by which all mathematical concepts can be traced via metaphor to our embodied cognition in our physical world. Even if Lakoff and Núñez have offered a viable theory about where mathematics comes from, this should not be mistaken for a theory of how mathematics is understood or what mathematics is today.

4 Mathematics Education Research on Mathematicians' Proof Reading

4.1 The Importance of Proof Reading

As with conceptual understanding, the issue of proof reading is of both educational and philosophical importance. In university mathematics courses, proofs are common both in lectures (e.g., Mills 2014) and in textbooks (e.g., Raman 2004). Indeed, much of students' time in university mathematics courses is spent studying proof. Unfortunately, there is evidence that students do not understand much of what they read. Numerous studies have found that university mathematics students with substantial training in proof are unable to distinguish between valid and invalid arguments (e.g., Alcock and Weber 2005; Inglis and Alcock 2012; Ko and Knuth 2013; Selden and Selden 2003; Weber 2010). Understanding a proof should extend beyond checking a proof for correctness. For instance, a proof may be used to provide explanation or illustrate a new mathematical method. However, there is also evidence that students do not recognize these broader purposes of proof (e.g., Healy and Hoyles 2000; Weber and Mejía-Ramos 2014). When students observe a proof in their lectures, they may miss the broader points that the professor is trying to convey (Cowen 1991; Lew et al. 2016). Improving students' ability to read proofs can increase their understanding of mathematics, especially in the proof-oriented courses taught at the university level.

The ways in which mathematicians read proofs have philosophical consequence as well. Proof is a primary means by which mathematicians persuade each other about the veracity of theorems and, more generally, how they communicate mathematical knowledge to one another. Philosophers sometimes cite mathematicians' practices with proof to account for the fact that mathematics is reliable and objective and that mathematicians generally agree on what statements are true and what theorems are established (e.g., Azzouni 1994; Berry 2016). To understand the role proof can play in these regards, it is important not only to know what proof is but how the mathematical community reads these proofs.

4.2 Hypothesis Generation Versus Hypothesis Testing

In the previous section, we claimed that the mathematics education research on concept understanding has involved exploratory studies focused on hypothesis generation. Here we describe an alternative approach to conducting empirical

research which involves *hypothesis testing* (Inglis and Aberdein 2020). Researchers who study mathematical practice often form hypotheses about how mathematicians behave. These hypotheses are often generated from the types of exploratory studies described in the previous section, but they sometimes emerge from other sources as well, such as the researcher's informal conversations with mathematicians or reflections on her own experience doing mathematics. As a concrete example that we will discuss in this section, a researcher may hypothesize that mathematicians will find arguments more persuasive if they come from an authoritative source. To test the viability of her hypothesis, the researcher uses deductive reasoning to form an observational prediction that she would expect to see if her hypothesis is true. For instance, in our hypotheses on the role of authoritative sources, a researcher might predict that mathematicians would evaluate a specific argument as more persuasive if they knew that the argument came from a famous mathematician than if they were not aware of who wrote the argument. The researcher then conducts an empirical study to determine if her observational prediction occurs. If the prediction is realized, this is strong support for the researcher's hypothesis, especially if the prediction is surprising or is inconsistent with what other popular competing hypotheses would predict. If the prediction is not observed, this casts doubt upon the hypothesis. While hypotheses testing studies often do not offer conclusive proof that a hypothesis about mathematical practice is true or false, they can offer much stronger empirical support for or against hypotheses than can be obtained by exploratory studies (Hypothesis generation studies allow the researcher a greater number of degrees of freedom to interpret their data than hypothesis testing studies. For further discussion, see Lindsay et al. (2016).) In general, hypothesis testing studies are uncommon in both PMP and mathematics education, but they have been used regularly in mathematics education research on mathematicians' proof reading.

4.3 Competent Performance in Proof Validation

Mathematics education research into university students' reading of mathematics began in earnest with Selden and Selden's (2003) study on whether students could reliably distinguish between correct proofs and invalid arguments. In their paper, they presented eight students with four purported proofs of the claim, "If n^2 is divisible by 3, then n is divisible by 3." One argument contained the inference that because $3x = nn$, then 3 divides n. Selden and Selden declared the argument was invalid because this inference contained a gap that could not be filled. However, on their first reading of the proof, only one of the eight students judged this ostensibly invalid proof to be incorrect (although students' performance improved due to the interviewer asking the students questions that prompted reflection).

Weber (2008) and Inglis and Alcock (2012) investigated the reasoning processes that mathematicians used to determine if a proof was valid. In both studies, one of the items that the mathematicians considered was the aforementioned argument from the Selden and Selden study. All eight of the mathematicians participating in Weber's study noted that the gap identified by Selden and Selden could be bridged with the

theorem, "if a prime p divides ab, then p divides a or p divides b." All were hesitant with their judgments about the validity of the proof and only five of the eight mathematicians judged the argument to be invalid. Similarly, only 7 of the 12 mathematicians in Inglis and Alcock's study judged the argument to be invalid. Based on this finding, the authors of these studies hypothesized that mathematicians may disagree about the validity of a proof when it contains large gaps.

To test this hypothesis, Inglis, Mejía-Ramos, Alcock, and Weber (2013) presented 109 mathematicians with an argument justifying why the antiderivative of x^{-1} was ln x (This proof was similar to another proof in Inglis and Alcock's (2012) study where mathematicians disagreed about the validity of the proof.) The last line of the proof commuted the limit and integral in an algebraic expression without justification for why such a step was permissible. This gap in the proof could be bridged – the commutation of the limit and integral was with respect to a uniformly continuous function – but the proof contained no indication that there was a gap in the proof at all. The participants were told that this proof was submitted to be published in the *Mathematical Gazette* and were asked if the argument was a proof. Inglis et al. predicted that mathematicians would disagree on the validity of this proof.

Inglis et al.'s (2013) prediction was confirmed: 27% of their participants judged the argument to be a valid proof and 73% disagreed. Participants were asked what percentage of mathematicians would agree with their evaluation. The average response was 75%. Among mathematicians who thought the proof was valid, this average was 65%. For those who thought the proof was invalid, the average was 78%. Hence, while participants collectively believed that the majority of mathematicians would agree with their judgment, they were generally aware that a substantial portion of the mathematical community would disagree with them. Finally, Inglis et al. wanted to rule out that the possibility that the disagreement was merely the result of a performance error – that is, that those who declared the proof to be valid simply overlooked what was problematic in the last line of the proof. To address this, participants were told that another mathematician had said the proof was invalid since one cannot assume that the integral and limit commute without considering the type of convergence involved. Participants were asked if this critique was enough to render the proof invalid. Only one participant who judged the proof to be valid agreed with this, suggesting that the judgment of validity was not simply a matter of oversight.

The results from this study suggest that mathematicians do not always agree on whether an argument constitutes a proof. These findings offer a challenge to philosophical theories that are based on the premise that mathematicians agree on what constitutes a proof. For instance, Azzouni (2004) claimed that "mathematicians are so good at agreeing with one another whether some proof convincingly establishes a theorem" (p. 84) and used this claim to support the conclusion that the correctness of a proof can be checked by a mechanical process, and Berry (2016) argued that the norm that published proofs are readily available provides mathematical practice with the virtues of autonomy (i.e., an individual mathematician can verify the truth of any theorem herself) and consensus (i.e., mathematicians agree on what are or are not theorems). Berry's argument relies on his claim that "any mathematician can

(without much effort) find his or her own explicit reasons for believing any Publically Accepted Claim . . . journals rightly believe the results they publish are Reliable and *expect the arguments for them to be found convincing by all*" (p. 117, italics are our emphasis). The aforementioned findings about mathematicians' disagreement do not disprove Azzouni's or Berry's conclusions; however, they do challenge their premises. Mathematicians do not *always* agree on whether a proof convincingly establishes a theorem. It may be the case that they agree *often enough* with respect to the published literature, but justifying such a premise requires further argumentation.

Our results place constraints on philosophical accounts of how proof can work in mathematical practice. For instance, philosophical accounts that posit that mathematicians use similar processes for checking a proof would need to account for the fact that mathematicians sometimes reach different conclusions on the proof status of some arguments and, further, are aware that mathematicians would disagree with their judgments.

4.4 How Do Mathematicians Check Proofs for Correctness?

Earlier in the section, we noted that there are many studies in mathematics education that document how university students cannot distinguish between correct proofs and invalid arguments (e.g., Ko and Knuth 2013; Selden and Selden 2003). These studies identify a mathematics education research problem in need of remediation: how can we help students learn how to check proofs for correctness? To address this issue, mathematics educators need to know how students should be reading proofs to assess their correctness. Some mathematics educators have studied how mathematicians read proofs to delineate the processes needed to read proofs competently.

Weber and Alcock (2005) argued that checking a proof for correctness involves a process that they called "inferring warrants." To illustrate, consider the statement, "Since 7 is prime, 1007 is prime." Weber and Alcock observed that when mathematicians checked the correctness of this statement, they did not consider whether 1007 is a prime number. Rather, they rejected the inference as invalid because it appeared to be based upon the general principle that adding 1,000 to a prime number produced a prime number and this general principle is false. Of course, the general principle was not explicitly stated in the statement that the mathematicians considered; mathematicians inferred the person making this assertion must have had this general principle in mind. Weber and Alcock then hypothesized that when mathematicians read a new statement of the proof, checking its validity sometimes involves identifying previous statements in a proof and a general inferential scheme from which the new statement can be derived.

To test Weber and Alcock's (2005) hypothesis, Inglis and Alcock (2012) conducted a task-based eye-tracking experiment, which recorded those parts of the text that 12 mathematicians and 18 university mathematics students fixated upon as they checked the validity of 12 purported proofs. Inglis and Alcock identified particular inferences in a proof that required inferring a warrant. For instance, one proof began as follows:

1. Suppose there are finitely many primes of the form $4k + 1$.
2. Then these primes can be listed $p_1, p_2, p_3, \ldots, p_n$.
3. Define a number a as follows: $a = p_1 p_2 p_3 \ldots p_n + 4$.

Inglis and Alcock judged line 2 as requiring an implicit warrant – namely that finite lists can be enumerated in a bounded list (i.e., we would not ordinarily be able to assert that any arbitrary class of integers could be enumerated as a list of n elements). In contrast, Inglis and Alcock said that line 3 did not require a warrant as stipulating the meaning of a could always be done, regardless of how the previous variables in the proof have been defined. Based on their assumption that inferring warrants for line x would involve looking at line x, then line x-1, then line x again, Inglis and Alcock predicted that mathematicians would be more likely to show an $x \rightarrow x\text{-}1 \rightarrow x$ eye-movement pattern than students when line x required inferring a warrant compared to when it did not. This prediction was borne out. Especially interesting was the fifth line in the proof described above: "Every number that leaves remainder 1 when divided by 4 is divisible by a prime that also leaves remainder 1 when divided by 4." This statement is simply false (9 is a counterexample) and all 12 mathematicians believed the falsity of the statement was sufficient to render the proof invalid. (In contrast, only 10 of the 18 students judged the proof to be invalid, once again highlighting students' limited ability to identify errors in proofs). The mathematicians in the study spent a great deal of time oscillating their attention between lines 4 or 5 in this proof, apparently searching in vain for an implicit warrant to justify this false statement. Students, in contrast, rarely moved their attention back and forth between lines 4 and 5. The main implication that Inglis and Alcock drew for pedagogical purposes is that students needed to devote more effort in inferring warrants as they read a proof, but this also supports the conclusion that mathematicians infer warrants when reading proofs in their practice.

The next topic we consider is the role of examples in proof validation. Weber (2008) conducted a task-based study in which eight mathematicians were asked to think aloud as they determined if eight purported proofs were correct. Weber was especially curious how mathematicians determined whether new statements in a proof followed from previous statements when the correctness of a new statement was not clear. In most cases, mathematicians' justifications were based on deductive argumentation, where the mathematicians wrote a subproof or gave an informal argument for why the new statement was
a logical consequence of previous statements. However, there were also instances in which mathematicians used empirical evidence to justify the new assertion – that is, they concluded the new assertion was acceptable because it held for some examples that the mathematicians checked. For instance, one mathematician encountered the following consecutive lines in the proof: n is congruent to 3 (mod 4). Note that n is not a perfect square. Below is the transcript of how the mathematician concluded the obvious implicit warrant that numbers congruent to 3 modulo 4 are not perfect squares:

> I'm using examples to see what, where the proof is coming from. So 5^2 is 25 and that's 1 mod 4. 36 is 0 mod 4. 49 is 1 mod 4, 64 is 0 mod 4. I'm thinking that, ah! So it is. . . 24 times 24 is 0 mod 4. So a perfect square has to be 1 mod 4, doesn't it? n^2 equals 1 mod 4 or 0 mod 4. Alright. (Weber 2008, p. 443)

When asked about his reasoning later in the interview, this mathematician concluded that reasoning from patterns in this case was reliable since these patterns usually held and could be verified by induction, while acknowledging that such reasoning often would not work in topology, which was his area of research.

To test the hypothesis that mathematicians would sometimes accept statements in a proof because they held for particular examples, Mejía-Ramos and Weber (2014) conducted a survey with 118 mathematicians. In the survey, the participants were asked questions about how and why they read proofs. Two of the questions from the survey were as follows:

Q1. When I read a proof in a respected journal and I am not immediately sure that a statement in a proof is true, it is not uncommon for me to increase my confidence in the statement by checking it with one or more carefully chosen examples.
Q2. When I read a proof in a respected journal and I am not immediately sure that a statement in a proof is true, it is not uncommon for me to gain a sufficiently high level of confidence in the statement by checking it with one or more carefully chosen examples to assume the claim is correct and continue reading the proof.

Mejía-Ramos and Weber's hypotheses were that more mathematicians would agree than disagree in responding to Q1 and Q2. For Q1, 79% of the respondents agreed with the statement and 13% disagreed. For Q2, 56% of the respondents agreed and 30% disagreed. The remainder, in each case, responded they were neutral with regards to the statement. In each case, there were significantly more (in the sense of statistical inference) mathematicians who agreed with the statement than who disagreed. Of Mejía-Ramos and Weber's 118 respondents, 54 reported having substantial experience refereeing papers. They were also asked Q1 and Q2 with respect to refereeing. For Q1, the results were similar. For Q2, 43% of the mathematicians agreed and 30% of the mathematicians disagreed. The difference between those who agreed and disagreed was not statistically significant for Q2, but the results indicate that a nontrivial number of mathematicians will accept statements in a proof based on empirical evidence, even when they are refereeing papers.

The findings about mathematicians' use of empirical evidence provide a challenge to philosophical accounts for how proof is essential to ensuring the reliability of mathematics. A common account is that empirical evidence in support of an assertion, no matter how seemingly persuasive, is unreliable. Yet proof, because of the notion of logical necessity, provides an extremely high level of reliability (see Berry 2016, for one elaboration of such a viewpoint). The difficulty is that mathematicians sometimes use empirical evidence to check specific assertions within a proof. From our perspective, this suggests that an account of proof that posits that (i) mathematicians read proofs to gain certainty that theorems are true, (ii) certainty

is gained by checking that each line of the proof is valid, and (iii) empirical evidence cannot provide this certainty, seems inconsistent with the data presented in this subsection. If empirical evidence cannot provide certainty that a proof is correct, then either some mathematicians are not reading proofs to gain certainty (even when they referee) or their certainty is coming from another source beyond establishing the validity of each line in the proof (We believe that (i), (ii), and (iii) may all be false. Later in this section, we present evidence that mathematicians do not always check proofs for correctness (see Mejía-Ramos and Weber 2014) and mathematicians may use the overarching method used in the proof to conclude that it is correct rather than a line-by-line check. Further, there appear to be *some* cases in which mathematicians gain certainty or near certainty in a mathematical claim based on empirical evidence (see Paseau 2011, for a discussion).)

4.5 Factors Mathematicians Consider When Assessing the Persuasiveness of Arguments

An interesting debate in mathematics education concerns what evidence should be used by students to convince themselves that mathematical claims are true (see Stylianides et al. 2017, or Weber et al. 2014, for a review of this literature). The general premise among mathematics educators is that students should be convinced by the same types of evidence as mathematicians (e.g., Harel and Sowder 1998). A particularly interesting question concerns the role authority play in mathematicians' acceptance of a proof and what role authority should play in students' acceptance of a proof.

Based on an open-ended interview study, Müller-Hill (2010) found that mathematicians would be more accepting of an argument if it came from an authoritative source, even in the context of refereeing. For instance, one mathematician in her study said:

> Let's say a famous mathematician comes up with a paper and I have to referee it. Then I am preoccupied with the fact that he is a famous mathematician and so that it will probably be correct. And then you say, 'yes, this really seems plausible, but I'm not really sure if it's true' and then you end up with the question, 'is this because I don't have enough knowledge'. (Müller-Hill 2010, as cited and translated in Geist et al. 2010, p. 162)

To avoid misinterpretation, there are two points worth noting. First, the role that authority plays in the Müller-Hill quote above concerns the correctness of an argument, not the truth of a claim. The issue at stake in this question is not whether mathematicians will believe a claim because an authority says it is so, but whether they will believe a proof is correct because it came from an authoritative source. Second, the excerpt from Müller-Hill does not say that mathematicians would accept *any* argument from an authoritative source, even one that contains a clear mistake. Rather, what is claimed is that the identity of the author of the argument influences how the argument is read and a mathematician may be more inclined to grant the

benefit of the doubt if the argument came from an authoritative source. Other mathematics educators have made claims consistent with the excerpt above. For instance, Hanna (1983) asserted that to mathematicians, the author having an unimpeachable reputation as an expert matters more than the rigor of an argument in deciding its acceptability. Like Müller-Hill (2010), Weber (2008) quoted mathematicians stating that the author of an argument would influence how mathematicians would read it.

To test the hypothesis that authority affects the persuasiveness of an argument to mathematicians, Inglis and Mejía-Ramos (2009) conducted a randomized controlled experiment. As Inglis and Aberdein (2020) discussed, experiments offer a powerful means of testing hypotheses about mathematical practice, especially when these hypotheses predict that a particular factor influences mathematicians' judgments or performance. To see whether a particular factor *F* (in this case, the authority of the author) influences performance, mathematicians who participate in an experiment are randomly divided into a control group and an experimental group, where each is asked to complete a task. The tasks that the control group and experimental group receive are identical in all respects, *except* factor *F* is present in the experimental group's task but not the control group's task. If there is an observed difference between the control group and the experimental group's performance, then the difference can only be attributable to the presence of factor *F* or due to chance, as *F* is the only difference between the tasks that the two groups completed. If the performance difference between the groups is statistically significant, this controls the probability that the difference was due to chance and it is reasonable for a researcher to conclude that it was due to factor *F*.

Inglis and Mejía-Ramos (2009) asked 190 mathematicians to evaluate (on a scale of 0 through 100) how persuasive they found a visual proof of the Fixed Point Theorem. The control group and experimental groups received the same tasks, except the experimental group was told that J.E. Littlewood wrote the argument and the control group was not. The experimental group rated the argument as 17 points more persuasive than the control group, a statistically significant difference. Because the only difference in the tasks between the groups is that the experimental group was told that Littlewood wrote the argument, it is reasonable to conclude that the mathematicians knowing that the argument came from an authoritative source led them to find it more persuasive. Similar results were reported by Inglis and Mejía-Ramos when mathematicians were asked to evaluate a heuristic (nondeductive) argument that was written by Timothy Gowers.

In Mejía-Ramos and Weber's (2014) survey, the large majority of mathematicians indicated that they would find proofs to be more persuasive if they were published in an academic journal, especially one that was of high quality, and if it came from an authoritative source that they trusted. The broad implication for these studies is that factors concerning social context influence mathematicians' acceptance of proofs. This supports philosophical accounts of practice such as Auslander's (2008) that describe the role of trust and testimony in the mathematical community's acceptance of claims and the growth of knowledge.

4.6 Why Do Mathematicians Read Proofs?

Weber and Mejía-Ramos (2011) conducted open-ended interviews on how and why mathematicians read proofs that were published in journals. Three interesting findings emerged: First, some mathematicians claimed they did not read proofs to check them for correctness; they assumed the proofs that they were reading were probably correct by dint of the fact that they were published. Second, all participants claimed that the primary reason they read the published literature was to learn about new techniques that they could use to solve problems in their own research. Mejía-Ramos and Weber's (2014) subsequent survey found that their respondents overwhelmingly agreed that they sometimes did not check the proofs that they read for correctness and their primary reason for reading proofs was to identify new techniques that they could use. Third, their participants collectively viewed their understanding of the proof as consisting of four components: being able to offer a high-level summary of the proof, apply the methods of the proof to a new context, break the proof into subproofs and understand how these subproofs or modules related to each other, and relate the ideas of the proof to specific examples (Mejía-Ramos et al. 2012). These results corroborate claims from several philosophers on the nature of proof, such as Rav's (1999) claim that proofs to mathematicians are primarily about revealing methods and Avigad's (2020) recent claims on the role of modularizing and examples in the ways that proofs are written.

Broadly speaking, Weber and Mejía-Ramos' (2011) findings are consistent with the claims in the philosophical literature that for mathematicians, fully understanding a proof goes beyond being able to logically justify each of the steps in a proof (e.g., Feferman 2012; Thurston 1994). However, if this body of research presents an accurate account of mathematical practice with regard to proof reading, we would expect to find evidence for their claims in how mathematicians read proofs. Eye-tracking studies to date have failed to find this evidence. For instance, if mathematicians sought to understand proofs in terms of the global methods that were employed, we might expect mathematicians reading a proof to go globally through the proof (evidence of viewing the proof as a unified whole) rather than focusing only on consecutive lines within the proof (evidence of viewing the proof as a chain of specific inferences). However, when Inglis and Alcock (2012) conducted their eye-tracking study, they found evidence of the latter behavior but not the former. Further, if understanding a proof is different than checking a proof for correctness, we would expect mathematicians who were reading a proof for understanding would exhibit different behaviors than mathematicians who were reading a proof with the aim of checking for correctness. Yet when Panse et al. (2018) conducted an eye-tracking study in which an experimental group of mathematicians was asked to read a proof with the aim of understanding and a control group was asked to read a proof with the aim of checking for correctness, the authors could find no difference between the two groups' eye movements.

These results do not necessarily imply that checking a proof for correctness is tantamount to understanding a proof, or even that mathematicians will not engage in different behaviors when reading the proofs for different purposes. But these results

do pose a philosophical puzzle. What type of behavior do mathematicians exhibit when reading a proof? Does this behavior constitute evidence that mathematicians try to view a proof holistically, rather than as a series of individual assertions? If checking a proof for correctness is different than checking a proof for understanding, what types of different behaviors would be consistent with this hypothesis? And why weren't these behaviors documented in the eye-tracking studies that were conducted?

5 Concluding Remarks

Research on mathematicians' practices has been flourishing in the mathematics education research community for some time. As this chapter has shown, there is a growing literature focused on what mathematicians do, why they do it, and what mechanisms they use while doing it. The rationale for this interest is a belief that a detailed understanding of the answers to these questions should be of use to teachers and curriculum designers. Specifically, an understanding of expert mathematical practice should help to inform (i) the goals of the curriculum, (ii) teachers' judgments about whether students have achieved these goals, and (iii) pedagogical methods that are likely to be most effective at helping students succeed.

Because of this belief that an understanding of expert mathematical practice is educationally relevant, mathematics education researchers have conducted empirical research on a number of topics that are of interest to PMP researchers. Here we have reviewed recent research on mathematicians' understanding of mathematical topics, as well as work on mathematicians' reading of proofs. But these topics are merely illustrative: The mathematics education literature also includes work on mathematical language (Burton and Morgan 2000) and aesthetic judgments (Inglis and Aberdein 2020).

Although mathematics education researchers are interested in understanding mathematical practice, we should not lose sight of the differences between educational and philosophical research on the topic. We have noted differences in terms of both goals and typical research methods. Because of their desire to (eventually) have a positive impact on educational practice, there may be differences between the issues that attract mathematics education researchers' and philosophers' attention. Nevertheless, there are also important overlaps.

As befitting academics working in an empirical social science, mathematics education researchers typically warrant their claims using empirical evidence collected in laboratory settings. Here we have reviewed a variety of examples, including studies which used task-based interviews, which tracked mathematicians' eye movements, and which deployed controlled experimental techniques. These methods can be criticized for lacking authenticity and not taking mathematical context seriously. In contrast, in the PMP literature, there is a much greater reliance upon conceptual analysis, introspective accounts, and historical case studies. While these methods have the advantages of exploring authentic mathematics and giving proper weight to

mathematical context, they are limited in terms of generalizability and run the risk of confirmation bias.

If our observations about the research methods typically used by mathematics education researchers and philosophers are right, then there is the potential for significant cross-fertilization between the two disciplines. More specifically, the research methods used by mathematics education research, particularly those which use large samples and hypothesis testing, can address some of the limitations inherent in introspective accounts and historical case studies. Equally, the authenticity gained by studying mathematicians' accounts – both historical and contemporary – of their own practices can help to address the inevitable artificiality introduced by empirical lab-based methods.

The value of mathematics education research to PMP goes beyond an expansion of research methods. We have suggested that it can contribute in at least three ways: by corroborating or challenging claims made by the PMP literature, by constraining future PMP theorizing, and by producing surprising empirical findings that provoke interesting philosophical questions. In sum, deeper connections between the two research communities are likely to benefit both.

Abstract

Formal logic has often been seen as uniquely placed to analyze mathematical argumentation. While formal logic is certainly necessary for a complete understanding of mathematical practice, it is not sufficient. Important aspects of mathematical reasoning closely resemble patterns of reasoning in non-mathematical domains. Hence the tools developed to understand informal reasoning, collectively known as argumentation theory, are also applicable to much mathematical argumentation. This chapter investigates some of the details of that application. Consideration is given to the many contrasting meanings of the word "argument"; to some of the specific argumentation-theoretic tools that

Argumentation schemes · Argumentation theory · Mathematical argumentation · Mathematical reasoning · Mathematical rhetoric · Problem choice · Toulmin layouts

1 Introduction

Since logic developed the tools to adequately represent formal derivations, many philosophers of mathematics have been tempted to conclude that formal derivation suffices to account for all interesting features of mathematical practice. However, there have always been other philosophers who perceived the shortcomings of such a reduction. Here, for example, is Henri Poincaré:

> If you are present at a game of chess, it will not suffice, for the understanding of the game, to know the rules for moving the pieces. That will only enable you to recognize that each move has been made conformably to these rules, and this knowledge will truly have very little value. Yet this is what the reader of a book on mathematics would do if he were a logician only. To understand the game is wholly another matter; it is to know why the player moves this piece rather than that other which he could have moved without breaking the rules of the game. It is to perceive the inward reason which makes of this series of successive moves a sort of organized whole. This faculty is still more necessary for the player himself, that is, for the inventor (Poincaré 1913, 218).

One response to this limitation of formal logic is to recognize an analogy with a similar limitation in another domain: formal logic is also an imperfect tool for understanding everyday reasoning. Solutions have been proposed for that problem: systems of informal logic, argumentation theory, or dialectic have been devised since antiquity to address ordinary reasoning (van Eemeren et al. 2014). Hence some philosophers of mathematical practice have reasoned that these theories might also lend themselves to the understanding of mathematical reasoning (Aberdein 2009).

This chapter surveys the uses to which argumentation theory has been put in order to understand mathematical practice. Section 2 addresses the many ambiguities implicit in the word "argument" – and how they are specifically related to mathematics. Section 3 discusses two prominent proposals for the application of particular tools from argumentation theory to mathematics: Toulmin layouts and argumentation schemes. Section 4 considers the argumentative aspects of mathematical practices beyond proof and Sect. 5 focuses on the contribution of communities of mathematical practice to such argumentation.

2 What Is an Argument?

Several overlapping distinctions may be drawn in our understanding of arguments.

- **Argument-that/Argument-about:** A sequence of statements whereby premises offer support for a conclusion is an argument. But, an exchange of conflicting views held by different people is also an argument. We may refer to the former as an *argument-that* and to the latter as an *argument-about*. Arguments-that are also known as arguments$_1$ and arguments-about as arguments$_2$ (O'Keefe 1977). As Michael Gilbert helpfully glosses the distinction, "one person makes an argument$_1$ and [at least] two people have an argument$_2$" (Gilbert 2014, 21). Although the most familiar mathematical arguments tend to be arguments-that, arguments-about arise in mathematics too, such as priority disputes, contested axioms or principles, or debates over the legitimacy of a technique or the admissibility of a proof. A salient recent example is the contested status of Shinichi Mochizuki's claimed proof of the *abc* conjecture (Aberdein 2023).
- **Process/Product:** Arguments-that are sometimes represented as products of the argument-about process, but this is arguably a mischaracterization: "If, as part of organizing the domain of argumentation theory, we merely want to distinguish acts of arguing from arguments-as-objects, we should not use the misleading process/product labels to do so. At the very least such labels imply a relationship that does not exist and so distort our perceptions of the domain of study" (Goddu 2011, 87). Nonetheless, we may usefully distinguish between an argument understood as an act of arguing and the informational trace that act leaves behind (a transcript, a recording, etc.), also often called an argument (Sundholm 2012, 948). This distinction straightforwardly applies to mathematics. (For further reflection on proofs as acts of proving or proof-events, see Goguen 2001; Stefaneas and Vandoulakis 2014, 2015.)
- **Monologue/Dialogue/Polylogue:** The number of participants in an argument may vary considerably. Most attention has traditionally been paid to monologues and dialogues: arguments-that are characteristically presented as monologues, arguments-about as dialogues. If dialogues are understood loosely, as also covering argumentation with more than two participants, that distinction would exhaust the options. However, some authors have made a case for differentiating the two-participant dialogue from the many-participant polylogue (Lewiński 2014). The Polymath Project, a series of crowd-sourced proofs of open conjectures, is a rich source for research on mathematical polylogues (Allo et al. 2021).
- **Small scale/Large scale:** Arguments can vary significantly in scale. The scale of an argument may be measured in several conceptually distinct ways. The duration of an argument may range from arguments that take seconds to arguments which last for hundreds of years. The size of an argument may range from a few inferences expressed in short sentences about a simple issue to inferentially complex structures involving a great many very long sentences. Likewise,

mathematical proofs can vary in length from a few lines to tens or even hundreds of pages. In exceptional cases, proofs can be so long as to defy the capacity of any single mathematician to survey the whole (Coleman 2009). This can arise in proofs achieved by traditional means, such as that of the classification of finite simple groups, the components of which comprised thousands of pages in several hundred articles by dozens of mathematicians (Steingart 2012). It is even more acute in the case of computer-assisted proofs, such as that of the four-color theorem or the Kepler conjecture, or indeed the subsequent computer verification of these proofs (Gonthier 2008; Hales et al. 2017).

- **Static/Dynamic:** Static arguments have achieved a final and definite form; dynamic arguments are fluid and ongoing. In general, the evolution of knowledge may be understood as the product of dynamic argumentation. Dynamic arguments are common in everyday life – but they are also central to the development of scientific thought. A well-known and influential analysis of a dynamic argument in mathematics is Imre Lakatos's *Proofs and Refutations*. Lakatos shows how the protracted search for a proof of the Descartes–Euler conjecture, which relates the quantities of vertices, edges, and faces of convex polyhedra, involved significant redefinition of most of the concepts used in that conjecture (Lakatos 1976). (For further discussion, see Sect. 4.3 below or Reyes 2021.)
- **Centralized/Distributed:** Arguments may be either centralized or distributed with respect to several factors including time, people, space, and media. A highly centralized argument may be restricted to what one person communicates in one place at one time in one mode of expression. But arguments may involve a varying cast of arguers and be drawn out over long periods, in multiple locations and media. Large-scale arguments are characteristically distributed: As a mathematical example, the classification of finite simple groups involved many years of work by a large, geographically widespread collective of mathematicians (Steingart 2012).
- **Sequential/Parallel:** Logic, whether formal or informal, tends to reconstruct arguments as a linear sequence of premises from which intermediate statements are derived, culminating in a final conclusion. (Some logical systems prefer to invert this sequence.) However, argumentation in natural contexts often occurs in a more parallel fashion: Several strands of argument may be developed simultaneously, the conclusion may be derived from initial premises and then reinforced by subsequent subarguments, and so forth. Parallel arguments are also more likely to arise in projects with many participants, whether by accident or design: "To permit a large collaboration, . . . long proofs have been broken up into series of shorter lemmas" (Hales et al. 2017, 11). The educationists Christine Knipping and David Reid have proposed more fine-grained subdivisions of parallel arguments in mathematics (Knipping and Reid 2019; for further discussion, see Sect. 3.1 below.)

The seven overlapping distinctions addressed so far have received unequal interest in the philosophy of mathematics. The formal logical approach mentioned in the introduction best coheres with a small-scale, static, centralized, sequential product like a published proof. Much recent work in the philosophy of mathematical

practice focuses on mathematical arguments along the other dimensions. Some further distinctions arise from consideration of the goals of the arguers:

- **Persuasive/Directive/Polemic:** That arguments may be distinguished by their objective is an ancient idea: Aristotle distinguished forensic arguments (concerned with past acts), display arguments (concerned with present circumstances), and deliberative arguments (concerned with future acts) (Aristotle 1991, 1358b). Erik C. W. Krabbe and Jan Albert van Laar propose an updated distinction between three different functions of reasoning: persuasive (to convince the other party), directive (to get the other party to act), and polemic (to intimidate the other party) (Krabbe and van Laar 2007, 29 f.). They contrast these "inherently argumentative" functions with three further functions of reasoning: explanatory (to enhance understanding), explorative (to investigate connections between statements), and probative (to establish new knowledge).
- **Adversarial/Nonadversarial:** On a strict interpretation, all arguments begin in conflict: a difference in belief, or concerning how to act, or of some other kind. On a broader interpretation, arguments need not be strictly adversarial, hence they may proceed from other situations, including shared uncertainty or one party knowing what another does not.

These nine different dimensions of comparison interact in important ways. Firstly, they are not pairwise independent. For example, as the scale of an argument increases, we may tentatively expect both the number of participants and the number of different objectives to increase, but the likelihood of the argument being either static, centralized, or sequential to tend to zero. Secondly, the last two dimensions combine to produce what Douglas Walton calls *dialogue types* (see Fig. 1, adapted from Walton and Krabbe 1995, 81). Further complicating this picture, Walton and Krabbe observe that dialogues can shift from one type to another (for example, an inquiry might turn into a persuasion dialogue if one inquirer becomes an advocate for a particular result) or be embedded in a dialogue of a different type (a deliberation over which course of action to pursue might contain an inquiry into the merits of one action, say). Walton maintains that arguments may arise in any dialogue type (Walton 1998); Krabbe is more conservative and regards argumentation as restricted to adversarial contexts (the lefthand fork of Fig. 1) (Krabbe and van Laar 2007, 33).

How do these distinctions apply to argumentation in mathematics? The most widely discussed case is that of mathematical proof, which many authors have maintained is intrinsically argumentative. But even here, we may distinguish multiple distinct activities which give rise to arguments of different kinds. For example, Krabbe observes the following distinct stages:

1. Thinking up a proof to convince oneself of the truth of some theorem
2. Thinking up a proof in dialogue with other people (inquiry dialogue; probative functions of reasoning)
3. Presenting a proof to one's fellow discussants in an inquiry dialogue (persuasion dialogue embedded in inquiry dialogue; persuasive and probative functions of reasoning)

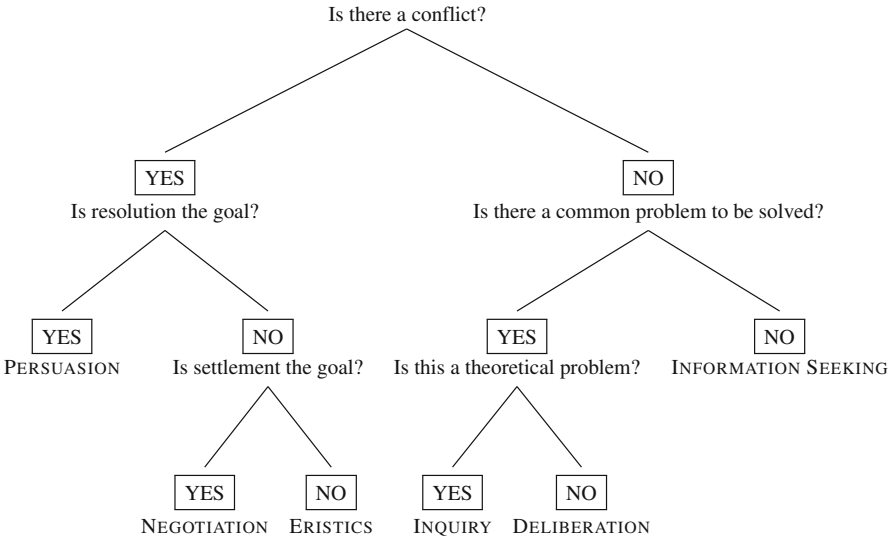

Fig. 1 Determining the type of dialogue (after Walton and Krabbe 1995, 81)

4. Presenting a proof to other mathematicians, e.g., by publishing it in a journal (persuasion dialogue; persuasive and probative functions of reasoning)
5. Presenting a proof when teaching (information-seeking and persuasion dialogue; explanatory, persuasive, and probative functions of reasoning) (Krabbe 2008, 457)

This sequence is familiar from many mathematicians' descriptions of the proving process, although in actual examples some steps may be repeated as proof attempts come unstuck.

In deference to his intrinsically adversarial conception of argument, Krabbe only considers three dialogue types as hospitable to proofs. In other work, one of us has suggested that proofs (or other mathematical arguments) may be found in other dialogue types too (see Table 1, from Aberdein 2021, 165; see also Aberdein 2007b, 148). "Oracular" information-seeking owes its inspiration to an influential aside of Alan Turing concerning a machine "supplied with some unspecified means of solving number-theoretic problems; a kind of oracle as it were" (Turing 1939, 172). An oracle is a "black box" – it supplies answers but not explanations. For some skeptics of computer-assisted proofs, this is a compelling analogy for the role that the computer plays in such proofs (e.g., Tymoczko 1979). Deliberation differs from inquiry in seeking only a provisional conclusion. Mathematicians aspire to more permanent stability for their results. Nonetheless, there are circumstances where they are obliged to settle for less than they would wish, despite the rigor of their arguments. These include the "architectural conjectures" upon which many mathematical research programs depend (Mazur 1997, 198). Negotiation characteristically adds resource sensitivity to the provisional outcome typical of deliberation.

Table 1 Some mathematical dialogue types

Dialogue type	Initial situation	Main goal	Goal of proponent	Goal of respondent
Inquiry	Open-mindedness	Prove or disprove conjecture	Contribute to main goal	Obtain knowledge
Persuasion	Difference of opinion	Resolve difference of opinion with rigor	Persuade respondent	Persuade proponent
Pedagogical information-seeking	Respondent lacks information	Transfer of knowledge	Disseminate knowledge of results and methods	Obtain knowledge
Oracular information-seeking	Proponent lacks information	Transfer of knowledge	Obtain information	Inscrutable
Deliberation	Open-mindedness	Reach a provisional conclusion	Contribute to main goal	Obtain warranted belief
Negotiation	Difference of opinion	Exchange resources for a provisional conclusion	Contribute to main goal	Maximize value of exchange
Eristic	Personal conflict	Reveal deeper conflict	Win in the eyes of onlookers	Win in the eyes of onlookers

While idealized accounts of mathematical practice disregard such factors, they are unavoidable in some contexts, especially in applied mathematics. (And it has been controversially suggested that "semi-rigorous" proofs might come with price tickets, costing the computational resources necessary for certainty [Zeilberger 1993].) Even eristic dialogues can be the context for mathematical reasoning, as demonstrated in the mathematically inventive quarrels of early modern mathematicians such as Girolamo Cardano and Niccolò Tartaglia (Toscano 2020).

A final distinction among the different senses of argument cuts across most of those discussed above and arises not from argumentation theory but directly from mathematical practice. Here it is presented by Joel David Hamkins:

- **Hard/Soft:** "A hard argument is one that is technically difficult; perhaps it involves a laborious construction or a difficult calculation; perhaps it involves bringing disparate fine details together in just the right combination in order to succeed; or perhaps it involves proving various specific facts about a comparatively abstract construction, perhaps relating disparate levels of abstraction. A soft argument, in contrast, is one that appeals only to very general abstract features of the situation, and one needs hardly to construct or compute anything at all" (Hamkins 2020, 166).

Hamkins's use of "hard" and "soft" echoes G. H. Hardy's division of analysis into "the 'hard, sharp, narrow' kind as opposed to the 'soft, large, vague' kind" (Hardy 1929, 64). It also owes something to Alexander Grothendieck's celebrated analogy between two strategies for solving mathematical problems and two ways of opening

a nut: cracking it with a hammer or softening it in water until it opens with light pressure (McLarty 2007, 301). Grothendieck favored the latter strategy, of immersing problems in a much wider theory from which a solution could (eventually) be readily inferred. This in turn is suggestive of Freeman Dyson's division of mathematicians into birds and frogs: "Birds fly high in the air and survey broad vistas of mathematics out to the far horizon. They delight in concepts that unify our thinking and bring together diverse problems from different parts of the landscape. Frogs live in the mud below and see only the flowers that grow nearby. They delight in the details of particular objects, and they solve problems one at a time" (Dyson 2009, 212). Hard arguments play to the tightly focused strengths of the frogs; soft arguments require the birds' sweeping perspective.

3 Proof as Argumentation

The view mentioned in Sect. 1, that formal derivation suffices to account for all interesting features of mathematical practice, squarely focuses on the role of mathematical proof. Pure mathematicians trade in proofs. But, even in the domain of mathematical proof, formal logic does not capture all there is of interest. Toulmin layouts and argumentation schemes, as we will see below, are useful methods of examining mathematical proofs. But, notably, such techniques tease apart the descriptive and normative aspects of (apparent) proof. Whereas a formal derivation is either correct or not, strictly speaking, a derivation at all, the methods of argumentation theory provide the means to describe proofs independently of whether they succeed as proofs.

3.1 Toulmin Layouts

One of the most influential treatments of informal argumentation is that of Stephen Toulmin (1958). His "layout" can represent deductive inference, but encompasses many other species of argument besides. In its simplest form, shown in Fig. 2a, the

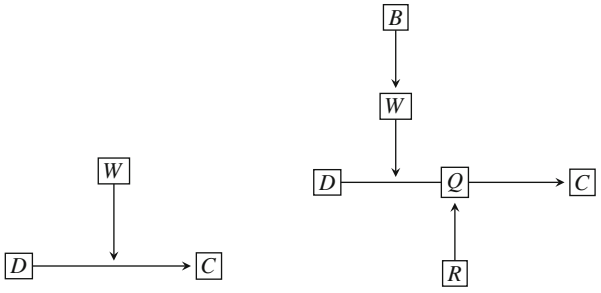

Fig. 2 Toulmin layouts

(a) Basic Layout (b) Full Layout

layout represents the derivation of a claim (*C*), from data (*D*), in accordance with a warrant (*W*). This DWC pattern resembles a deductive inference rule, such as *modus ponens*, but it can be used to represent looser inferential steps. The differences between the types of inference which the layout may represent are made explicit by the additional elements of the full layout shown in Fig. 2b. The warrant is justified by its dependence on backing (*B*), possible exceptions, or rebuttals (*R*), are indicated, and the resultant force of the argument is stated in the qualifier (*Q*). Hence the full layout may be understood as "Given that *D*, we can *Q* claim that *C*, since *W* (on account of *B*), unless *R*." In a frequently cited example (derived from Toulmin 1958, 104), "Given that HARRY WAS BORN IN BERMUDA, we can PRESUMABLY claim that HE IS BRITISH, since ANYONE BORN IN BERMUDA WILL GENERALLY BE BRITISH (on account of VARIOUS STATUTES . . .), unless HIS PARENTS WERE ALIENS, SAY."

Toulmin wrote *The Uses of Argument* in England in the 1950s as a critique of what he perceived as a formalizing trend in contemporary philosophy; the Toulmin layout was subsequently adopted by communication theorists in America in the 1960s and 1970s; from there it seems to have passed to mathematics educationists in Germany in the 1990s. (Although Toulmin himself briefly considers a mathematical example, Theaetetus's proof that there are exactly five platonic solids [Toulmin et al. 1979, 89]. For discussion, see [Aberdein 2005, 290 ff.].) In particular, Götz Krummheuer is usually credited with the first sustained application of the Toulmin layout to mathematical argumentation (Krummheuer 1995; for a recent survey, see Krummheuer 2015).

Toulmin draws a distinction between analytic and substantial arguments depending on whether the claim is already at least implicit in the backing. This may suggest that only analytic arguments occur in mathematics. But that overlooks the emphasis Toulmin places on how out of the ordinary analytic arguments are: "it begins to be a little doubtful whether any genuine, practical argument could ever be properly analytic" (Toulmin 1958, 127). Granted, immediately after this passage, Toulmin places arguments in (pure) mathematics among the analytic arguments. However, the philosophers and educationists who have applied Toulmin's work to mathematics endorsed his account of argument, not his philosophy of mathematics. They have typically treated (at least some) mathematical arguments as substantial rather than analytic. For example, "It is the substantial argumentation that is seen here as more adequate for the reconstruction" of mathematics classroom situations (Krummheuer 1995, 236). In other words, the part of Toulmin's work that we should apply to many mathematical arguments is what he has to say about nonmathematical arguments.

Much subsequent work applying the Toulmin layout to mathematical reasoning has concerned ways in which it may be extended to cover cases that he does not directly address – including many of the less favored sides of the distinctions drawn in Sect. 2 above. Toulmin's own later work discusses how more than one layout may be chained together to represent a multistep argument (Toulmin et al. 1979, 79). Other authors have shown how more complicated structures, including linked and convergent arguments, may be represented by combinations of layouts (Aberdein

2006, 214). Christine Knipping and David Reid have paid particular attention to larger-scale structures of parallel argument, distinguishing source-like argumentation structure, where "arguments and ideas arise from a variety of origins, like water welling up from many springs," from "reservoir structure," wherein arguments "flow towards intermediate target-conclusions that structure the whole argumentation into parts that are distinct and self-contained," and spiral argumentation structure in which "the final conclusion is proven in many ways" (Knipping and Reid 2019, 18 ff.). Matthew Inglis and colleagues have argued persuasively for the relevance of the full Toulmin model to mathematical arguments, rather than the simplified DWC or DWBC versions that have found widest application among mathematics educationists (Inglis et al. 2007). In particular, they observe that nondeductive warrants can play an essential role in mathematical argumentation, just so long as this is signaled by the use of appropriate qualifiers. Work has also been done to explore the connections between the Toulmin layout and other models of argument applicable to mathematics (Pease and Aberdein 2011), or to link it to broader conceptual analyses of mathematical cognition, such as the "ck¢-enriched" Toulmin model (Pedemonte and Balacheff 2016).

3.2 Argumentation Schemes

Argumentation schemes are stereotypical patterns of reasoning. Although their origins lie in the topoi of classical rhetoric, they have lately found extensive application in the analysis and evaluation of argumentation. This revival is substantially due to the work of the argumentation theorist Douglas Walton. Most attention has been paid to defeasible schemes typical of informal reasoning, although deductive inference rules can also be considered special cases of argumentation schemes. The defeasible nature of the reasoning is not made explicit among the premises, but captured by an additional device, critical questions, which point to possible exceptions. Many of the defeasible schemes may ultimately be understood as more or less specialized instances of the very general scheme of *Defeasible Modus Ponens* (Walton et al. 2008, 366). In Scheme 1, we have presented it in a way designed to bring out its similarities to the Toulmin layout:

Argumentation Scheme 1 *Defeasible Modus Ponens*
Data P.
Warrant As a rule, if *P*, then *Q*.
Therefore,
Qualifier presumably,
Conclusion . . . *Q*.

Critical Questions

1. *Backing:* What reason is there to accept that, as a rule, if *P*, then *Q*?
2. *Rebuttal:* Is the present case an exception to the rule that if *P*, then *Q*?

The strength of the argumentation scheme approach lies in its heterogeneity: An influential (but not exhaustive) survey identifies over one hundred different schemes (Walton et al. 2008, 308 ff.). Hence schemes are typically presented with much greater specificity than Scheme 1. For example, Scheme 2 is a scheme for Argument from Analogy:

Argumentation Scheme 2 *Argument from Analogy*
Similarity Premise Generally, case C_1 is similar to case C_2.
Base Premise A is true (false) in case C_1.
Conclusion A is true (false) in case C_2.

Critical Questions

1. Are there differences between C_1 and C_2 that would tend to undermine the force of the similarity cited?
2. Is A true (false) in C_1?
3. Is there some other case C_3 that is also similar to C_1, but in which A is false (true)? (Walton et al. 2008, 315).

Analogies in mathematics can be formal and thereby capable of rigorous proof (for a specific example and further discussion of this scheme, see Aberdein 2013b, 373). They can also be informal heuristics, for example, the "strong analogy between the pluralist nature of set theory and what has emerged as an established plurality in the foundations of geometry" (Hamkins 2020, 296; for further discussion of this analogy, see Berry 2020). Analogical reasoning has been a topic of wide interest and mathematical analogies in particular have been the subject of focused discussion (Schlimm 2008; Bartha 2013; Priestley 2013).

In more recent work, Walton proposed a partial taxonomy of schemes (Walton and Macagno 2015, 22), although he acknowledged that some schemes remained outside this classification. Many of these schemes have been applied to mathematical arguments: Table 2 is based on (Walton and Macagno 2015, 22, Table 1), but adds references to prior work in which such applications have been developed. Just as Walton's classification of schemes is incomplete, so is their application to mathematics. Some of these schemes may be of limited usefulness in the analysis of specifically mathematical argumentation, but others have direct application.

By varying which schemes are treated as admissible, it is possible to capture different conceptions of mathematical rigor. To this end, one of us has proposed a threefold distinction among the ways schemes may be employed in mathematical reasoning (Aberdein 2013b, 366 f.):

- **A-schemes** correspond directly to derivation rules. (Equivalently, we could think in terms of a single A-scheme, the "pointing scheme" which picks out a derivation whose premises and conclusion are formal counterparts of its data and claim.)
- **B-schemes** are exclusively mathematical arguments: high-level algorithms or macros. Their instantiations correspond to substructures of derivations rather

Table 2 Walton and Macagno's partial classification of schemes (adapted from Walton and Macagno 2015, 22), with prior applications to mathematical argumentation indicated

Discovery arguments	Applying rules to cases	Practical reasoning	Source-dependent arguments

than individual derivations (and they may appeal to additional formally verified propositions).

- **C-schemes** are even looser in their relationship to derivations, since the link between their data and claim need not be deductive. Specific instantiations may still correspond to derivations, but there will be no guarantee that this is so and no procedure that will always yield the required structure even when it exists. Thus, where the qualifier of A- and B-schemes will always indicate deductive certainty, the qualifiers of C-schemes may exhibit more diversity. Indeed, different instantiations of the same scheme may have different qualifiers.

B-schemes are essentially what Saunders Mac Lane calls "processes of proof" or general rules, algorithmic procedures that are ultimately reducible to elementary logical inferences although not necessarily so analyzed by the mathematicians who routinely employ them: "whenever a group of elementary processes of proof occurs repeatedly in the course of many proofs, it is desirable to formulate this group of steps once for all as a new process" (Mac Lane 1935, 123). Much more recently, Yacin Hamami has used B-schemes, which he terms "hl-rules" or higher-level rules of inference, to defend the "standard view" of mathematical rigor, that rigorous proofs are those for which there is a routine translation into a formal derivation (Hamami 2022).

Hamami's account of rigor has three components: a descriptive thesis, a normative thesis, and a philosophical thesis asserting the conformity of the other two theses. Relative to some mathematical practice $\mathcal{M}$, these theses may be stated as follows. The descriptive thesis states that a mathematical proof P is rigorous$_D$ if and only if for every mathematical inference I in P, there exist $D \in \mathcal{D}^*$ and $V_1, \ldots, V_n \in \mathcal{V}^*$ such that (1) $D(I) = \langle I_1, \ldots, I_n \rangle$ and (2) $Vi(Ii) = \texttt{valid}$ for all $i \in [\![1, n]\!]$, where the set $\mathcal{D}^*$ consists of decomposition (or proof search) processes, whereby a mathematical inference may be rewritten as a sequence of immediate mathematical inferences, and the set $\mathcal{V}^*$ consists of hl-rules, whereby immediate mathematical inferences are judged valid if they correspond to instances of the hl-rules. The normative thesis states that a mathematical proof P is rigorous$_N$ if and only if P can be routinely translated into a formal proof. Hamami defines "routine translation" as the composition of three successive translations between proofs understood at four levels of granularity: vernacular level proofs, comprised of inferences presented at the level of formality normal to $\mathcal{M}$; higher-level proofs, comprised of inferences instantiating hl-rules in $\mathcal{M}$; intermediate-level proofs, comprised of inferences instantiating primitive rules of inference in $\mathcal{M}$; and lower-level proofs, comprised of inferences instantiating rules of inference in a purely formal system. The conformity thesis states that if P is rigorous$_D$ then P is rigorous$_N$. Hamami's account of rigor corresponds to one of four alternatives that one of us has discussed elsewhere (Aberdein 2013b, 369). It may be contrasted with the more conservative policy of only admitting A-schemes and thereby treating only formalized mathematics as truly rigorous and more liberal options in which C-schemes are also admitted, thereby tolerating a greater diversity of innovation in mathematical proof.

4 Mathematical Reasoning as Argumentative

In Sect. 3, we saw that to understand proof through the lens of argumentation theory is to see it in the context of a greater diversity of types of mathematical argument. While proofs are a vital component of modern mathematical practice, it is not the only aspect of mathematical reasoning to which argumentation theory may be applied. We now turn to these other aspects. Our discussion begins with general claims about mathematical reasoning and rhetoric. We then turn to a number of issues which surround proof including problem choice, reasoning about refutations, and presentation of mathematical information.

4.1 Mathematics and Rhetoric

A first connection between mathematical reasoning and argumentation theory involves rhetoric. Rhetoric, the study of the art of persuasive argument, has long been set in opposition to mathematics. It was thought that mathematics, as an objective, rational, and atemporal field, has little to do with the study of persuasion. But a number of authors have challenged this idea. An early paper by Philip J. Davis and Reuben Hersh identified two areas where mathematics and rhetoric intersect (Davis and Hersh 1986). The first involves importing or applying mathematics to theories in the social sciences, such as psychodynamics and economics. Such appeals to mathematiziation are rhetorical and argumentative moves, but they are not argumentation within mathematical reasoning. However, as Davis and Hersh point out, there is rhetoric in mathematics too, since "all proofs are incomplete, from the viewpoint of formal logic" (Davis and Hersh 1986, 66). Each proof requires rhetorical elements to convince the intended audience that the result is true. The mathematician relies on the audience's background knowledge or intuition to patch up gaps in the proof and understand the intentions of the prover.

Like Davis and Hersh, Edward Schiappa discusses multiple ways in which mathematical reasoning can be rhetorical. The first intersection, again, is the rhetorical use of mathematics. Mathematical methods can be used to persuade in a variety of arguments. Schiappa cites examples ranging from mundane advertisement – "four out of five dentists agree" – to the discovery of Neptune to argue that mathematical reasoning plays a role in lending credibility to arguments outside its purview (Schiappa 2021). The second intersection is the role of rhetoric within mathematics: the argumentative and stylistic modes of persuasion in mathematical arguments. Each aspect of mathematical practice historically required a social and persuasive component. Acceptance of axioms and stipulated definitions depends on the audience one aims to persuade. Even the available concepts which mathematicians reason about can be the result of rhetoric. For example, G. Mitchell Reyes argues that, since there was no empirical or geometric verification for infinitesimals, their substance was found in the rhetorical argumentation which surrounded them (Reyes 2004). Schiappa also argues that the language of mathematics is rhetorical since it is human-made. Symbols and concepts like the infinitesimal or the number zero were

additions where "social acceptance was not assured, meaning was contested, and alternatives competed" (Schiappa 2021, 49). Relatedly, in this collection, Reyes examines the relationship between rhetoric and mathematics in Lakatos's *Proofs and Refutations* (Reyes 2021).

4.2 Problem Choice

In addition to the rhetorical components pervasive in nonproof, there is room for argumentation in the process around proofs. Perhaps the most fundamental part of solving a problem, and of proving a theorem, is selecting a problem. Problem choice in mathematics has frequently been associated with the beauty and intrinsic worth of problems. Under this view, there is a special sensibility mathematicians employ when choosing a subject. According to Jacques Hadamard, mathematicians "feel that such a direction of investigation is worth following; [they] feel that the question in itself deserves interest . . . everybody is free to call or not to call that a feeling of beauty" (Hadamard 1945, 127). This approach to problem choice has been supplemented in recent years. Morten Misfeldt and Mikkel Willum Johansen interviewed research mathematicians about the factors which influence problem choice (Misfeldt and Johansen 2015). In line with Hadamard's claims, certain external factors, like funding, were not very influential on problem choice. Misfeldt and Johansen found that problem choice was largely motivated by personal interest, perceived ability to solve the problem, and the values of the community. It was not enough for mathematicians to be interested in the problem, they had to be assured that the mathematical community would be interested. Mathematicians expressed "the need to have an audience—the right audience—for their work" (Misfeldt and Johansen 2015, 368). This connection between an audience and an arguer is an area which argumentation is primed to explore.

Elsewhere, one of us has looked at problem choice through an argumentative lens by applying Chaïm Perelman and Lucie Olbrechts-Tyteca's notion of the contact of minds to problem choice in mathematics (Ashton 2018). The contact of minds is a set of conditions which must be met before argumentation can occur. Contact of minds requires four things: the arguer must attach importance to the audience, the speaker must not be beyond question, the audience must be willing to consider being convinced, and they must share a common language. Contact of minds is a prerequisite of any argumentation and mathematical arguments are no different. Ashton argues that it is an audience-based factor that influences problem choice alongside traditional considerations of beauty, intrinsic worth, and practical benefits. But the contact of minds was not originally meant to be applied to mathematics: Perelman and Olbrechts-Tyteca specifically oppose their study of argumentation to the mathematical sciences. Argumentation, they claimed, was distinct from mathematics since argumentation was social and its conclusions were probable (Perelman and Olbrechts-Tyteca 1969). But barring mathematical practice from the domain of argumentation is inapproporiately limiting (Dufour 2013; Ashton 2018, 2021). Misfeldt and Johansen's interviews indicate that mathematicians consider the

interest of other mathematicians while choosing problems. Given that problem choice is broader than merely the structure of proof, a choice about what to research is a choice of what to argue about. In this way, the process of choosing a problem to research is distinctly social and related to the mathematical community (Ashton 2018; discussed further in Sect. 5).

4.3 Reasoning About Refutations

The influential informal logician Ralph Johnson (2000) follows the rhetoricians Perelman and Olbrechts-Tyteca (1969) in denying that proofs can be arguments because there are features of proof, such as necessity, that are incompatible with the social dimension of arguments. For Perelman and Olbrechts-Tyteca, mathematics deals in demonstrations which are mechanically checkable and result in certainty, regardless of the audience. Mathematical reasoning, for them, does not involve uncertainty or controversy. Likewise, Johnson viewed proofs as lacking a dialectical tier. For Johnson, arguments have two components. The first component of argument is the illative core which is a discursive structure where reasons support the conclusion. But this logical aspect alone is not a full argument. A dialectical tier must supplement the illative core. Dialectical tiers are where arguers discharge their dialectical obligations by responding to objections, criticisms, or implications of their view. According to Johnson, proofs do not have dialectical tiers since they are conclusive and anyone trained in the field must recognize that they are conclusive. But refutations are a natural part of mathematical reasoning. Reasoning about purported refutations may best be understood in terms of argumentation.

In an idealized view of proof, one in which proof cannot be an argument, the reader of a proof is an expert who "needs nobody to grasp a proof, otherwise she is not an expert" (Dufour 2013, 69). Such a view, according to Dufour, ignores the important role of checking a proof for correctness. There may still be legitimate room for refutations at this stage. As Fallis (2003) notes, proofs have many intentional gaps. The gaps are purportedly something a reader could fill in, with enough time and background knowledge. Verifying that a proof is correct requires checking these gaps. If the gaps cannot be traversed by either the reader or author, the proof itself may be refuted. Sometimes large gaps may result in the apparent refutation of otherwise good proofs. According to Dufour, Galois experienced such problems of communication (Dufour 2013, 71). Galois's exaggerated brevity led his audience to believe that the mathematics itself was insufficiently developed. Proofs may be refuted because of unintelligible or untraversable gaps. These gaps, and their relationships to audience understanding, are evidence that reasoning about the correctness of proofs, and their refutations, involves argumentation.

Contra Johnson, Ian Dove has argued that proofs do have dialectical tiers (Dove 2007). In particular, Dove argues that the method of monster barring seen in Lakatos's *Proofs and Refutations* is part of a dialectical tier (Lakatos 1976). Lakatos reconstructs a series of purported proofs of Euler's formula. Cauchy's proof of Euler's formula for polyhedra is considered and then counterexamples are raised

which are not convex and not simply connected. Dove argues that there is a dialectical tier for Cauchy's proof of Euler's formula since (a) objections are raised to the proof and (b) the objections receive responses in the proof. The method of response is to bar exceptions to the formula so that Euler's formula holds for simply connected, convex polyhedra. In other words, monster barring to improve a conjecture is one way a proof can have a dialectical tier.

Both Dove and Dufour found that reasoning about refutations is an argumentative practice. Purported proofs are not always uncontroversial and incorporating refutations involves filling out a dialectical tier or considering a relevant audience.

4.4 Presenting Reasoning

After a problem has been chosen and its solution has been verified, mathematical reasoning must be disseminated to a larger public. There is much work to be done to discover how mathematicians incorporate audience consideration while presenting their solutions. But Line Edslev Andersen's interviews with working mathematicians indicate that audience consideration does feature into how papers are revised. Andersen's interviews provide insight into how mathematicians write for mathematicians (Andersen et al. 2021), how peer reviewers receive and evaluate papers (Andersen 2017), and how mathematicians choose which gaps to include in their papers (Andersen 2020). Additionally, mathematical results must be translated to students in a pedagogical setting. Results also often need to be communicated to scientists or mathematicians in other fields. In each of these cases, it is common to reword or recast a proof to aid in communication. All "strategic rewordings belong to the field of mathematical argumentation" (Dufour 2013, 73). Some of these rewordings may even be usefully cast within Johnson's concept of a dialectical tier. This is a rich area for further research, but, as Dufour points out, one must first admit mathematical proofs into the realm of argumentation. Section 5 examines how communities play a role in mathematical practice broadly, not just in presenting reasoning.

5 Mathematical Communities as Argumentative

Throughout this chapter, we have looked at the different aspects of mathematical practice that involve argumentation. Mathematicians present and produce argumentations. Their choice of problems and reasoning while solving problems also involved argumentation. But arguments are presented to, or developed with, an audience in mind. We now turn to mathematical audiences and communities. We argue that mathematical audiences influence which investigations are undertaken and how they are undertaken.

Given that the interest of this section is mathematical audiences, the receivers of mathematical arguments, one might begin by asking what kind of interaction mathematicians have with their audiences. Mathematics is often portrayed as an

isolated activity. Mathematicians lock themselves in an attic and spend days proving complicated conjectures alone. Indeed, stories of famous mathematicians seem to support such an idea. Andrew Wiles did work on his proof of Fermat's last theorem in an attic. And mathematical advances can be so particular, as in the case of Mochizuki's purported proof of the *abc* conjecture, that only a handful of people can verify or understand them. But this isolated view is not an accurate portrayal of mathematical practice.

Without an appropriate community, or engagement with that community, mathematical investigations can falter. Besides the obvious importance of mentors or coauthors, there needs to be a certain level of engagement with a larger community of mathematicians. Take, for example, William Thurston's discussion in *On Proof and Progress in Mathematics* (Thurston 1994). According to Thurston, mathematicians tend to follow fads. Fad-following is in line with his claim that there is a vital social component to mathematical progress. He drew this conclusion from his own experiences. When Thurston first entered the field of foliations, he rapidly solved a number of open problems. But the field seemed to empty out within a few years of his entrance and Thurston lost interest soon after. In response to this experience, he tried to develop and present infrastructure instead of proving theorems. He writes that:

> I have put a lot of effort into non-credit-producing activities that I value just as I value proving theorems: mathematical politics, revision of my notes into a book with a high standard of communication, exploration of computing in mathematics, mathematical education, development of new forms for communication of mathematics . . . I think that what I have done has not maximized my "credits" . . . I do think that my actions have done well in stimulating mathematics. (Thurston 1994, 177)

We can see that, for Thurston, the health of the mathematical community is invaluable to retaining mathematicians who are interested in that area. This is part of their tendency to "follow fads" to newly exciting communities.

Audience and community involvement seem important, but what exactly does argumentation theory have to offer in this area? As one of us has argued, Thurston's story exemplifies a broader issue, namely that problem choice in mathematics rests on the assurance that there exists a "contact of minds" between the audience and the mathematician (Ashton 2018). As we can see, the interest and activity of a mathematical community is vital to successful mathematical practice.

In addition to the role that communities play in problem choice, they play an important role in the ongoing dialectic involved in problem-solving. The method of proofs and refutations described by Lakatos relies heavily on community involvement in problem-solving. A first "proof" is suggested to show that, for polyhedra, $V - E + F = 2$, where V is the number of vertices, E the number of edges, and F the number of faces of the polyhedron. The proof faces a number of global and local counterexamples, that is, counterexamples to the conjecture and to specific proof steps, respectively. Accommodating these counterexamples requires a reconceptualization of the definition of polyhedron. In Section 4, we saw that reasoning about those refutations involved filling out a dialectical tier. It is also

important that community involvement plays an essential role in the reasoning. The history of the proof is recounted using the story of a class attempting to solve the problem. But it is clear that the refinements of definition, the counterexamples, and the resulting proofs are all products of dialectical engagement between the initial prover and an audience.

This community involvement plays out on a historical scale, as in (Lakatos 1976), but also in other collaborative problem-solving. For example, communities play a key role in crowdsourced mathematics such as Mathoverflow and (Mini-)Polymath. These activities have been studied by Ursula Martin and Alison Pease who connect the activities undertaken to the method of proofs and refutations (Martin and Pease 2013a, b). Building on these datasets, in later work with Joseph Corneli and other colleagues, they model mathematical arguments by analyzing how the discourse unfolds (Corneli et al. 2019). They use what they call Inference Anchoring Theory + Content to further understand how these dialogues introduce and track salient features of mathematical progress. This is done by examining the dialogue within a community of mathematicians.

So far we have considered the role that an external audience plays in problem choice. We have also looked at how we could identify communities in terms of the argument schemes that they allow or even disavow. But the final role of mathematical audiences is best described as an internal one. The core idea is that mathematical audiences play an important role in the development of proofs and other mathematical arguments. Valentin Bazhanov, for example, has argued that proofs are an appeal to a scientific community (Bazhanov 2012). A new result is offered to the community as a purported proof. To become a proof, the community must be persuaded that the argument is reliable and reproducible. This decision is borne out in dialogue.

Catarina Dutilh Novaes argues for a dialogical conception of proof (Dutilh Novaes 2021). According to the dialogical conception, the concept of proof is an embodiment of a semiadversarial dialogue between two people: Prover and Skeptic. Skeptic grants certain premises to Prover. Prover then puts forward statements claimed to follow from the premises. At each move, or inference, Skeptic has three potential moves. He brings up objections, counterexamples, and requests for clarification. If all of the steps are indefeasible, that is, without counterexamples, the proof is a winning strategy for Prover. Of course proofs are not usually dialogues between two interlocutors following Prover–Skeptic rules. Dutilh Novaes argues that the Skeptic is actually internalized into the method itself. In this sense, Skeptic, who is a particular kind of audience, plays a vital role in what constitutes proof.

In addition to the internalized skeptic, one of us has argued that the audience under consideration in a proof is actually a universal audience (Ashton 2021). This is a concept drawn from Perelman and Olbrechts-Tyteca: An argument to the universal audience is one that is meant to convince all people. The universal audience itself is an imagined audience – an arguer can never stand before all people and ask whether or not they assent to his argument. Rather, the universal audience is an abstraction from experiences with real audiences that the arguer has encountered. The account applies also to mathematics: mathematicians encounter real audiences in their education and practice. In addition, they learn what certain groups of real audiences

react to – knot theorists accept inferential moves involving diagrams that certain algebraists might not. By considering all these different, real audiences, mathematicians construct an internalized audience which reflects the standards of reasonableness found within each audience. In this way, mathematicians construct their own universal audience.

According to both Dutilh Novaes and Ashton, there is an internalized audience which, through experience with real audiences, is vital to proof development. In one case, a proof is an argument to an internalized skeptic. In the other, it is an argument to an internalized standard of reasonableness. Whether the mathematician aims to convince the adversarial skeptic or "all reasonable people," there is clearly a role for the audience in standards of proof. In other words, proofs should be examined in terms of the audiences who could have influenced them.

Communities, conceived of as audiences to mathematical arguments, are a vital component of the practice on a number of levels. The assurance of an interested audience and the contact of minds can influence research programs and problem choice. The ongoing dialogue between provers and the mathematical community helps to verify results, introduce new methods, and clear hidden assumptions. In addition to these explicit, external roles, the internalized audience plays an important role in proof development and the associated normativity. Given all this, it's clear that no account of argumentation in the philosophy of mathematics could be complete without a thorough discussion of the role of these audiences.

Abstract

What does rhetoric, the study of argument and persuasion, have to do with mathematics, the study of patterns of relations (in number, geometry, topology, . . .) and their necessary entailments? The following chapter explores a growing body of research that seeks to address this question – scholarship that pursues the counterintuitive idea that rhetoric and mathematics might just have more to do with each other than we have been taught to believe. It argues that many of the seeds for contemporary study of rhetoric and mathematics emerge from Imre Lakatos's *tour de force*, *Proofs and Refutations*. There we find a rejection of mathematical formalism and the *telos* of absolute truth, an emphasis on the arts of mathematical practice, and a model of informal mathematics that positions rhetorical argument as an engine of mathematical innovation. The book thus opens the way, however unintentionally, for understanding informal mathematics as intimately intertwined with rhetorical practice. The chapter concludes with discussion of how contemporary scholars have built upon Lakatos's work and, in recent years, expanded beyond it.

1 Introduction

Since the rise of modern science in the sixteenth century, rhetoric and mathematics have been estranged – the former aligned with persuasion and manipulation, the latter with rationalism and pure reason (see Cifoletti 2006). (Giovana Cifoletti's work shows that prior to the sixteenth century rhetoric and mathematics were not diametrically opposed – that instead they were often profitably interconnected – suggesting that the current opposition is both historically particular and mutable.) Only recently has this perspective started to break down, with increasing numbers of scholars becoming interested in how rhetoric and mathematics intertwine. In this essay, I suggest that one way to understand the story of the slow emergence of research on rhetoric and mathematics – and the themes and contours therein – is to consider closely the groundbreaking work of Imre Lakatos's *Proofs and Refutations* (1976). There we will find many of the seeds of what has grown into a lively interdisciplinary study of the myriad rhetorical-mathematical entanglements that mark our age.

Soon after its original publication, *Proofs and Refutations* was recognized as a *tour de force* in the study of reasoning and concept formation in mathematics. It was, in Thomas Kuhn's words, "a brilliant analysis of the permissible rejoinders to mathematical refutations [that] provides the most telling arguments I know against a naïve falsificationist position." (Kuhn 1970, pp. 13–14). Philip Kitcher, another luminary in the philosophy of science and mathematics, opined, "*Proofs and Refutations* presents a program that needs to be taken seriously by anyone who is interested in the nature of mathematics. We shall understand mathematics better when Lakatos's ideas are developed and we gain a clear idea of their merits and shortcomings" (1977, pp. 782–783). In the last two decades *Proofs and Refutations* has begun to garner the attention it deserves, specifically among scholars interested in the history and philosophy of mathematical practice, yet in the midst of that literature little attention has been paid to the role of rhetoric in Lakatos's treatise. Attending to *Proofs and Refutations* more closely, I argue, reveals many of the ways that rhetoric and mathematics intertwine, granting us an opportunity to see how contemporary research into rhetoric and mathematics has both built upon and extended Lakatos's work.

What made *Proofs and Refutations* a *tour de force*? First, in focusing on informal rather than formal mathematics the book challenged the orthodox formalist model dominant within mathematics at the time – a model that emphasized the proof procedures of formal mathematics over the practices of innovation characteristic of informal mathematics (this captures Lakatos's sense of formalism, and he appears to be targeting Hilbert's (1925) work as a classic example; on formalism as a system of

logical rules that one "plays" as one might play chess see Rotman 2000, pp. 5–7). Second, it was unique in its fallibilist approach, rejecting as pathological the *telos* of absolute truth, which according to Lakatos could never explain the growth of mathematics or the evolution of the field. Third, it established the importance of historical context not only for understanding but, more crucially, for practicing mathematics. And finally, it argued for a dialectical heuristic that rendered issues of mathematical criticism, conceptual polysemy, and conceptual translation vital to the growth of mathematical knowledge. In so doing, *Proofs and Refutations* not only offers a counterstatement to any prevailing emphasis on proof, justification, and infallibility in studies of mathematics, it also illustrates the role of argumentation and symbolic action in mathematical concept formation. The book thus opens the way, however unintentionally, for understanding informal mathematics as intimately intertwined with rhetorical practice.

To develop these points, the chapter begins with close textual analysis of Lakatos's treatise so that we might see how rhetoric (as the study and practice of argument) emerges as crucial to the practices of mathematical innovation. From that vantage, we can then trace the paths that scholars have taken to extend Lakatos's work, expand our grasp of mathematical practice, and begin to develop an understanding of mathematics not as the language of truth but as a powerful translation machine that is rapidly reshaping the social-material world.

2 The Problems with Formalism

On the first page of his introduction, Lakatos positions his book as a counterstatement to mathematical formalism. Formalism – the notion that in order for mathematics to be irrefutably true it must be "formalized" into an internally consistent language governed by a set of purely logical rules – dominated the philosophy of mathematics in the mid-twentieth century. Lakatos viewed formalism as a kind of mathematical dogma that fundamentally misrepresented mathematical practice:

> Formalism disconnects the history of mathematics from the philosophy of mathematics, since, according to the formalist concept of mathematics, there is no history of mathematics proper. . .. Formalism denies the status of mathematics to most of what has been commonly understood to be mathematics, and can say nothing about its growth. None of the 'creative' periods and hardly any of the 'critical' periods of mathematical theories would be admitted into the formalist heaven, where mathematical theories dwell like the seraphim, purged of all the impurities of earthly uncertainty (Lakatos 1976, pp. 1–2).

This passage establishes Lakatos's critiques of the formalist model of mathematics and gives a sense of his authorial voice (sharp, irreverent, sometimes biting; these characteristics of voice matched, by all reports, Lakatos's scholarly personality – see Larvor 1998; Kampis et al. 2002; Lakatos et al. 1999). The formalist desire for internal consistency and validity leads one to believe that the most important question to ask of a mathematical argument is whether there is a series of valid

inferences from the premises to the conclusion. If there is not – if the argument is somehow logically inconsistent due, for example, to conceptual development – then the argument is deemed irrational. This is why Lakatos argues formalism cannot account for the growth of mathematical knowledge: formalists separate creation from justification – or informal mathematics from formal mathematics – and then argue that only the latter can be studied and established as purely rational. The bifurcation is misguided for Lakatos because it implies that informal mathematics is an irrational or quasi-rational practice.

Lakatos uses both style and content to develop his critiques of formalism. Instead of a series of statements, deduced from accepted axioms, leading to a conclusion (a common argumentative form in mathematics), the reader enters a dialogue between a "Teacher" and his students wherein each student loosely corresponds with one or several actual mathematicians whose work was important to the discussion at hand. The purpose of the class is to determine the mathematical relationship between the number of "edges," (E) "vertices," (V) and "faces" (F) of polyhedra. The dialogue begins with the Teacher reminding the class that in the previous lesson they "arrived at a conjecture concerning polyhedra, namely, that for all polyhedra $V - E + F = 2$. We tested it by various methods. But we haven't yet proved it. Has anybody found a proof?" Lakatos then has his first student character, Sigma, respond, "'I for one have to admit that I have not yet been able to devise a strict proof of this theorem. As however the truth of it has been established in so many cases, there can be no doubt that it holds good for any solid. Thus the proposition seems to be satisfactorily demonstrated.' But if you have a proof, please do present it" (1976, p. 7). As the dialog unfolds, Lakatos weaves in historical footnotes pointing to the historical specificity of particular statements or arguments. In this case, he is actually quoting Euler, who was the first mathematician to come up with the polyhedra conjecture. The remainder of the book proceeds accordingly, with different students – each representing a host of different mathematicians who worked on polyhedra – raising counterarguments to the original conjecture, revising the original, or proposing a novel conjecture – all of which traces the historical process of growth of mathematical knowledge of polyhedra. In so doing Lakatos dramatizes the deliberative process on the Euler conjecture that took place within mathematical communities over several centuries.

If such stylistic choices (use of dialogic form; emphasis on historical context) were not enough to clarify Lakatos's views of formalism, he makes his position explicit in a way only Lakatos can. After several counterexamples to Euler's original conjecture, Lakatos has Delta play the formalist: "I turn in disgust from your lamentable 'polyhedra,' for which Euler's beautiful theorem doesn't hold: I look for order and harmony in mathematics, but you only propagate anarchy and chaos" (1976, p. 19). Lakatos then clarifies that throughout history mathematics has been plagued by such thinking, leading many a great mathematician to reject counterexamples to particularly "elegant" theorems as "monsters," aberrations better ignored than seriously addressed. These "monster-barrers," as Lakatos calls them, dwell in a "formalist heaven" in which "order" and "harmony" are more important than the growth of mathematical knowledge. With each counterexample that emerges the

monster-barrer simply retreats to a safe haven, reducing the purview of the original theorem and labeling the exceptions monsters. Monster-barrers proceed thus because they believe the purpose of proofs is to "prove" a theorem irrefutably true. As such, they view the deductive style of proof that moves from proven premises through valid logical inference to an irrefutable conclusion (theorem) as the only legitimate form.

From the formalist perspective counterexamples are not simply problems to solve, they are dangerous – destructive of the order and harmony mathematics promises. Lakatos summarizes the consequences of formalist dogma near the end of *Proofs and Refutations*:

> As long as a counterexample was a blemish not only to a theorem but to the mathematician who advocated it, as long as there were only proofs or non-proofs, but no sound proofs with weak spots, mathematical criticism was barred. It was the infallibilist philosophical background of Euclidean method that bred the authoritarian traditional patterns in mathematics, that prevented publication and discussion of conjectures, that made impossible the rise of mathematical criticism. . . . Mathematical or scientific criticism cannot exist while we only appreciate a mathematical or scientific result if it yields perfect truth. . . . The idea – expressed so clearly by Seidel – that a proof can be respectable without being flawless, was a revolutionary one in 1847, and, unfortunately, still sounds revolutionary today (1976, p. 139).

Here Lakatos underscores how the formalist desire for certainty can function ideologically to quell criticism and obstruct mathematical growth. For Lakatos formalism is more about *ethos* than *logos* – more about capturing the *ethos* of authority of absolute truth than capturing the way mathematics actually develops. "Deductivist style hides the struggle, hides the adventure. The whole story vanishes, the successive tentative formulations of the theorem in the course of the proof-procedure are doomed to oblivion while the end result is exalted into sacred infallibility" Lakatos goes on to explain that this style "while claiming objectivity, in fact fosters a private guild-language . . . [and] suffocates criticism." "Deductivist style," Lakatos concludes, "tears the proof-generated definitions off their 'proof-ancestors,' presents them out of the blue, in an artificial and authoritarian way. It hides the global counterexamples which led to their discovery" (1976, pp. 142–144).

Ultimately, formalism – and the strict deductivist style it promotes – is a problem for Lakatos because it renders mathematics nothing more than a formal abstraction, ignoring any consideration of mathematical heuristic, plausible reasoning, and the evaluative language of mathematicians, who often judge certain results deep and some proofs more worthy of celebration than others. Formalism contends that static deductive rationality is *the* form of rationality proper, thus neglecting study of conceptual formation, conceptual change, and knowledge growth in mathematics. Formalists want to formalize mathematics so as to identify it with infallible truth but they can give no account of the content they formalize. In their narrow view of rationality and mathematical proof they leave little room for interaction between mathematical conjectures, proofs, and refutations that for Lakatos are absolutely

crucial to the growth of mathematical knowledge. Against this formalist backdrop he offers a dialectical heuristic that seeks to account for these processes.

3 A Dialectical Heuristic for Informal Mathematics

For Lakatos the dialectical unity of proofs and refutations is fundamental to mathematical innovation. Proofs do not merely prove, they allow the mathematician to deconstruct a conjecture, to establish its assumptions (lemmas), and thus to aid in the process of criticism through counterexample. Those counterexamples act as refutations that then lead the mathematician back to examination of the proof for hidden assumptions. Here one begins to see why Lakatos ultimately rejected Karl Popper's criterion of falsification for differentiating between science and nonscience (see Popper 1966). When one is confronted by a mathematical refutation, one does not simply cast out the conjecture as false and move on (as strict falsificationists would have it). Equally important, one does not simply retreat into a safe haven of validity (as exception-barring formalists would have it). One returns to the proof and attempts to improve it and the conjecture simultaneously. This is why the Teacher says early in the dialogue that, though it may sound counterintuitive due to prevailing formalist dogma, he is just as interested in "proving" false conjectures as he is true ones: many mathematicians, the Teacher laments, think

> that a proof necessarily proves what it has set out to prove. My interpretation of proof will allow for a false conjecture to be 'proved,' i.e. to be decomposed into subconjectures. If the conjecture is false, I certainly expect at least one of the subconjectures to be false. But the decomposition might still be interesting! I am not perturbed at finding a counterexample to a 'proved' conjecture; I am even willing to set out to 'prove' a false conjecture! (1976, p. 23).

In contrast to the simplistic and impoverished formalist notion of proof, Lakatos's sense of proof harkens back to the ancient Greeks before the rise of the Euclidean axiomatic method: "I propose," says the Teacher, "to retain the time-honoured technical term 'proof' for a *thought-experiment – or 'quasi-experiment' – which suggests a decomposition of the original conjecture into subconjectures or lemmas*, thus *embedding it* in a possibly quite distant body of knowledge" (1976, p. 9).

The consequences of defining proofs as "thought-experiments" are many: one immediately sees, for instance, that for Lakatos the purpose of proof is not to prove a conjecture but to open the way for analysis – the lifeblood of mathematical innovation. And this analysis, as it emerges in the book, is decidedly dialectical, tacking back and forth between proofs and refutations and in the process transforming the concepts involved. As Alpha points out, "Discovery does not go up or down [as deductivist style would lead one to believe], but follows a zig-zag path: prodded by counterexamples, it moves from the naïve conjecture to the premises and then turns back again to delete the naïve conjecture and replace it by the theorem. Naïve conjectures and counterexamples do not appear in the fully fledged deductive structure: the zig-zag of discovery cannot be discerned in the end-product" (1976, p. 42). Indeed, much of

Lakatos's book is designed to tear away the mask of deductivism to reveal the dialectical argumentative structure within the doing of mathematics. The dialogue dramatizes this dialectical argumentative structure with the concept "polyhedron," showing how the dialectical process, which took place over several centuries, changed and improved the concept.

Consider, for example, how the proof-deconstruction of the original Euler conjecture immediately reveals its hidden assumptions. On the first page of the dialogue the Teacher, in response to Sigma's (Euler's) request for a proof, states the following:

> In fact I have one. It consists of the following thought-experiment. *Step 1*: Let us imagine the polyhedron to be hollow, with a surface made of thin rubber. If we cut out one of the faces, we can stretch the remaining surface flat on the blackboard, without tearing it. The faces and edges will be deformed, the edges may become curved, but V and E will not alter, so that if and only if $V - E + F = 2$ for the original polyhedron, $V - E + F = 1$ for this flat network – remember that we have removed one face. . . . *Step 2*: Now we triangulate our map – it does indeed look like a geographical map. We draw (possibly curvilinear) diagonals in those (possibly curvilinear) polygons which are not already (possibly curvilinear) triangles. By drawing each diagonal we increase both E and F by one, so that the total $V - E + F$ will not be altered. *Step 3*: From the triangulated network we now remove the triangles one by one. To remove a triangle we either remove an edge—upon which one face and one edge disappear, or we remove two edges and a vertex—upon which one face, two edges and one vertex disappear. Thus if $V - E + F = 1$ before a triangle is removed, it remains so after the triangle is removed. At the end of this procedure we get a single triangle. For this $V - E + F = 1$ holds true. Thus we have proved our conjecture (1976, pp. 7–8). (In the book Lakatos provides illustrations to help the reader follow this proof procedure.)

I cite the dialogue at length here because it reveals much about Lakatos's dialectical heuristic. Note that in the very first step we see the Teacher imbedding Euler's naïve conjecture in a "quite distant body of knowledge," namely, topology. (Some might find suspicious the fact that Lakatos begins in the middle of the story, so to speak, but the purpose of the dialogue is not to present an historical account but rather a rational reconstruction. I will deal with this distinction and its implications later in the chapter.) Euler conceived of polyhedra as solid three-dimensional objects. The first major innovation was to redefine polyhedra as systems of faces, edges, and vertices with two dimensions, one dimension, and zero dimensions, respectively. The turn to topology to prove Euler's conjecture was Cauchy's breakthrough 55 years after Euler, in 1813. This move is a crucial part of mathematical invention because it stretches the original Eulerian concepts beyond their initial conceptualization. In so doing, it introduces the change and growth in mathematical concepts that calls for a dialectical understanding of mathematical practice in the first place.

Where does that change and growth come from? It emerges out of the interaction between seemingly unrelated bodies of knowledge. Consider, for example, how the turn to topology shifted the intellectual terrain: instead of imagining polyhedra as solid three-dimensional objects, one can imagine them as skins stretched into two-dimensional topological surfaces. This reimagining of the problem enabled a novel mathematical proof of the Euler conjecture to emerge that revealed several hidden

presuppositions. For when one follows the Teacher's proof-procedure one can more easily detect counterexamples that expose assumptions in the argument. All one need do is envision instances in which the proof-procedure fails: imagine, for instance, a smaller cube set *inside* a larger cube (called a "nested cube"). This counterexample reveals a significant hidden assumption in the original conjecture, namely, that "*a polyhedron is a solid whose surface consists of polygonal faces*" (1976, p. 14). If this definition stands then the nested cube is a polyhedron and Euler's conjecture must fall; that is, unless one is willing to return to the proof and refine it. In Lakatos's dialogue this is a dynamic process, for mathematicians do not respond uniformly to counterexamples. Some (perhaps most according to Lakatos) respond simply by redefining the concepts in question to quarantine the counterexamples (this is the monster-barring technique). Delta, impersonating Jonquières's response to the nested cube counterexample in the late 1800s, redefines a polyhedron as "*a surface consisting of a system of polygons,"* effectively transforming the nested cube into "*two* polyhedra – two surfaces, one completely inside the other" (1976, pp. 14–15). Against this new definition of polyhedra, however, new counterexamples arise, to which Delta (this time impersonating Möbius) responds "of course I did not mean that any system of polygons is a polyhedron. By polyhedron I meant *a system of polygons arranged in such a way that (1) exactly two polygons meet at every edge and (2) it is possible to get from the inside of any polygon to the inside of any other polygon by a route which never crosses any edge at a vertex*" (1976, p. 15). Thus we see – even in the most conservative monster-barring responses – the growth of our knowledge of polyhedra through the interactions and translations between geometry and topology. Those processes stretch the original conception of polyhedra; they are at once moments of innovation and enablers of knowledge growth.

For Lakatos, what is also important here is that one sees a dialectical heuristic for informal mathematics begin to emerge, in this case between definition and counterexample. Although monster-barring is the most simplistic form of this dialectic (a kind of negative dialectic), it nevertheless shows a rational pattern of call and response, and in the process the concept of polyhedra *becomes more precise and sophisticated*. The purpose of *Proofs and Refutations* is to develop an understanding of the complex dialectical patterns of argument that animate informal mathematics. Lakatos eventually codifies this pattern (or heuristic) of informal mathematical reasoning in his first appendix:

> *(1) Primitive conjecture. (2) Proof (a rough thought-experiment or argument, decomposing the primitive conjecture into subconjectures or lemmas). (3) 'Global' counterexamples (counterexamples to the primitive conjecture) emerge. (4) Proof re-examined: the 'guilty lemma' to which the global counterexample is a 'local' counterexample is spotted. This guilty lemma may have previously remained 'hidden' or may have been misidentified. Now it is made explicit, and built into the primitive conjecture as a condition. The theorem – the improved conjecture – supersedes the primitive conjecture with the new proof-generated concept as its paramount new feature* (1976, pp. 127–128).

Lakatos then notes that while these four steps are the most common in informal mathematical reasoning they are sometimes augmented by the following three:

"*(5) Proofs of other theorems are examined to see if the newly found lemma or the new proof-generated concept occurs in them: this concept may be found lying at cross-roads of different proofs, and thus emerge as of basic importance. (6) The hitherto accepted consequences of the original and now refuted conjecture are checked. (7) Counterexamples are turned into new examples – new fields of inquiry open up*" (1976, pp. 127–128). These seven capture Lakatos's understanding of the broad patterns that inform the practice of doing informal mathematics, yet they are not immutable and they do not compose a method. No, for Lakatos anything that evolves has within it the capacity for its own self-overcoming.

4 The Principle of Fallibility

It would be easy to interpret Lakatos's seven steps as *the method* of reasoned argument in informal mathematics. To do so, however, would be to miss the principle of fallibility at the heart of his thinking. A crucial dimension of his heuristic, in other words, is that it remains open to the new and the unimagined. The purpose of the dialectic of proofs and refutations is not – in contrast to formal mathematics – infallible truth; the purpose is to understand the arts of mathematical invention and the processes of mathematical knowledge growth. Unlike Hegelian dialectic, Lakatos's dialectical thinking never ends in an ultimate synthesis (for discussion of Hegelian and Lakatosian dialectics, see Dusek 2015; Larvor 1998). Every "proved" theorem is always provisionally proven and, if truly innovative, always opens up "new fields of inquiry." Moreover, the set of procedures he offers are not laws of reasoning; they are, according to Lakatos, a list of the most common patterns of arguing and thinking in informal mathematics. As he stated in his original thesis, "Nothing bores me more than the hopeless effort to build up a perfect *system* of heuristic rules. One can point out some tentative rules which may help us to avoid some deeply entrenched wrong heuristic habits. But attempting to turn heuristics into a system of rules which claim to take account of the art of discovery seems to me pathological." (Lakatos 1961, p. 75).

At the end of the dialectical process, then, one might have a better theorem, more sophisticated concepts, and increased knowledge of the mathematical objects under consideration, but one will not have absolute truth. The process increases one's knowledge and, for Lakatos, helps one approach the truth; but one must remain ever open to the possibility of the new and the unanticipated. One must avoid the *hubris* of certainty. Lakatos conveys this clearly in an early encounter between Beta and the Teacher. Overcome by this *hubris*, Beta rejects the idea of naïve conjectures as "guesswork," calling his conjecture "insight," to which the Teacher responds, "I abhor your pretentious 'insight.' I respect conscious guessing, because it comes from the best human qualities: courage and modesty" (1976, p. 30). Here we see a kind of Lakatosian mathematical identity emerging in which the dogma of the absolute is sternly rejected for the courage and humility of fallibilism. Beta plays the part well: by the end of the dialogue he has transformed: instead of espousing a formalist's *hubris*, he turns full circle, observing that the belief that a "'proof' indubitably

establishes the truth of the naïve conjecture," that it produces a "certainty . . . beyond doubt . . . is only a symptom of lack of imagination, of conceptual poverty. It produces smug satisfaction and prevents the growth of knowledge" (1976, p. 87).

A keen reader might think Lakatos wants it both ways: he wants to reject absolute truth and champion knowledge growth simultaneously. But how does knowledge grow except by the accumulation of true statements about mathematical objects? Lakatos would not necessarily disagree, given one adds an important qualification: mathematical knowledge grows as we accumulate more and more sophisticated provisionally true statements – provisional precisely because the possibility of a new counterexample emerging to the latest iteration of a theorem always exists; more sophisticated because the new statement has incorporated the previous counterexamples, transforming them into examples, and thus expanded the theorem's domain of validity. It is only one's "lack of imagination," as Beta put it, which closes one off from the possibility of future counterexamples and allows one to be filled with dogmatic certainty. Lakatos's concern is not with certainty per se but with its dogmatic obstruction of knowledge growth. As he clarifies at the end of *Proofs and Refutations*,

> The dominance of the exception-barring method shows how the Euclidean method can, in certain problem situations, have deleterious effects on the development of mathematics. Most of these problem situations occur in growing mathematical theories, where growing concepts are the vehicles of progress, where the most exciting developments come from exploring the boundary regions of concepts, from stretching them, and from differentiating formerly undifferentiated concepts. In these growing theories intuition is inexperienced, it stumbles and errs. There is no theory which has not passed through such a period of growth; moreover, this period is the most exciting from the historical point of view and should be the most important from the teaching point of view. These periods cannot be properly understood without understanding the method of proofs and refutations, without adopting a fallibilist approach" (1976, p. 140).

Thus, the principle of fallibility embeds in Lakatos's dialectical philosophy a skepticism (perhaps even a fear) of all absolutist claims. There is no single logic of mathematical invention. Mathematical invention is a practice that must be allowed to evolve in response to new problems. For Lakatos, however, this does not mean it is an irrational practice. To the contrary, he finds the need for a rational heuristic all the more essential precisely because of his mathematical fallibilism, which left unbalanced could render informal mathematics nothing more than a subjective guessing game. Part of Lakatos's dialectical task, then, is to walk a tightrope between rationalism and fallibilism, between reason and possibility. (Unfortunately, Lakatos loses this balance in his later work on scientific research programs, where he attempts to establish a unifying logic of science that can be used to demarcate between science and nonscience.) One can see the delicacy of this task best in the dialectic Lakatos constructs between problem situations and historical contexts.

5 Problem Situations and Historical Contexts

When one considers the treatment of time in *Proofs and Refutations*, one begins to see how cunningly its form reinforces its content. For just as the art of mathematical invention "follows a zig-zag path," as Alpha notes, so the reader's path tacks back and forth between the dialogue and the historical footnotes. This method of presentation humanizes mathematics even as it reinforces Lakatos's balance of rationalism and fallibilism; it also constructs a useful dialectical tension between rational reconstruction of the problem situations relevant to polyhedra and the particularities of historical contexts out of which these problem situations emerged.

One of the great rhetorical benefits of Lakatos's temporal style is the way in which it rehumanizes mathematics. We have already observed how the deductivist style of presentation can dehumanize mathematics, shrouding it in a fog of mysticism for the uninitiated. Both the dialogue and the historical footnotes challenge this tendency. Instead of starting with the end product (the latest theorem of polyhedra) and then being asked to use it to solve similar or related problems, Lakatos begins with Euler's original conjecture and traces the dialectical story from there; but his is a story feathered with surprisingly flawed characters – at once intelligent and small-minded, curious and arrogant, generous and impatient. Lakatos's students – meant to represent many of the greatest mathematicians of the eighteenth and nineteenth centuries – are a far cry from the heroic image of the individual mathematical genius one often finds in histories of mathematics and in mathematics textbooks. Flawed as they are, these characters subtly encourage a questioning, irreverent, skeptical habit of mind that – as a resource of criticism and counterexample – is crucial for mathematical innovation. Equally important, Lakatos's characters allow the reader to identify with the mathematical "geniuses" of the past and view their accomplishments as incremental, collaborative, and, most importantly, within the realm of the possible (see Marchi (1976) for a similar argument about the humanizing effects of Lakatos's work).

In addition to humanizing mathematics, playing the dialogue against the historical footnotes allows Lakatos to negotiate –without attempting to resolve – the dialectic between fallibilism and rationalism. To understand Lakatos's position here we need to distinguish between rationalism in individuals and rationalism in historical processes. Lakatos accepted that individuals were both rational and irrational, and his dialogue accentuates both, but he also thought that if one accepts the premise that mathematics does in fact progress toward mathematical truths, then as a historical process mathematics must have a rational heuristic guiding it. That is why, even as he has individual characters animate his dialogue, the dialogue itself is not interested in individual rationalism so much as it is in developing a rational reconstruction of the problem situation related to polyhedra and teasing out the rational heuristic guiding informal mathematics. (This is not to say that individual rationalism plays no role in *Proofs and Refutations*; to the contrary, Lakatos positions individual rationalism in dialectical tension with the rationalism of mathematics itself, which results in an interesting de-centering of individual agency. I address this issue in the next section.) In isolation, the dialogue's rational reconstruction

would take Lakatos toward the philosophical dead-end of static rationality (see Lakatos 1976, p. 93); the historical footnotes help him avoid this, introducing the fragmented, irregular, discontinuous nature of historical specificity and thus maintaining the dialectical tension between rationalism and fallibilism. (Lakatos argues against the static rationality of logical positivism – itself an outgrowth of the merger of formal logic and mathematics in the nineteenth century – because it treats conceptual evolution as an irrational process and insists on fixed conceptual meanings.) Lakatos follows Popper in this respect, rejecting the notion of historical necessity that Popper and many others saw in Hegel's dialectic (see Popper 1966). For to accept historical necessity would be to reduce "free human beings to the status of mere conduits for world historical forces" (Larvor 1998, p. 78), erasing the openness and possibility that Lakatos positions as fundamental to mathematical innovation.

One might say in the end that Lakatos uses the dialogic form to bend and mold the fragmentary, irrational material of history into a rational, coherent narrative. However, he does not conceal that history, nor its role as constitutive of possibility and thus, for Lakatos, of mathematical innovation itself.

6 Natality: The Emergence of Rhetorical Study of Mathematical Discourse

Having traced the development of Lakatos's dialectical heuristic for informal mathematics and some of its philosophical implications, what now can be said of the relationship between rhetoric and mathematics? Wherein lie the Lakatosian seeds for study of their imbrication? Perhaps the best way to address these questions is to examine the earliest scholarly efforts to explicitly link the two fields.

While *Proofs and Refutations* advanced a paradigmatic shift in focus in philosophical circles from formal to informal mathematics, the field of rhetorical studies also underwent a paradigm shift in the mid-twentieth century. This is why, when contemporary scholars claim mathematics has rhetorical dimensions *they are not claiming math is merely another form of persuasion, deception, or manipulation*. Surely mathematics can be put to such ends, as many scholars have shown (see Gould 1996; Rotman 2000; O'Neil 2016), but in examining the connections between rhetoric and math, contemporary scholars often have something different in mind. Indeed, the old senses of rhetoric as oratory, or persuasion, or, in Aristotle's words, "the faculty of discovering the possible means of persuasion" (1924, p. 15; 1.2, 1355a) must be temporarily put aside if we are to understand the deeper entanglements between rhetoric and math. The possibility for study of those entanglements emerged in the twentieth century out of a recalibration that shifted the field of rhetoric from a narrow focus on public oratory to a broader examination of argumentation and other forms of symbolic inducement. Out of the work of scholars like Kenneth Burke (1945, 1957, 1969), Chaim Perelman (1982), and Lucie Olbrechts-Tyteca (Perelman and Olbrechts-Tyteca 1969), a novel theoretical platform was established for beginning to think from a rhetorical perspective about the role of

argument in mathematical concept formation as well as the role of mathematics in political discourse (its influence on public policy, for instance; see Schiappa 2021 for a survey of this research). That potentiality, however, lay fallow for several decades, not taken up in earnest until Philip Davis's and Reuben Hersh's pioneering essay "Rhetoric and Mathematics," which not by chance was published 11 years after *Proofs and Refutations* in 1987 (in fact, they published a different version of this essay in their book *Descartes' Dream* (1986), and Hersh's indebtedness to Lakatos can be traced back to Hersh (1979)).

Philip Davis and Reuben Hersh were both trained mathematicians, but they had read Lakatos's work and they were intrigued by Perelman's and Olbrechts-Tyteca's new theory of rhetoric as the study of argument. Their real interest, however, lay in how the study of mathematical argument both within and outside the field might advance scholarly understanding of mathematical innovation, mathematics pedagogy, and the influence of mathematics in matters political. Their essay was the first to establish substantive connections between rhetoric and mathematics, and they showed "that mathematics is not really the antithesis of rhetoric, but rather that rhetoric may sometimes be mathematical, and that mathematics may sometimes be rhetorical" (Davis and Hersh 1987, p. 54). In their essay one gains the double sense in which Davis and Hersh mean to discuss rhetoric and mathematics: in the first sense they consider how mathematics is *used* rhetorically in other fields (in economics, for example). In the second sense Davis and Hersh maintain that there are "rhetorical modes of argument and persuasion" (p. 54) at play in the *doing* of mathematics. Here, like Lakatos, they are interested in showing the non-foundational nature of mathematical proof.

Already in the first beginnings of contemporary study of rhetoric and math, then, one can detect affinities with Lakatos's work. In calling for study of the rhetorical modes of argument within mathematical communities, Davis and Hersh are clearly extending Lakatosian principles, especially the embrace of fallibilism and rejection of formalism. But they also go beyond Lakatos, who thought of rhetoric as oratory and persuasion and so would have rejected the centrality of "rhetorical modes of argument" in mathematical practice. Yet if we shift to a more contemporary notion of rhetoric as the study of particular arguments and why they become compelling to particular audiences, then the idea of analyzing practices of mathematical argument from a rhetorical perspective begins to make more sense. Add to that Davis's and Hersh's call to study the ways mathematical discourse increasingly influences public culture, and one has a compelling case for the study of both the force of rhetorical argument in mathematics and the force of mathematics in the traditional rhetorical domains of public deliberation.

Much of the work on rhetoric and mathematics since the 1980s has followed the two-fold approach of Davis and Hersh, either investigating argumentation among mathematicians or the mobilization of mathematics within other contexts (see Ashmore 1997; Bernard 2003; Hunt 1991; McCloskey 1998; Mercer 2006; Merriam 1990; Miller 2003; Potter et. al. 2016; Wynn 2009). Deirdre McCloskey's (1998) work on the rhetoric of economics, for instance, examines the rhetorical force of mathematics among economists – taking up Lakatos's critiques of formalism and

extending them to criticize economic positivism, which McCloskey shows is often more about reputation and authority (e.g., ethos) and using math as a cudgel than it is about expanding our knowledge or understanding of economic processes. Likewise, James Wynn's (2009) study of how mathematization changed the field of Biology traces the strategies of argument for and against mathematical approaches to biological inquiry, teasing out the topoi of mathematical arguments and how they slowly transformed the concept of evolution and rewrote biological epistemology.

A number of scholars have also taken up the other strand of Davis's and Hersh's original study, examining everything from how mathematicians argue with one another to how rhetorical style influences student perception of and identification (or dis-identification) with mathematics (Ernest 1999; Aberdein 2009; Aberdein and Dove 2013; Carrascal 2015). (A broad collective of researchers is now embracing Andrew Aberdein's description of informal mathematics as a "species of argument" that has more in common with "ordinary" or "informal" argument than a finished axiomatic-deductive proof. Begoña Carrascal shows how the study of the practices of mathematical invention can enhance the reasoning skills of student mathematicians and thereby improve math pedagogy.) Numerous studies of mathematics education, for instance, link formalism with an axiomatic rhetorical approach in the classroom, which tends to alienate students while communicating that mathematics is an abstract language of truth primarily about rule-driven problem-solving (Boaler 2000; Rav 2007; Ho and Hedberg 2005).

These studies of rhetoric and mathematics have taught us much, yet the notion of rhetoric they deploy remains fairly traditional in flavor. By that I mean to say that these studies are primarily interested in issues of "suasion" and how particular arguments either persuade or dissuade particular audiences (whether of mathematicians, biologists, economists, or lay citizens). There is, however, a different sense of "argument" operative in *Proofs and Refutations* that a few rhetorical scholars have built upon in the twenty-first century. To see this different sense of argument, consider how much analytic work the concept "argument" does in Lakatos's analysis. Consider, for instance, how the *performance* of argument in *Proofs and Refutations* demystifies and humanizes mathematical practice. By dramatizing mathematical arguments over polyhedra Lakatos shows that, contrary to popular belief, the practices of arguing and reasoning in informal mathematics are strikingly similar to forms of argument in other fields of inquiry. Most serious inquiry goes through a process of making claims (conjectures), seeking evidence to support those claims (confirming examples), engaging with counterexamples, attending to the warrants (hidden assumptions) those counterexamples reveal, making those warrants explicit (lemma incorporation), and either rebutting the counterexamples or qualifying one's argument in response to the counterexamples. This process of arguing and thinking will ring familiar to any student of Stephen Toulmin's *The Uses of Argument* (1958). It is a generic form of "proof construction" practiced in myriad disciplines.

But argument provides an even more fundamental service in Lakatos's work. For it is dialogic argument that enables him to map the topography of invention found in particular problem situations and historical contexts and thus begin to reveal the patterns of inventional practice in informal mathematics. Argument is the means by

which Lakatos fashions his rational heuristic. Argument is not necessarily constitutive of that rational heuristic for Lakatos – he considers himself to be *discovering* the patterns of thinking in the history of mathematics – but it is nonetheless an essential vehicle for *revealing* and *understanding* those patterns and for distinguishing between those that advance and those that obstruct mathematical knowledge growth. Productive patterns include an agonistic model of intellectual engagement, proof-deconstruction via thought-experiment, and translation procedures between seemingly unrelated bodies of knowledge; regressive patterns appear in the form of monster-barring and formalist commitments to static rationality. Argument thus plays an essential role in *understanding* mathematical innovation (a topic I examine extensively in Reyes 2020); it is simultaneously the mathematician's means for exploring uncharted territory and Lakatos's cartographic tool – his proverbial pen and ink. (One implication here is that argument plays a role in both mathematical innovation and mathematics pedagogy, for it is in the mode of *understanding – how* rather than *knowing* that a rhetorical-argumentation approach to mathematics is especially useful.)

In *Proofs and Refutations*, then, argument is not merely a means of communication, persuasion, and critique; it is also an analytic tool for discovering something new about mathematical practice. Equally important, for Lakatos the practice of argument in mathematics is positively linked with mathematical knowledge growth, such that argument becomes an engine rather than an obstacle to the growth of mathematics.

Over the last two decades rhetorical scholars have taken up and extended the notion of argument – and thus rhetoric – as an engine of mathematical invention. My earliest work on rhetoric and mathematics, for example, examined the invention of the Calculus and the rise of the concept of infinitesimals (Reyes 2004). In that study I wanted to show that rhetoric (as argument) was not merely a means to communicate or critique Newton's and Leibniz's ideas but, instead, actually *constituted* the idea of infinitesimals – one of the more important concepts in the history of mathematics. In this sense, we are no longer talking about the *rhetoric of* mathematics – how mathematicians argue and persuade one another, how math is deployed in other domains – but the *rhetoric in* mathematics – how argument and symbolic action function as constitutive agents within mathematical practice.

Two projects in particular exemplify how rhetoric plays constitutive roles in the arts of mathematical innovation. The first is Brian Rotman's semiotic approach to mathematics (see Rotman 1987, 1993, 2000), which culminates in his book *Mathematics as Sign*. The second is George Lakoff and Rafael Núñez's *Where Mathematics Comes From* (2000), which offers a cognitive-metaphorical paradigm for understanding mathematical practice (for extended analysis of these works see Reyes 2014). Rotman – another trained mathematician – shows perhaps better than any other how the dominant perspectives among mathematicians (either realism or formalism) conceal the materiality of mathematical discourse. One consequence, Rotman contends, is that mathematicians tend to accept metaphysical explanations of math (its a priori existence, for example) and ignore the embodied practices of inscription elemental to both formal and informal mathematics. As a result, the

means of production of mathematical knowledge are hidden and the constitutive work of the mathematical sign is systematically denied. Close study of the semiotics of mathematics, Rotman shows, leads to the conclusion that the meaningfulness of a mathematical statement does not come from a formal mathematical code but from the ideas that motivate those inscriptions, which emerge from outside of mathematics. To the keen reader, this will sound conspicuously similar to Lakatos's notion of concept stretching in which a particular thinker either stretches a concept outside of mathematics into a mathematical domain or vice versa. In either case, such practices, which both Rotman and Lakatos show are vital to mathematical innovation, remain invisible to the staunch formalist, for whom only the mathematical code matters.

Against Rotman's semiotic analysis, Lakoff and Núñez's approach appears comparatively more direct (though perhaps less philosophically rich). Absent from all the research on mathematics, Lakoff and Núñez contend, is analysis of the ideas implicit in equations (what Rotman called the "meta-code"), the ways mathematical ideas are weaved together in mathematical statements, and why the veracity of a mathematical statement comes from those ideas and their interdependence. "Many of the confusions, enigmas, and seeming paradoxes of mathematics," they explain, "arise because conceptual metaphors that are part of mathematics are not recognized as metaphors but are taken as literal" (2000, p. 6). Deliteralizing those metaphors will thus help clarify some of the conflicts within mathematics, but, they caution, doing so will not eliminate mathematics' metaphorical content: "Conceptual metaphor . . . [enables] us to reason about one kind of thing as if it were another. This means that metaphor is . . . a *grounded, inference-preserving cross-domain mapping* – a neural mechanism that allows us to use the inferential structure of one conceptual domain (say, geometry) to reason about another (say, arithmetic)" (2000, p. 6). Sophisticated mathematical ideas, Lakoff and Núñez argue, often weave several conceptual metaphors together; only through metaphoric analysis, then, can we begin to reveal their highly complex conceptual content (research building on this approach includes Fauconnier and Lakoff 2013; Confalonieri et al. 2018).

Coursing through all these disparate research projects, then, is an abiding interest in the ideas that animate mathematical statements, which for these authors is what makes math both meaningful and dynamic. More importantly, these books and articles have expanded the space for researchers to explore connections between rhetoric and math, whether through semiotic analysis, cognitive-metaphor analysis, or rhetorical analyses of mathematical invention. Scholars like Joseph Mazur, for example, have examined how the semiotics of math function in many ways like words, rendering tropological thoughts concrete through metaphor, analogy, and mathematical translation. Such translation practices simultaneously constrain and enable the ideas of the practicing mathematician, and Mazur contends that even conventional notions of mathematical beauty can be understood in semiotic terms: "Cultural predispositions of aesthetically persuasive symbols may play into our emotional appreciation of beauty." And in mathematics, he contends, beauty is at least partially "attributable to the illuminating efficiency of smart and tidy symbols" (2014, p. 220; along these lines also see Csiszar 2003).

Other scholars of the rhetoric *in* math have been, like Lakatos, more focused on invention than aesthetic convention. Joseph Little, for instance, has examined the importance of analogical inference in Hantaro Nagaoka's 1904 Saturnian account of atomic spectra. Nagaoka's rhetorical analogies "provided the underlying conceptual scheme for Nagaoka's discursive problem space, and in so doing licensed the axioms and subsequent lines of mathematical reasoning that would be seen by his audience as logically permissible in undertaking a solution" (Little 2021). Likewise, Lynn Stalling's (2000) and Kay O'Halloran's (2005) research examines the historical evolution of mathematical discourse, though in a more diachronic mode than Little. In study of the change of mathematical symbolics over time, O'Halloran shows that algebra's "mathematical symbolism developed as a semantic resource with a grammar through which meaning was *unambiguously* coded in ways which involved *maximal economy* and *condensation*" (2005, p. 97).

Taken together, these studies of the rhetoric *in* mathematics have helped break down the walls between the two fields, contributing to our understanding of the evolution of mathematics and helping scholars better grasp the arts of mathematical innovation, many of which are intimately connected (as Lakatos and others have now shown) with traditional rhetorical strategies of argumentation, analogical reasoning, metaphorical enfolding, and semiotic translation.

7 Extension: Mathematics as a Translative Rhetorical Force

My latest research extends many of the insights of the above literature while simultaneously pushing the boundaries of that literature. For coursing through the great diversity of research projects on rhetoric and mathematics is a general acceptance (my own early work included Reyes 2004) of the twentieth-century theory of rhetoric as the study of argument and symbolic action. As such, this research often finds itself tethered to "the symbolic," whether in the context of professional mathematicians or lay publics. And while that tethering enables a certain kind of scholarly focus on the discourses of mathematics, it also often tacitly reinforces a "two-worlds" philosophy that tends to separate "words" and "things." The problem here is that mathematics often begins with words and symbols and diagrams but ends with things – that is, with hardened mathematical objects that are themselves hybrids of human and nonhuman agency. Those mathematical objects are often combined into complex propositions that end up *mattering* precisely because, as Karen Barad eloquently put it, "matter is . . . not a thing but a doing, a congealing of agency" (2007, p. 184). Indeed, as any practicing mathematician can attest, when one does math one is not alone; instead, one interacts, thinks with, and thinks through different mathematical codes. And it is precisely the interplay of agencies (human, discursive, nonhuman) that give rise to a mathematical proposition that *matters* – one that can function as a *principle of composition* with the potential to transform the world. This is how mathematics underwrites the worlds of capital and technoscience – not because it is true in some transcendental sense but because it is a powerful form of discursive translation, collapsing distance by mobilizing traces, transforming

particularities of difference into stable similarities of form, and, because of that formal coherence, encouraging associations and combinations between phenomena that, left untranslated in the world, have no relation whatsoever. Those relations do not exist a priori, just waiting to be discovered; they are fabricated extensions of the existing collective. From this perspective, mathematical statements are not representations of reality, they are multipliers of reality.

To understand mathematical discourse and practice in this way, however, requires a new understanding of rhetoric not merely as the study of argument and symbolic action, but also (and perhaps more fundamentally) as the study of symbolic-material relations, how those relations emerge and become materially manifest, and how those manifestations ultimately transform and expand reality (humans included). In short, the goal is to understand how math functions as a translative rhetorical force. Only in this way, I argue, can we collapse the artificial distinction between the technical spheres of mathematical innovation and the public spheres of mathematical application. Only in this way do we explicitly begin to reject the bifurcation between words and things and begin to think of both in terms of relations and networks of relations – a basis from which we can begin to understand the traffic mathematics enables between symbolicity and materiality. From this relational perspective, the ultimate goal is to comprehend how the symbolic-material worlds of technical mathematical discourse become materially manifest and, in those manifestations, accelerate the becoming (the ontological transformation) of the collective of relations we call reality (for a more developed version of this position see Reyes 2019).

To describe math as a translative rhetorical force, then, suggests a certain kind of shift in our thinking about both rhetoric and mathematics. Associating mathematics primarily with the study of timeless, a-historical, a priori objects (as mathematical realists do) has alienated it from rhetoric, wherein history, culture, and context are crucial and must be taken seriously (Perelman and Olbrechts-Tyteca (1969) offer a classic critique of Descartes' mathematical ontology from this perspective). Likewise, associating rhetoric primarily with argument and persuasion has long alienated it from the mathematical arts of demonstrative proof and refutation. None of these associations, however, are permanent or essential, and one might say the liveliness of both rhetoric and math (as fields of study) can be measured by their capacities for evolution and diversification. If, however, we can begin to think of both in terms of the relations that form the networks that compose the social-material world, then we can escape their estrangement and begin to take their increasingly consequential relations seriously.

Thinking of both rhetoric and mathematics through the lens of relationality has real potential. Not only can it offer scholars an avenue of escape from the pieties of mathematical realism and formalism that Lakatos so effectively exposed, more importantly it promises a better explanation and understanding of both how mathematics evolves and how it has become the meta-discourse of our current social-material world. The ideologies of purification in mathematics – which can be found in most arguments for mathematical infallibility – come at a high cost, blinding us from the very practices that enable the emergence and articulation of new mathematical relations with enough agential force to unleash not only whole new realms of

math but also whole new worlds of social-material possibility (in Reyes 2020 I explore imaginary numbers as exemplars of this process). This is why I argue that, from a rhetorical-relational perspective, mathematics becomes both better understood and more interesting. From this perspective, math is not a truth-production machine; it is a collection of powerful translation machines. Or, put differently, a collection of languages and ways of thinking (for every language is a way of thinking) that translate those that learn to "speak" them just as much as they do the world that such "speaking" re-articulates. From this vantage point, one might ask not just "What problems can mathematics solve" but also "Who do we become when we think mathematically," "What becomes of the world through a particular mathematical lens," and "How do particular mathematical networks function as principles of composition." (By "principle of composition" I do not mean a principle of writing in a composition classroom but instead a principle out of which the networks of relations that compose our world emerge.)

Ultimately, mathematics can and should be understood in light of the networks and relations it renders, the ways it simultaneously concentrates and conceals power, the means by which it translates the objects of its gaze, the productive metaphorical structures it uses, and who we become when we do math. In short, it can and should be understood in its myriad rhetorical forms. Lakatos's work opened the way for such understanding and perhaps now one can see how more recent scholarship has built upon and extended his original insights. And while we have come some distance in grasping the links between rhetoric and mathematics since Lakatos, much work remains if we are going to come to grips with the increasing translative rhetorical force of mathematical discourse in the twenty-first century.

Abstract

Mathematicians often speak of conjectures as being confirmed by evidence that falls short of proof. For their own conjectures, evidence justifies further work in looking for a proof. Those conjectures of mathematics that have long resisted proof, such as the Riemann hypothesis, have had to be considered in terms of the evidence for and against them. In recent decades, massive increases in computer power have permitted the gathering of huge amounts of numerical evidence, both for conjectures in pure mathematics and for the behavior of complex applied mathematical models and statistical algorithms. Mathematics has therefore become (among other things) an experimental science (though that has not diminished the importance of proof in the traditional style). We examine how the evaluation of evidence for conjectures works in mathematical practice. We explain the (objective) Bayesian view of probability, which gives a theoretical framework for unifying evidence evaluation in science and law as well as in

mathematics. Numerical evidence in mathematics is related to the problem of induction; the occurrence of straightforward inductive reasoning in the purely logical material of pure mathematics casts light on the nature of induction as well as of mathematical reasoning.

Keywords

Mathematical conjectures · Bayesian · Logical probability · Problem of induction · Riemann hypothesis · Numerical evidence

1 Introduction

Mathematical practice cannot consist solely of someone's writing down mathematical proofs and someone else's publishing and reading them. That may be the final output (in formal pure mathematics), but there are many preliminary activities that must take place on the way. Much of it involves evaluating inconclusive evidence as to whether a hoped-for theorem is true and whether one's attempts at proving it are likely to succeed.

It is similar in the art of navigation (prior to google maps), and for the same reasons: navigation cannot consist just of paths from A to B. Back of house (in the metaphor of Reuben Hersh 1991), there must be work to plan how to find them, to choose among alternatives, and to estimate whether a developing path is on the right track. In mathematical research too, one must navigate a path to the final result, a polished proof, and there are probabilistic skills needed to evaluate progress.

Especially in the early stages of work on a problem, mathematicians need not merely hunches and beliefs, but ones that are as a matter of fact well supported by the evidence. The working mathematician must begin by asking questions like: Which of the many conjectures that could be generated are worth investigating? Which ones are relevant to the problem at hand? Which can be confirmed or refuted in some easy cases, so that there will be some indication of their truth in a reasonable time? Which might be capable of proof by a method in the mathematician's repertoire? Which might follow from someone else's theorem? Which are unlikely to yield an answer until after the next review of tenure? The mathematician must answer these questions to allocate time and effort. But not all answers to these questions are equally good. To stay employed as a mathematician, a proportion of these questions must be answered *well* (Franklin 1987).

The area where a mathematician must make the finest discriminations of this kind – and where he might, in theory, be guilty of professional negligence if he makes poor decisions – is as a supervisor advising a prospective Ph.D. student. It is usual for a student beginning a Ph.D. to choose some general field of mathematics and then to approach an expert in the field as a supervisor. The supervisor (after estimating that the student is capable of a Ph.D.) then selects a problem in that field for the student to investigate. In mathematics, more than in any other discipline, the initial choice of problem is the crucial event in the Ph.D.-gathering process. The problem must be unsolved at present, not being worked on by someone who is likely to solve it soon, but most importantly, tractable, that is, probably solvable, or at least partially

solvable, by three years' work at the Ph.D. level. It is recognized that of the enormous number of unsolved problems that have been or could be thought of, the tractable ones form a small proportion, and that it is difficult to discern which they are. The skill in rational evaluation of conjectures required of a supervisor is high.

The next stage in successful mathematical practice is applying for a grant. While it is not unknown to ask for money for already completed work, a grant application normally talks up the importance of an unsolved problem or general area, its "impact," and the applicant's prospects of making progress on it. Expert referees for grants will usually have rather fixed ideas on what problems in their fields are important, and as fellow pure mathematicians they will ignore the applicant's claims that the research will eventually lead to a cure for cancer and world peace. Thus much of the applicant's effort must go into arguing persuasively that the problem is at least largely solvable with the resources the grant will provide and that the applicant and team are the perfect people to do it. For established researchers, the correct strategy is to exhibit their track records and speak confidently of their expected timeline of results (several examples in Zeilberger 2012). It is more difficult in the case of early-career researchers, both for the applicant and the evaluators, as there is less track record to go on so the evaluators need to consider whether the applicant's approach is realistic in the light of both the problem and the applicant's background. They may be tempted to fall back on proxy indicators of "promise" such as "having been supervised by a Fields medallist."

None of that argument involves presenting proofs. It is probabilistic in nature but bears on the provability of theorems – and their provability with given resources, not their provability in principle.

With the grant won, or not, the next task is to work on the actual prospective theorems, developing insights and talking to fellow experts on the problem, and constantly evaluating the evidence that progress towards a solution is being made. We look at examples of evidence for several conjectures below.

It is not adequate to describe the relation of evidence to hypothesis as "subjective," "heuristic," or "pragmatic": although those descriptions may be true as far as they go. For the practice of evaluating conjectures to be successful there must be an element of what it is rational to believe on the evidence. The Bayesian perspective on evidence, to be explained below, gives a philosophical account of that.

2 The Relation of Conjectures to Proof

Although it is not the only possibility, in the practice of pure mathematical research consideration of the probability of conjectures is usually allied to the traditional view that the main aim of pure mathematics is to construct semiformal but rigorous proofs of theorems.

As one researcher describes the process:

> The computer is often used as an exploratory tool in problem solving. This exploratory analysis is very important in gaining insight into problems and theorems and often leads to

> new conjectures. Heuristic reasoning may then lead from the conjecture to a formal theorem whose validity leads itself to further numerical investigation. When these numerical investigations present overwhelming numerical evidence that the proposed theorem is true, the researcher sets upon a search for a mathematical proof. (Schuster 1985); a more extensive account in (Wilf 2008), many examples in (Borwein and Bailey 2004).

That is how mathematicians speak in cases such as the Riemann hypothesis, considered below, where evidence has been collected and published over a long timespan because a famous conjecture has resisted proof.

Although purely computational evidence is not generally publishable by itself, it is possible to prove some restricted cases of a conjecture and exhibit computational evidence that it holds more generally (e.g., Boij 1999).

However, there are some other possibilities for how probabilistic reasoning can work in mathematical practice, other than simply providing evidence towards a traditional formal or semiformal proof.

One is that there may be probabilistic proofs, that is, proofs or "proofs" that in their nature provide only a high probability that the result is true. A well-known case is probabilistic testing of primality, widely used in cryptography, where an algorithm delivers only a high probability that a number is a prime (Rabin 1980).

In the light of such examples, there has been some discussion of whether mathematicians should abandon their model of formal deductive proof and rest content with some probabilistic substitute (e.g., (Fallis 1997), discussion in (Easwaran 2009); related arguments in (Paseau 2015; Sørensen 2016)). A popular article on the topic titled *The death of proof* by the journalist John Horgan (1993) attracted some heated responses (e.g., (Krantz 2011), but some support in (Zeilberger 1993)) and by and large mathematical practice has remained committed to the deductive model of proof as the ideal. That ideal is likely to gain support from current projects on fully automated theorem provers (a progress report in (Ornes 2020)). The results may be hard for humans to survey, but they are fully deductive proofs which do not contain human errors and sloppiness.

We should also not forget the role of arguments from authority in mathematics. (Inglis and Mejía-Ramos 2009). While mathematics in principle offers the possibility of understanding any result by following its proof, it is impossible in practice to do that for all the results one must know. Mathematicians, like other people, rationally attribute high probability to the theorems signed off by respected experts. Refereeing depends on it. So does learning mathematics. (Consequences for pedagogy considered in (Aberdein 2019), Sect. 5.)

3 Applied Mathematics and Statistics: Understanding the Behavior of Complex Models

Even more than in pure mathematics, numerical evidence has come to the fore in the large areas of applied mathematics and computational statistics that have been opened up by the vast increases in computational power in recent decades. In such

fields, one is typically dealing with a very complex mathematical object such as a simulation of climate, whose mathematical properties are well beyond the reach of analytic methods or proof. Understanding how it works – that is, its internal behavior rather than its match with the modeled outside reality – can only be approached by experimenting with its output and applying normal (probabilistic) scientific methods for drawing conclusions from experiments.

A typical area for such work is computational fluid dynamics. One begins with a complex physical phenomenon which one hopes to understand, such as turbulence generated by nonbreaking surface waves in the ocean (Tsai et al. 2015). One replaces the physical phenomenon with some standard numerical simulation of it, which one can run on a powerful computer with various choices of parameters. The simulation is a strictly mathematical object whose relation to the physical phenomenon being modeled needs understanding; for one thing, typically the model is discrete and the physical phenomenon continuous (at least at the scale being considered). But experimental evidence is available that the model and phenomenon behave quite similarly, or there would be no point in the simulation. One can therefore hope to understand the modeled reality by experimenting with and analyzing the model.

The behavior of the simulation (now considered in abstraction from its role in imitating the phenomenon) is a purely mathematical question. In principle it might be addressed by solving equations and writing proofs, but almost always the simulation is too complex for that to be possible. One can only perform (numerical) experiments, that is, run the simulation with different choices of parameters (such as total energy in the system and various initial conditions), and see what happens. If the phenomenon to be explained sometimes occurs and sometimes does not, progress has been made in understanding its causes. But the different simulation runs are only samples of the simulation's mathematical behavior, so there is an essentially probabilistic inference from the runs to the overall behavior, just as there is for any conclusion from finite experimental evidence to a general law.

Something similar occurs in "big data" applications where one sets up an algorithm intended to solve some statistical problem such as fraud detection or handwritten character recognition. Before testing the system "in the wild" on real data, one often seeks first to understand its performance in principle – does it have the inherent capacity to find certain structures in data? (The question is particularly urgent if there is a shortage of real data; example in (Hoffmann et al. 2019).) That is a strictly mathematical question and so in theory subject to proof, but with a complex system of the sort typically used, proof is not attainable. So one tests it on synthetic data, that is, computer-generated data into which one has inserted structures of the kind one hopes the system will be able to detect. If the system detects them, something is known about its performance. A run with purely synthetic data is an experiment that gives rise to purely mathematical knowledge.

Or one may want to compare different available mathematical methods for a type of task, such as spatial prediction where again there is a shortage of real data. Simulated data give a sufficient quantity of data to evaluate the capacities of the different methods (e.g., Harris et al. 2010). Again, the numerical experiments result in a purely mathematical conclusion.

4 The Objective Bayesian Perspective on Evidence

There is no agreed account of what Bayesianism means, but here we present a version that is suitable as a theoretical framework for the evaluation of evidence for conjectures in pure mathematics (Taken from (Franklin 2011, 2016) but based on (Keynes 1921; Jaynes 2003)). It is the version called (fully) objective Bayesianism or logical probability.

It holds that the relation of evidence to conclusion is a matter of strict logic, like the relation of axioms to theorems in mathematics but less conclusive. Given a fixed body of evidence – say in a trial in court, or in a dispute about a scientific theory, or in evaluating numerical evidence for a mathematical conjecture – and given a conclusion, there is a fixed degree to which the evidence supports the conclusion. If we could agree just what the standard of "proof beyond reasonable doubt" is, then, in a given trial, it is an objective matter of logical fact whether the evidence presented does or does not meet that standard, and so a jury is either right or wrong in its verdict on the evidence.

It is not essential to the Bayesian perspective that the relation of evidence to conclusion should be given a precise number. It is unlikely that in typical legal, scientific or mathematical cases a numerical probability could be calculated, even if it existed in principle. It is sufficient for objective Bayesianism that it is sometimes intuitively evident that some hypotheses, on some bodies of evidence, are highly likely, almost certain, or virtually impossible.

The most central theses of Bayesianism do not concern numbers but are certain qualitative principles of evidence. The first is the simplest principle of logical probability, called by Pólya ((1954), 4; further in (Mazur 2014)) "the fundamental inductive pattern" or "verification of a consequence." It is as follows:

q is a (nontrivial) consequence of hypothesis p
q is found to be true
So, p is more likely to be true than before

(In short, "Theories are confirmed by their consequences or predictions.") That is, taken for granted as rational in scientific experiment or historical inquiry (except by strict Popperian falsificationists). The point of drawing predictions from theories and checking if they are true is normally taken to be that confirmation of predictions supports a theory. That is as applicable to mathematical conjectures as to scientific theories: the simplest possible consequences of a general mathematical statement such as "All odd numbers have odd squares" are its instances such as "The square of 131 is odd," which can be checked by calculation. Finding the consequences to be true gives some degree of support for a generalization and can justify further work.

It is true that in some clearly defined circumstances, it is natural to associate a number with the degree to which evidence supports a conclusion. Those circumstances are cases of the "proportional syllogism" or "statistical syllogism," where the sole relevant evidence is a proportion in a set. If the sole evidence bearing on

whether a certain patient will be cured of disease A by drug B is that 89% of patients with disease A are cured by drug B, then it is natural to assign a number to the probability, on that evidence, that the patient will be cured; namely 0.89. (Even with the proportional syllogism, however, arguments with imprecise numbers are often the most applicable, such as "The vast majority of flights arrive safely, therefore I can relax on takeoff.")

When numbers are applicable, it is usual to model the relation of evidence e to conclusion h by a number $P(h \mid e)$, between 0 and 1 inclusive, "the (logical) probability of h given e," which satisfies the usual axioms of conditional probability:

$$P(\text{not} - h \mid e) = 1 - P(h \mid e)$$

$$P(h_1 \text{ and } h_2 \mid e) = P(h_1 \mid e) \times P(h_2 \mid h_1 \text{ and } e)$$

The theorem of probability that is most useful for updating evidence is the celebrated Bayes' theorem which expresses how the probability of evidence given a hypothesis relates to the probability of the hypothesis given the evidence:

$$P(h \mid e\&b) = P(e \mid h\&b) \times P(h \mid b)/P(e \mid b)$$

(where h is read as hypothesis, e as (new) evidence, and b as the background knowledge that is taken for granted in the context of the problem). Thus, new evidence supports a hypothesis which makes the evidence likely (but only if the evidence is surprising).

While Bayes' theorem gives its name to Bayesianism, we emphasize that for the purpose of theory evaluation in general, the numerical theorem is much less important than qualitative consequences of it such as Pólya's "fundamental inductive pattern."

Another intuitively appealing such consequence, also easily derivable, is that the more surprising a consequence of h (that is, the lower its "prior" probability $P(e \mid b)$ on the background knowledge b), the more it increases the probability of h. (Thus Einstein's surprising prediction of the gravitational bending of light gave strong support to the theory of general relativity when it was observed to be true.)

If one takes those principles to be logical, they are as applicable to evidence for conjectures in pure mathematics as they are for theories in science or allegations in courts.

The appearance in Bayes' theorem of the "prior" probabilities $P(h \mid b)$ and $P(e \mid b)$ calls attention to the need to have some knowledge of them. For example, if one takes a "dogmatic" prior according to which a hypothesis is impossible, $P(h \mid b) = 0$, then no amount of evidence will dig one out of that hole: according to Bayes' theorem, the "posterior" probability $P(h \mid e \,\&\, b)$ will still be zero after any evidence e. Some logical intuition will be needed to evaluate whether a mathematical proposition is inherently unlikely or not, but such intuition seems to be available in simple cases; for example, it seems intuitively unlikely that the square of every odd number should be odd unless there was some good mathematical reason for that.

Other versions of Bayesianism are possible, such as subjective Bayesianism which requires only the axioms and does not constrain prior probabilities (Howson and Urbach 2006) and a version of objective Bayesianism that falls short of claiming that the probabilities involved in evidence evaluation are matters of strict logic (Williamson 2010). These are less attractive in the very abstract reasoning of pure mathematics where it seems that any considerations that genuinely count can only be logical; but in any case those versions agree on the qualitative principles of probability such as Pólya's inductive pattern, which are the main concern in explaining rational methods of evaluating the strength of conjectures.

5 Evidence for and Against the Riemann Hypothesis

Much of what has been said so far – both about the process of evaluating evidence for conjectures and the general principles of Bayesian reasoning – can be illustrated by the evidence that has accumulated for and against the Riemann hypothesis, currently the most famous unsolved problem of mathematics. Because the hypothesis has resisted proof for so long, the mathematical community has been much more explicit than usual about the evidential situation.

Expert opinion is that the Riemann hypothesis is almost certainly true, and that a proof is not exactly imminent but may not be far off. Naturally, some of the considerations are only comprehensible to true experts, but some of them are comparatively shallow and can be widely appreciated.

Very relevant in this case are the shallowest arguments, those from authority. How people think about arguments from authority in mathematics is evident in reactions to people who claim to have proved the Riemann hypothesis. If someone unknown presents his "result" on BBC news and at a conference run by someone who has accepted fake papers, he will not be taken seriously (Steckles and Lawson-Perfect 2018). If the aged Fields Medallist Sir Michael Atiyah presents a sketch of a proof, it is still met with skepticism, because of the difficulty of the problem, the minimal amount of information provided, and the author's track record of making unestablished proof claims in his old age (Amit 2018). On the other hand, when Alain Connes (2016) learnedly explains the comparative strengths of different strategies that may lead to a solution, mathematicians in general will nod in agreement, whether they understand it or not. He is the expert.

The Riemann hypothesis states that "With certain trivial exceptions, all the (infinitely many) roots of the Riemann zeta function have real part equal to ½." For the present purpose an understanding of the Riemann zeta function as a function in the complex plane is not necessary, it is only important that the hypothesis is a simple universal proposition like "all ravens are black." It is also true that the infinitely many nontrivial roots of the Riemann zeta function have a natural order, so that one can speak of "the first million roots." (One of many popular but informed accounts is (Derbyshire 2003).)

As a straightforward generalization, the Hypothesis is susceptible to purely inductive evidence, that is, just calculating many zeros starting from the first one

Table 1 Number of roots of the Riemann zeta found to have real part ½

Worker	Number of roots found to have real part ½
Gram (1903) Backlund (1914) Hutchinson (1925) Titchmarch (1935/6)	15 79 138 1041
Lehmer (1956)	25,000
Meller (1958)	35,337
Lehman (1966)	250,000
Rosser, Yohe, and Schoenfeld (1968)	3,500,000
Brent (1979)	81,000,001
Te Riele, van de Lune et al. (1986)	1,500,000,001
Gourdon (2004)	10^{13}
Platt and Trudgian (2020)	3×10^{12} with more rigor

and checking that they have real part ½. (We consider inductive evidence in mathematics in Sect. 7 below.) That process was begun by Riemann after he made the conjecture in 1859 and has of course been much assisted by increasing computer power. The results have been, as they developed (Table 1):

Inductions in mathematics can certainly dwarf those in science.

While this inductive evidence is generally taken to be quite strong (to some indeterminate degree), there is also a reason to deny it is close to certainty. That comes from the close connection of the Hypothesis with the prime number theorem. This theorem states that the distribution of primes thins out logarithmically, or more exactly, the number of primes less than x is (for large x) approximately equal to the integral $\int_2^x \frac{dt}{\log t}$.

If tables are drawn up for the number of primes less than x and the values of this integral, for x as far as calculations can reach, then it is always found that the number of primes less than x is actually *less than* the integral. On this evidence, it was thought for many years that this was true for all x. Nevertheless, Littlewood proved that this is false. While he did not produce an actual number for which it is false, it appears that the first such number is extremely large – well beyond the range of computer calculations. That gives some reason – it is very hard to say how strong – for believing that there might be a very large counterexample to the Riemann Hypothesis even though there are no small ones.

The reasons why most mathematicians' confidence in the Riemann hypothesis does approach certainty are not taken from further numerical evidence but from its connections with other theses that are or "ought to be" right. The first of these was the prime number theorem just mentioned. It is a consequence of the Riemann Hypothesis and was proved independently in 1896. The support given by this proof is thus an instance of Pólya's schema, mentioned above, "theories are confirmed by their consequences or predictions." However, the prime number theorem is not a very strong consequence of the Riemann hypothesis: the Riemann Hypothesis "says a lot more," so the support given by the prime number theorem is only moderate.

Two other considerations (among those accessible to ordinary mathematicians) are much stronger. One is the remarkable "Denjoy's probabilistic interpretation of the Riemann Hypothesis," an easily understood thesis in number theory which is equivalent to the Riemann Hypothesis and is independently intuitively plausible. We will not review it here (for a very brief account see (Franklin 2014), Chap. 15). The other is again a result of its connection with the prime number theorem. That theorem gives a crude estimate of the density of primes (namely, the density of primes around a large number N is $1/\log N$). The Riemann Hypothesis implies a much more fine-grained knowledge of the distribution of primes (namely, that the difference between the number of primes up to x and the integral above is $O(\sqrt{x}\log x)$, the best possible). If the Riemann Hypothesis is true, that fine-grained distribution is the simplest and most natural one, but if the Hypothesis is false, some more complicated and unnatural phenomenon must be present. The type of probabilistic reasoning involved is what Mazur (2014) calls "reasoning from randomness": that after known constraints have been taken into account, the rest should be random. (To take a simpler example, given that all primes except 2 and 5 have last digits 1, 3, 7, or 9, one can initially expect these digits to occur equally often; that is, uniformly distributed as they would be if chosen at random.)

The Riemann Hypothesis is also supported by an argument from analogy (identified by Mazur as another probabilistic argument form common in mathematics). In some famous and difficult work, André Weil proved that the analogue of Riemann's Hypothesis is true for certain other zeta functions, and his related conjectures for an even more general class of zeta functions were proved to widespread applause in the 1970s. One expert says "It seems that they provide some of the best reasons for believing that the Riemann hypothesis is true – for believing, in other words, that there is a profound and as yet uncomprehended number-theoretic phenomenon, one facet of which is that the roots ρ all lie on Re $s = ½$" (Edwards 1974, 298). However, not all experts are convinced of the closeness of the analogy and outsiders are in no position to judge.

The Riemann Hypothesis, then, is a remarkable testbed for displaying the diversity of probabilistic evidence that can bear on a mathematical conjecture.

Similar stories could be told with the other famous unsolved problems of mathematics. For example, Goldbach's conjecture is generally strongly believed to be true (on the basis of both simple numerical and other evidence) but also to be very unlikely to be proved soon (Review in (Baker 2009), Sect. 3.2; evidence for some other currently unsolved conjectures listed in (Aberdein 2019), Sect. 1). It is also instructive to follow the historical development of evidence for now-proved conjectures, like Fermat's last theorem and the classification of finite simple groups. In those cases, the growing confidence of experts both that the conjecture was true and that proof was imminent turned out to be justified (Franklin 2014, Chap. 15). It has indeed been argued that there is a certain observable regularity in the time-to-proof of mathematical conjectures in general (Hisano and Sornette 2013). It would be hard to deny that probabilistic evidence in mathematics is worthwhile, in the face of evidence that it has proved in the past to be a reliable guide to the (provable) truth.

6 Probabilistic Relations Between Necessary Truths

There is one difficult question that needs consideration in applying Bayesian theory or nondeductive logic in *mathematics* in particular. P($h \mid e$) is intended to be a measure of the support that evidence e gives to hypothesis h. If e entails h, then P($h \mid e$) is 1, since h is certain given e. But in mathematics, the typical case is that e *does* entail h, though that is perhaps as yet unknown. If, however, P($h \mid e$) is really 1, how is it possible in the meantime to discuss the (nondeductive or probabilistic) support that e may give to h, that is, to treat P($h \mid e$) as less than 1? In other words, if h and e are necessarily true or false, how can P($h \mid e$) be other than 0 or 1?

The answer is that, in both deductive and nondeductive logic, there can be many logical relations between two propositions. Some may be known and some not. To take an artificially simple example in deductive logic, consider the following argument:

If all men are mortal, then this man is mortal
All men are mortal

Therefore, this man is mortal.

The premises entail the conclusion, certainly, but there is more to it than that. They entail the conclusion in two ways: firstly, by modus ponens, and secondly by instantiation from the second premise alone. That is, there are two logical paths from the premises to the conclusion. More realistic cases are common in mathematics, when different mathematicians produce different proofs of the same theorem, that is, different logical paths from the axioms to the theorem.

Now just as there can be two deductive paths between premises and conclusion, so there can be a deductive and nondeductive path, with only the latter known. Before the Greeks' development of deductive geometry, it was possible to argue the following:

All equilateral (plane) triangles so far measured have been found to be equiangular
This triangle is equilateral

Therefore, this triangle is equiangular

There is a nondeductive logical relation between the premises and the conclusion: the premises inductively support the conclusion. But when deductive geometry appeared, it was found that there was also a deductive relation, since the second premise alone entails the conclusion. This discovery in no way vitiates the correctness of the previous nondeductive reasoning or casts doubt on the existence of the nondeductive relation. That relation cannot be affected by discoveries about any other relation.

So the answer to the question "How can there be probabilistic relations between necessary truths?" is simply that those relations are additional to any deductive relations. They may be known independently of them (and are often easier to know).

Once that is established, it is possible to understand Pólya's remark that non-deductive logic is better appreciated in mathematics than in the natural sciences (1954, vol II, 24). In mathematics there can be no confusion over natural laws, the uniformity of nature, propensities, the theory-ladenness of observation, pragmatics, scientific revolutions, the social relations of science, or any other red herrings. There are only the hypothesis, the evidence, and the logical relations between them.

7 The Problem of Induction in Mathematics

As we have seen, induction, or inference from the observed to the unobserved, is found in pure mathematics as well as in the natural and social sciences. That has significance for understanding the nature of induction as well as for mathematics. If induction works in just the same way in pure mathematics as in science, its rationality and justification would seem to be independent of any contingent facts about the world, such as the obtaining of natural laws or the uniformity of nature.

Let us take an easy example, even simpler than the ones above concerning the roots of the Riemann zeta function.

The first million digits of π are random
Therefore, the second million digits of π are random

The first few digits of π are
3.14159265358979323846264338327950288419716939937510582097494 4
. . .

It can be seen that they are random in the sense of lacking pattern. (That notion is formalized in several ways, as in "passes standard statistical tests for randomness" or "incompressible," not "probabilistically generated," "stochastic" (Eagle 2018); of course the digits of π are generated by a deterministic formula. For present purposes, "looking patternless" is sufficient.) It is easily checked that the first million digits of π do both look random and pass statistical tests for randomness (such as having about the same number of each digit). (Calculations now stretch to 4 trillion digits in hexadecimal (Bailey et al. 2012).

Intuitively, that is good evidence that the patternlessness will continue into the second million digits, just in the same way that observing a million black ravens is good inductive evidence that further observed ravens will be black. It is widely believed that the digits continue to be random indefinitely, although it is not proved even that there are about equal numbers of each digit (Marsaglia 2005). (Some claims that the digits of π fail a more subtle statistical test for randomness in (Ganz 2014) with debate in (Bailey et al. 2017) and (Ganz 2017).)

Gronau and Wagenmakers (2018) argue that this is a perfect case for appreciating the Bayesian perspective in pure mathematics. They apply a formal Bayesian analysis to the hypothesis that π is normal (in base 10), that is, that the ten digits appear equally often in its decimal expansion. They conclude that "After all [the first]100 million digits [of π] have been taken into account, the observed data are 1.86×10^{30} times more likely to occur under [the hypothesis that π is normal] than under [the alternative hypothesis that is it not]. The extent of this support is overwhelming." As with any Bayesian analysis with exact numbers, the final conclusion depends on a choice of prior probabilities, and the authors discuss possible choices.

It is true, as argued by Baker (2007) that there is a special problem with inductive arguments in number theory in that all the observed cases are of small numbers. Any number that can be calculated with is very small, compared to numbers in general. That bias in the evidence could raise a question as to whether any induction of the form "All observed numbers have property X, therefore all numbers have property X" could have high probability. That does not imply, however, that inductive arguments in mathematics are generally poor. Firstly, a bias in the evidence towards small numbers does not affect inductive arguments with more modest conclusions, such as "All observed numbers have property X, so the next number calculated will have property X." (For example, the argument above about the randomness of the digits of π only extrapolated a finite distance, thus keeping to small numbers.) Secondly, many other inductive arguments have a bias in the evidence, without thereby becoming worthless (though they may become less secure). For example, extrapolative inductive inference like "All observed European swans are white, therefore all swans in the world are white" is a worthwhile inductive argument, even though the extrapolation beyond the observed range weakens it.

It is nevertheless true that purely inductive evidence is less credible in mathematics than it might be elsewhere, because of the possibility that some mathematical reason against a generalization might apply only for huge numbers. As we saw, the purely inductive evidence for the Riemann hypothesis was a possible instance of that, and it is possible to have "overwhelming" numerical evidence for a conjecture, where the reasons for it being false also reveal why there should be such good evidence for it (Schuster 1985). That is not the same, however, as saying that the evidence was not good in the first place or that a blanket skepticism is justified.

The occurrence of inductive arguments in pure mathematics suggests something about their nature as well as the nature of mathematics. If inductive arguments work in the necessary matter of pure mathematics, apparently on the same basis as they work in science, it seems they cannot depend on any contingent principles, such as the uniformity of nature or the holding of natural laws. The digits of π are surely the same in all possible worlds, and the rationality of arguments about them independent of any differences between possible worlds. That is more compatible with logical justifications of induction (e.g., Stove 1986) than ones that rely on either contingent facts like natural laws or sociological facts about what reasoners do. Again, it is easier to appreciate the force of probabilistic reasoning in mathematical cases, free of distractions.

8 Conclusion

The Bayesian perspective brings some order into part of the vast backstory of mathematical practice that underpins published research output. It allows us to understand the nature of the variety of methods of evaluating evidence – for pure mathematical conjectures, for the behavior of mathematical models, and for the performance of statistical algorithms. Experimental evidence, checking of consequences, weighing of intuitions, arguments from analogy, and expectations as to uniform distributions work the same way in mathematics as they do in natural and social sciences. The Bayesian perspective explains the unity of those methods and why they have rational force. The fact that they do work in the necessary matter of mathematics suggests that they are matters of pure logic.

Abstract

The Polymath Project is an online collaborative enterprise that was initiated in 2009, when Timothy Gowers asked whether and how groups could work together to solve mathematical problems that "do not naturally split up into a vast number of subtasks." Gowers proposed to answer this question himself by actually trying to set up such a collaboration, based on interactions taking place in the comment-threads of a series of posts on a WordPress blog. Hence, the first project officially started in early 2009, to be proclaimed successful only 6 weeks later (Gowers and Nielsen 2009). From its inception until April 2018, 15 more Polymath problems (and a handful of smaller or related ones) have been launched. These projects have attracted attention from different scholarly communities, including the philosophy of mathematical practices, from the perspective of which the Polymath Project can be seen as a vast repository of mathematics in action. This chapter continues previous work by its authors on the topic in question and topics

related. More specifically, for the purposes of this volume, it is our aim to both summarize and expand upon these earlier contributions. The starting point is the above observation that in the past decade, the issue of "massively collaborative mathematics" (to be qualified below) has drawn quite some attention. However, does it also warrant intensive *philosophical* attention in particular? For, as exciting as these developments might be from mathematical and other points of view, the enhanced possibilities that have come with it do not per se give rise to any philosophical import. In Van Bendegem (2011), one of us has indeed tentatively argued for the philosophical relevance of these new dynamics of proof construction flowing from the wide availability and efficiency of Internet technology. We shall below briefly rehearse and update the argument given there.

Polymath Project · Massively collaborative mathematics · Dynamics of proof construction · Network analysis

1 Introduction

The Polymath Project is an online collaborative enterprise that was initiated in 2009, when Timothy Gowers asked whether and how groups could work together to solve mathematical problems that "do not naturally split up into a vast number of subtasks." Gowers proposed to answer this question himself by actually trying to set up such a collaboration, based on interactions taking place in the comment-threads of a series of posts on a WordPress blog. Hence, the first project officially started in early 2009, to be proclaimed successful only 6 weeks later (Gowers and Nielsen 2009). From its inception until April 2018, 15 more Polymath problems (and a handful of smaller or related ones) have been launched. These projects have attracted attention from different scholarly communities, including the philosophy of mathematical practices, from the perspective of which the Polymath Project can be seen as a vast repository of mathematics in action. This chapter continues previous work by its authors on the topic in question and topics related. More specifically, for the purposes of this volume, it is our aim to both summarize and expand upon these earlier contributions. The starting point is the above observation that in the past decade, the issue of "massively collaborative mathematics" (to be qualified below) has drawn quite some attention. However, does it also warrant intensive *philosophical* attention in particular? For, as exciting as these developments might be from mathematical and other points of view, the enhanced possibilities that have come with it do not per se give rise to any philosophical import. In Van Bendegem (2011), one of us has indeed tentatively argued for the philosophical relevance of these new dynamics of proof construction flowing from the wide availability and efficiency of Internet technology. We shall below briefly rehearse and update the argument given there.

In Allo et al. (2013), we have already proposed a preliminary theoretical model, based on epistemic logics, aimed at capturing (and understanding) how different

pieces of mathematical knowledge can be distributed within a larger community. As it happens, we shall also be borrowing arguments for the philosophical relevance of the phenomenon in question from that paper. The original contribution of the present chapter is of a more empirical nature, in that we study various Polymath projects in terms of the scientific communities themselves that emerged within and across them. We believe that this more social perspective can be particularly fruitful, as it allows us to address the two central goals of the Polymath Project jointly, namely enhanced efficiency and transparancy through collective proof-search processes. Although we admit that quantitative and network-oriented studies of the Polymath Project have been carried out before, this has never been executed at the present scale, and certainly not as an explicit contribution to the philosophy of mathematical practices.

Here is an overview of the chapter. We begin, in Sect. 2, by arguing in favor of the (potential) epistemological significance of considerations about social phenomena such as the Polymath Project. Section 3 continues with an overview of different (disciplinary) perspectives on said phenomena, in which we situate our own contributions. After that, the entire Sect. 4 is devoted to assessing the possible status of the Polymath Project as an instance of e-research. This concludes the first part of the chapter, which is rather surveying and reflective in kind. In the second part, we present the methodology and conclusions of our empirical work. Section 5 describes the nature and structure of the source material used. In Sect. 6, we make a global evaluation of various data concerning participation or affiliation, both to projects in general and to discussion-threads in particular. Next, Sect. 6 refines this analysis by also considering joint affiliations, giving rise to the tentative identification of collaborative networks per project. In a following step, Sect. 7 more specifically examines the role of core participants in the global project by means of the distribution of network links. Finally, in Sect. 8, we study the communities associated with single projects. We summarize our findings in Sect. 9.

2 Philosophical Import

In the years following the start of the Polymath Project, bold claims were made as to its repercussions. For example, Aron (2011) predicted that it would "democratise the process of mathematical discovery," while Nielsen (2012) firmly stated: "The Polymath Project is a small part of a much bigger story, a story about how online tools are transforming the way scientists make discoveries." Although we do not immediately share these very ambitious and drastic expectations, at the very least we would like to make a case for due philosophical attention to the developments in question.

Oddly enough, this requires a philosophical preparedness or openness to begin with. This attitude has been associated with accepting a degree of naturalism with respect to epistemological questions, making this type of philosophical questions about (the reliability of) mathematical results to an extent depend on matters of fact about mathematical inquiry as a process. As this chapter is part of a comprehensive handbook on the philosophy of mathematical practice, where this basic attitude is the

common point of departure, we shall not spend much time on arguing this general point. Once this is granted, clearly, the road to also take the Polymath Project as a legitimate topic of philosophical scrutiny (any significant results pending) is open. The reasons for opposing such a move are connected to the stubborn opposite philosophical apriority, namely that mathematical truths are cut loose from any empirical considerations related to their discovery or justification, and are thus independent of anything remotely connected to proof construction as a human affair. Neither individual nor collective beliefs have any bearing upon the acceptance of mathematical results. Only formal proof, proceeding by necessity from premises to conclusion, has the authority of establishing a mathematical knowledge claim.

There is a fundamental problem with the characterization just given, though. How does one establish that a particular formal proof is a or the correct one? Proofs do not tend to fall from the sky but are invariably conceived by concrete mathematicians (typically an individual or a small group of them) and subsequently have to be validated by others, a (mostly small) selection of peers, in order to have their validity substantiated. (Admittedly, the (growing) role of automated verification and other "proof technology" should also be acknowledged in this respect, a matter we can and will however not elaborate on here.) In other words, proofs have to be *recognized* to be correct, which typically involves any proofreaders to be *convinced* by the arguments on offer. Allow us to point to the fact that already at this stage, which is still to be associated with a rather traditional position within the epistemology of mathematics, an embryonic community of participating mathematicians is involved in sanctioning alleged results. This directly points to an irreducible reliance on what in the epistemological literature is called testimony, giving rise to fallibility. In the ideal world, that is, referees of proposed papers are supposed to establish whether the claims to absolute justification made by their authors are correct. However, we do not live in this ideal world, and the level of scrutiny of the refereeing process in reality varies greatly (Geist et al. 2010). Another aspect concerns the fact that published proofs are not just chains of formal derivations, but mostly also contain portions of motivational prose or drawings, sketchy (thus incomplete) arguments, and appeals to implicit knowledge. Ironically, these very aspects are often what makes proofs surveyable and robust to begin with (Van Bendegem and Van Kerkhove 2009). (We should also like to refer here to the chapter "The Social Epistemology of Mathematical Proof" by Line Edslev Andersen in the section "Proof" of this handbook for a more systematic discussion of various positions with respect to social proof dynamics.)

Let us now, however, get back to the more specific question that is facing us here: Is the Polymath Project an instance of an entirely new procedure of proof search in mathematics, or does it simply amount to the same old methods being implemented through new media, most notably the Internet? We are convinced the former is rather the case than the latter. In Allo et al. (2013), we have already made a first effort to clarify the matter from the perspective of epistemic logic, by suggesting a formal way to study and understand the construction of mathematical proof *within* communities, theoretically enabling one to model proofs-as-arguments from a perspective that emphasizes interaction and collaboration. In a similar vein, Van Bendegem (2011: Sect. 3) has

defended the idea that the way mathematical communities are organized does exert an influence on their problem-solving capacities and suggested the use of logics for multiagent systems (such as Dunin-Keplicz and Verbrugge (2010)) and dialogue logic to represent varying constellations of collaboration, whether or not including team leaders (as has been the case in the Polymath Project, see below).

Without being able to provide a knockdown argument allow us to add a philosophical rationale for at least exploring this possibility, inspired by Van Bendegem (2011: Sect. 2) (to which we refer for the complete, refined argument). The main point, we would like to make in this respect, exploits the idea introduced above that, given the finite world we live in, the problem-solving capacities of the mathematical community are limited. Hence, in mathematics, as elsewhere in human practice, we are dealing with an issue of resources. This gives rise to practical questions concerning the selection of problems that will be tackled and the efforts that will be made to do so (in terms of how many mathematicians will invest how much of their time in order to try and bring cases to a close). This in itself clearly does not preclude any of the possible problems to be tackled with a sufficient amount of research power.

Still, there is more to this. For in some cases, there appear to be absolute limits anyway, as problems present themselves the solution of which escapes the regular kind of individual-based, mathematical practice. Outside the area of massive or open collaboration, some proofs have indeed appeared to be well beyond the reach of individuals or smaller groups of them. A famous case in point is the Classification Theorem of Finite Simple Groups, also known as the Enormous Theorem (Van Bendegem and Van Kerkhove 2009: Sect. 4). This defies the view that, as the whole enterprise of mathematics is traditionally seen as the cumulation of individual achievements, no real interaction is needed beyond the obvious reliance on prior results. Yet, this description no longer covers the totality of mathematical inquiry.

In the present context, the crucial point is that the Polymath Project appears to have been conceived with this very same idea in mind. Here is what Timothy Gowers wrote on his blog in this respect: "I'm interested in the question of whether it is possible for lots of people to solve one single problem rather than lots of people to solve one problem each." (https://gowers.wordpress.com/2009/02/01/why-this-particular-problem/ (accessed 19 Jul 2020)) Cranshaw and Kittur (2011) confirm this, specifying that "Gowers was instead proposing to collaboratively solve a single problem that does not naturally split up into a vast number of subtasks." Given what was developed above, the philosophical relevance of studying the research dynamics that have been the product of this particular type of collaboration should be clear. As we develop our network analysis below (from Sect. 5 onward), we shall have the opportunity to point to various specific aspects of such philosophical interest.

3 Perspectives on Polymath

Several perspectives on the study of the Polymath Project can be adopted, corresponding to different categories of scholarly literature devoted to the topic. We are distinguishing three of them here (with a fourth appended to that).

First, one may think of Polymath as a specific (though atypical) example of science online (e-research, crowd / citizen science). This is the perspective adopted by scholars who study social and scientific practices online. Polymath indeed figures in some overviews of scientific collaborations online such as Franzoni and Sauermann (2014), and Michael Nielsen's "Reinventing Discovery" (Nielsen 2012). In Nielsen (2010), the latter described himself as an interested outsider participant of the first Polymath project (he later also contributed to the discussions in Polymath 4 and 8) and decisively contributed to the fame of the Polymath Project with his writings (Gowers and Nielsen 2009). Since Polymath indeed conforms to the definitions of e-science and crowd science, and undoubtedly shares some of the motivations of citizen science, this approach is well motivated, often highlighting features that remain absent from the small-scale analyses devoted to the fine-grained structure of mathematical arguments. Yet, as we shall argue in Sect. 4, since Polymath remains a rather unusual example of science online, this particular perspective cannot always do justice to the epistemic goals and achievements of the Polymath Project.

Second, one may think of Polymath as a rich and detailed repository of real mathematics in action. This is the traditional and most obvious perspective to adopt on the Polymath Project, when interested in the tiny and often messy details of mathematical practices. It is moreover a very natural perspective to adopt, since Polymath does effectively provide access to highly valuable data that normally remain hidden. Indeed, the entire project has been motivated by the desire to make the inner practice of research mathematics visible to outsiders to begin with, and most scholars of mathematical practice are to be considered a highly specialized group of such outsiders. From this perspective, the mathematical content of the collaboration (such as the types of arguments used by mathematicians) is the focus of attention. Other features are less salient, including social dynamics and the role of ICTs in the collaboration. As the targets are fine-grained analyses, and given the need to take into account the precise content of individual contributions, this kind of research has typically focused on smaller fragments of Polymath projects, leaving less room for overarching analyses. This approach also raises an important question: Can we really use Polymath as a source for the study of normal mathematical practices, or should we take the claim that it constitutes a "new kind of mathematics" seriously and therefore accept that we actually study a novel practice?

This second category notably includes work by Ursula Martin and Allison Pease, with its emphasis on problem-solving and argumentation in mathematics (as influenced by Lakatos, by Pólya, and by literature in formal argumentation), and with the stated intent to improve how large groups collaborate by making argumentative structures explicit. The focus is thereby on the use of ICTs in mathematics, relating to the metaphor of social machines (Lane et al. 2019: Sect. 5). Specifically, the third "mini" Polymath project was analyzed this way (these "mini" projects having been dedicated to Maths Olympiad-finals problems), identifying different categories of comments and the mathematical concepts these were relying on, and developing a typology of questions based on samples from MathOverflow, the discussion site for professional mathematicians on the StackExchange platform (Pease and Martin 2012; Martin and Pease 2013).

Incidentally, our own earlier work also belongs to this category (Allo et al. (2013), Van Bendegem (2011): Sect. 3).

The third category is dedicated to how specific information technologies are used for collaboration, and can naturally be related to hypertext research (in particular the use of blogs and wiki's) and humanistic computing. This category includes the work of Barany (2010), Cranshaw and Kittur (2011), and Varshney (2012). The authors of these papers try to identify specific features of how collaboration in the various Polymath projects has proceeded (e.g., remarks on noise-to-signal ratio, or the importance of leadership), propose criteria for success, and seek to evaluate to what extent collaboration in Polymath is successful. Unlike the present chapter, the focus in this work is limited to the first Polymath project. However, it does rely on social science methodology, network-analysis in particular, as will be done here. More recently, Kloumann et al. (2016) have specifically investigated the contrast between research-level Polymath projects (1–9) and "mini" Polymath projects, trying to disclose patterns of collaboration and linguistic features that can be used to distinguish collaboration on hard problems from collaboration on feasible ones.

The previously mentioned studies have inspired our current approach to Polymath as an epistemic community. This new dimension to the philosophical perspective arises naturally when taking into consideration the following features of the Polymath Project:

(i) The diversity of the epistemic goals and the value accorded to social-epistemic virtues like the openness of the enterprise, both in the sense of openness to potential contributors, and the disclosure of intermediate inputs. (Gowers 2010; Franzoni and Sauermann 2014)
(ii) The fact that Polymath is not governed by a technical platform, but by a set of social norms or rules that were initially put forward by Timothy Gowers (Van Bendegem 2011) and that still govern the interactions during the projects.
(iii) The presence of deliberative processes where questions concerning the research-agenda, or concerning the organisation and structure of the interactions, are collaboratively resolved. Some examples: (1) During the first Polymath project, there were several discussion-threads in which organizational and practical issues were discussed. This process led to further amendments to the rules Gowers initially proposed; (2) In September 2015, Gil Kalai posted a question on MathOverflow to crowdsource proposals for new Polymath projects. This question remains active, with regular input and occasional summaries and rankings of the proposals (https://mathoverflow.net/questions/219638/proposals-for-polymath-projects); (3) Projects typically start with a discussion-thread to gauge the interest before the project is officially launched.

Methodologically, this approach is continuous with some of the earlier quantitative and network-theoretic analyses of Polymath, including Cranshaw and Kittur (2011), Sarvate et al. (2011), and Kloumann et al. (2016). We do, however, subscribe to a more encompassing perspective on scientific communities, hoping to thereby lay the foundations for more substantial analyses of the socio-epistemological

dimensions of Polymath (or similar) projects. One type of questions, which can be explored along these lines, concerns the social norms or rules that govern this type of research, and especially the role of the "small contribution rule" that prevents the emergence of information-asymetries by asking for small and quick contributions, and discouraging longer periods of individual work (Wagenknecht 2014). Our research falls squarely within the category of "quantitative" approaches to the use of crowdsourcing in mathematical practices as recently identified by Pease et al. (2020: Sect. 4), in being aimed at developing and employing quantitative techniques (such as network-analysis) to study and test intuitions about said practices.

Before continuing with our own work, we shall in the upcoming section investigate in some more detail the perspective from e-science. But as announced, we cannot leave the current section without pointing to an obvious fourth category in the scholarly literature, broadly conceived. In this fourth category, we find insider and popular science (press) reports on the Polymath Project, which were the decisive element in how it gained notoriety, including in the first place Gowers and Nielsen's opinion piece in *Nature* (Gowers and Nielsen 2009) and Nielsen's book *Reinventing Discovery: the New Era of Networked Science*, in which Polymath featured prominently (Nielsen 2012). Additional inside reports include Nielsen (2010) and Gowers (2010), which covered the problem solved in the first Polymath project, the views about collaboration in mathematics that motivated the project, and lessons learned from organizing a large collaborative project. Finally, articles in *New Scientist* (Aron 2011), *Scientific American* (Castelvecchi 2010), *The Mathematical Intelligencer* (Nathanson 2010), and a short piece in *Nature* (Ball 2014) can be mentioned, as well as various blog posts and online publications such as *Quanta Magazine* (Klarreich 2013, 2015).

4 Polymath as E-Research?

The Polymath projects clearly fit the definition of e-research as research based on the use of digital tools and data – and the Internet in particular – for the distributed and collaborative production of knowledge (Meyer and Schroeder 2015: Chapt. 1). Because it leaves project participation and access to intermediate inputs entirely open, it also qualifies as a type of crowd science, as conceived in Franzoni and Sauermann (2014). Finally, because it is in principle open to amateur mathematicians, it is also a kind of citizen science. At the same time, the Polymath Project remains in several respects an outlier, and this presumably accounts for its relative absence from the literature in this field (with the exceptions noted in the previous section). We review some of the reasons for this exceptional status.

First, unless we compare it to paper and pencil mathematics, the Polymath Project is by contemporary standards a fairly low-tech enterprise. It relies on off-the-shelf tools, namely freely available blogging-platforms (and to a lesser extent Wiki software), and became possible through the availability of a LaTeX-plugin for WordPress. (See Gowers (2010). A richer discussion of this technological aspect was given by Jon Udell, a prominent voice on ICT research-infrastructure (https://blog.

jonudell.net/2009/07/31/polymath-equals-user-innovatio/.) Continuing on this theme, it is worth pointing out that the write-up process in Polymath 16 relied on the LaTeX-centric collaborative tool Overleaf (https://dustingmixon.wordpress.com/2019/08/05/polymath16-fourteenth-thread-automated-graph-minimization/#comment-24584).)
This is very different from most other types of e-research, which typically rely on the development of dedicated tools for collaboration and have in the case of Zooniverse even led to the creation of a reusable tool or platform for online collaboration (https://www.zooniverse.org/). Polymath, by contrast, is primarily defined by a set of rules, initially formulated by Gowers, which constitute a recipe for collaboration that can be easily reimplemented, and is only to a lesser extent characterized by the specific technology it relies on (blogs, but also wikis). Its appeal also remains limited to the formal sciences, with proposals to implement the same kind of open collaboration in AI (Zadrozny et al. 2015) and as a means to create research opportunities for mathematics undergraduates (Parsley and Rusinko 2017).

Second, Polymath is clearly a small-scale enterprise when compared to many collaborative online projects. The largest Polymath project (Polymath 8) attracted 180 participants, whereas the smaller projects (2 and 6) did not even reach 20 participants. Over a period of more than 9 years, 16 projects were initiated, and 622 distinct participants can be identified (see the detailed analysis below). By comparison, the seven Zooniverse projects reviewed in Sauermann and Franzoni (2015) reached between 3186 and 28,828 participants in their first 180 days. This makes the description of Polymath as "massive online collaboration" somewhat excessive when it is purely judged by the numbers. This is not really surprising. The scale of collaboration within mathematics is generally smaller than in other sciences (Grossman 2002), and this substantially lowers the threshold for what we may consider large, or even massive, collaborations. (Additionally, one could make the claim that there is a gap between Polymath-like "small science" and Zooniverse-like "Big Science.")

More importantly, Polymath does not fit the mantra of citizen science that "anyone can be a researcher." Even though participation is open to amateurs, and the choice for problems in combinatorics is at least partly motivated by the fact that knowledge of a small number of techniques can be sufficient to tackle open problems (Gowers 2000), active contribution is in reality limited to those with the required expertise (this being one dimension of the taxonomy of crowd science in (Franzoni and Sauermann 2014)). Polymath is meant to succeed in virtue of the fact that "different people know different things, so the knowledge that a large group can bring to bear on a problem is significantly greater than the knowledge that one or two individuals will have" (Gowers' initial post), or by leveraging so-called micro-expertise (Nielsen 2012: Chapt. 4). One may therefore hesitate to see this type of approach as one that relies on the illustrious Wisdom of Crowds, and even doubt that there is a clear kind of epistemic contribution that the Polymath projects are crowdsourcing. At this point, we can only indicate that the intended individual contributions are neither complete proofs (cfr. The one correct answer that is typically the goal on the StackExchange pages) nor clearly identifiable or even just potential fragments of such a proof.

Third, in contrast to both Zooniverse-like endeavors and large-scale collaborations in the sciences, the problem statement in Polymath projects is clear and explicit (Polymath 2 is probably an exception), but individual tasks are rarely clearly individuated and are never explicitly attributed to specific participants. Mainstream citizen science is typically based on a huge amount of similar tasks that are explicitly attributed to participants in such a way that all tasks are not only completed, but are also completed multiple times to allow for error correction. In Watson and Floridi (2018), large numbers of participants and hard-coded error correction strategies are explicitly related to the higher reliability of crowdsourced science. Similarly, outside the scope of citizen science, e-research and other large collaborative enterprises exhibit "a high degree of mutual dependence and task certainty" (Meyer and Schroeder (2015), building on the work of Whitley (2000)) that has no clear counterpart in the Polymath projects. This leads Franzoni and Sauermann (2014) to classify the Polymath projects as ill-structured projects that are characterized by the lack of independent subtasks (this being the other dimension of the taxonomy of crowd science referred to above).

The absence of hard-coded or other explicit error-correction procedures is equally important and should not entirely be traced to the lack of explicit subtasks (if the subtasks are unclear, the criteria for a successful microcontribution are equally unclear). Instead, it should also be linked to the fact that the aggregation of contributions is itself distributed instead of centralized. Because all contributions or comments are accessible to anyone, they are in principle open to scrutiny by every participant as well. The absence of procedures governing this has two potential drawbacks. First, it creates uncertainty concerning whether and how error-correction takes place. And second, it makes it hard for individual participants to identify the current state of the project (this being understood as what everyone should at a certain moment be agreeing on).

The open-ended and informal character of Polymath-contributions makes it harder to understand and explain the precise sense in which Polymath-like projects lead to more reliable or potentially more successful models for mathematical inquiry. Specifically, the highlighted contrasts with other forms of e-research and crowdsourced science reveal that epistemic success in Polymath cannot be retraced to good planning and reliable procedures. Other factors must instead be at play, and some of these factors may be grounded in the structure of the community or the specific shape of the patterns of interaction between the participants. As already highlighted, it would be a mistake to identify the epistemic value of Polymath-style collaborations to their potential to lead to mathematical results more quickly or efficiently. One explicit goal of the Polymath Project is precisely to reveal the inner workings of proof-search. Nielsen (2010: p.655) relates Polymath to "open science," but Gowers (2010: Sect. 2) is even more explicit, referring to the inefficiency of published proofs in conveying how they are discovered. If we take this goal into account it is immediately clear that a (hidden) centralized aggregation-procedure is of little use. We will need alternative criteria to understand why and how Polymath is valuable and potentially successful.

Fourth and last, it seems that Polymath-style research also diverges from mainstream e-research in the sense that, despite its high pace, Polymath can be understood as a form of slow science:

> I think with a large collaboration of this kind we can aim not only for success in settling the problems (which is, of course, the central goal) but also for higher standards in explaining the proof, improving the argument, making sure it is locally correct and detailed (hyperlinks can even allow to give details that are necessary for some while obvious for others), and in the exposition level of the paper. Since everything is in the open there is no pressure to rush on these matters. (Gil Kalai, comment of March 15, 2009 during Polymath 1) (https://gowers.wordpress.com/2009/03/10/polymath1-and-open-collaborative-mathematics/)

Thus, Polymath relies on "unused epistemic resources" in only one of two ways. It certainly does so in the sense that it seeks to reap the benefits of microexpertises that one would otherwise not have had access to, but it does not in terms of saving epistemic efforts (or attention). The latter point is underscored by several participants, pointing to the substantial investment of taking part, thereby denying that Polymath is mainly driven by reasons of economy, tapping into otherwise unused intellectual resources (Nielsen in Polymath 2014).

5 Description of the Data

After the previous, more encyclopedic, and philosophical sections, we now turn to the original, more technical contribution of this chapter, which is to offer a network-oriented analysis of the Polymath Project. We begin this endeavor in the present section, by describing the data that was used to this effect. Said data were obtained by scraping the discussion-threads of all the Polymath projects on the following blogs:

- Timothy Gowers' blog
- Tererence Tao's blog
- Gil Kalai's blog
- The Polymath-blog
- The Secret Blogging Seminar (only for some threads in Polymath 8)
- The Short, Fat Matrices blog run by Dustin G. Mixon (only for some threads in Polymath 16)

Lists of all the comment-threads were obtained from the Polymath-wiki at http://michaelnielsen.org/polymath1/index.php?title=Main_Page. The content and structure of the interactions was obtained by scraping and parsing the web pages of all comment-threads.

The structure of these data is related to:

Projects: There are 16 Polymath projects, each devoted to one research question.

Threads: Each project consists of a series of **blog-posts** and associated **discussion-threads**. Blog-posts are authored by the leader of the project. This is typically only one person. Polymath 1 is the main exception with parallel threads hosted on separate blogs.

Comments: Each discussion-thread is a succession of comments.

- With an author (which we refer to as **participants** in order to distinguish them from the authors of the blog-posts)

- With a content (of a given length or wordcount)
- Which are temporally ordered by their **timestamps**
- Which are organized in a tree-like structure, with:
  - Level 1 comments as child-nodes of the blog-post
  - Level $n + 1$ comments (for $n \geq 1$) as child-nodes of level n comments

In Fig. 1, the tree-like structure as well as the temporal ordering is depicted. The color of the nodes corresponds to the identity or at least the supplied name of the authors of the comments.

Where $n \geq 1$, the child-parent relation between comments is an explicit *reply-to* relation between the author of the child-comment and the author of the parent-comment, while the parent-child relation between these comments is an implicit *has reached* relation between the author of the parent-comment and the author of the child-comment. As said, we shall refer to the authors of comments as *participants*.

Participants can be identified within and across threads and projects by their supplied author-name. All these where compared for string-similarity. Similar names that could be retraced to the same commenter were reidentified, but ambiguous cases such as slight variants of the same name without surname were kept distinct. Various versions of "anonymous" are present in the data. Comments authored by an anonymous participant have not been attributed to a single participant but instead have been removed from the detailed analyses, with one exception. As we noticed an exceptionally high number of anonymous comments in Polymath 15 (more than in all other projects together), we decided that there were sufficient indications to

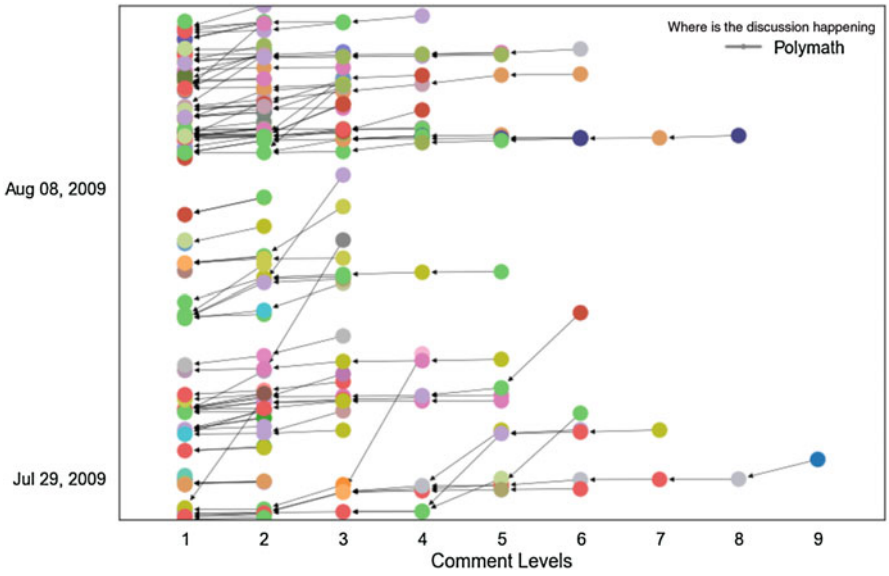

Fig. 1 Fragment of a discussion-thread in Polymath 4

identify these contributions as coming from a single participant, whom we renamed as "PM15 Anonymous" and treated as a regular identifiable participant.

The structure described captures the quantitative and relational information that can be obtained by scraping all the posts and discussion-threads.

While textual data could have been obtained from the content of the posts and comments, these have been left out of the analysis. First, this is not our focus here, but second, it does also avoid a further complication related to the fact that all LaTeX-content is rendered as figures, and hence unavailable for scraping. This makes the bulk of the mathematical content practically inaccessible to automated processing with standard tools for pulling data out of HTML such as Beautiful Soup, which naturally forms a huge obstacle to (comprehensive) detailed scrutiny. The codebase for our analysis can be found on GitHub at https://github.com/patrickallo/mathpracmod.

As we study the Polymath Project as a social network, we have placed most of our emphasis on the analysis of **relational data**. We can distinguish between the following types:

1. Relations that encode direct interactions
2. Relations that encode affiliations

   Relations derived from direct interactions are only defined between entities of the same kind. In our case, mainly participants. Affiliation-networks are, by contrast, bipartitite networks with relations only defined between entities of different kinds (Borgatti et al. 2018: Chapt. 13).

   When we study the Polymath community as a whole, we consider affiliations between participants and projects, and between participants and discusssion-threads. When we study the communities associated with a single project (particularly in Sect. 8), we consider affiliations between participants and threads, and between participants and episodes of intense interaction. Such episodes are identified by means of a clustering-algorithm.

   Given an affiliation-network, we can construct a so-called projected-graph that connects entities of one kind based on their joint affiliations. This gives rise to a third type of (derived) relational data:
3. Relations that encode joint affiliations

   It is thus natural to posit connections between participants based on their joint participation to projects, but the converse makes sense as well: We can connect projects based on the participants they have in common.

   When we describe the Polymath community as a whole, we consider coarse-grained affiliations. In such cases, the joint-affiliation relations we study are rather loose and do not even indicate that participants actually interacted. When we describe specific project-communities, joint affiliations to episodes do indicate actual interactions.

   Overall, we have found that the analysis of joint affiliations to episodes is a more reliable guide to the structure of interactions within Polymath than the analysis of direct interactions based on reply-to relations. We describe and motivate this procedure in more detail in Sect. 6.

When we consider affiliations, between participants and projects, and set the strength of an affiliation (the weight we assign to the edge) to a project to be the number of comments contributed by a participant to a project, then: (1) The degree of each participant in this bipartite network corresponds to the number of projects (the unweighted case) or the number of comments (the weighted case) of that participant. (2) The degree of each project in this bipartite network corresponds to the number of participants (the weighted case) or the number of comments (the unweighted case) in that project.

An important remark. Several fundamental metrics that are used to characterize relational data should be used with some caution in the present context, as they provide no insight beyond the analysis of the more basic scalar data used to deduce the existence of relations between participants and projects or threads. It is therefore useful to, first, make these connections explicit, and, second, to start our analysis with a direct exploration of these scalar data.

6 Global Participation Data

Let us begin by counting the comments and the participants in each project to get a first idea of their size as well as of the size of the global community involved (Fig. 2).

There have been 16 research-level Polymath projects over the 9 years between early 2009, when the first project was initiated, and early 2018, when the last two were. From 2009 to 2010, the first five projects were initiated, and from 2017 to 2018

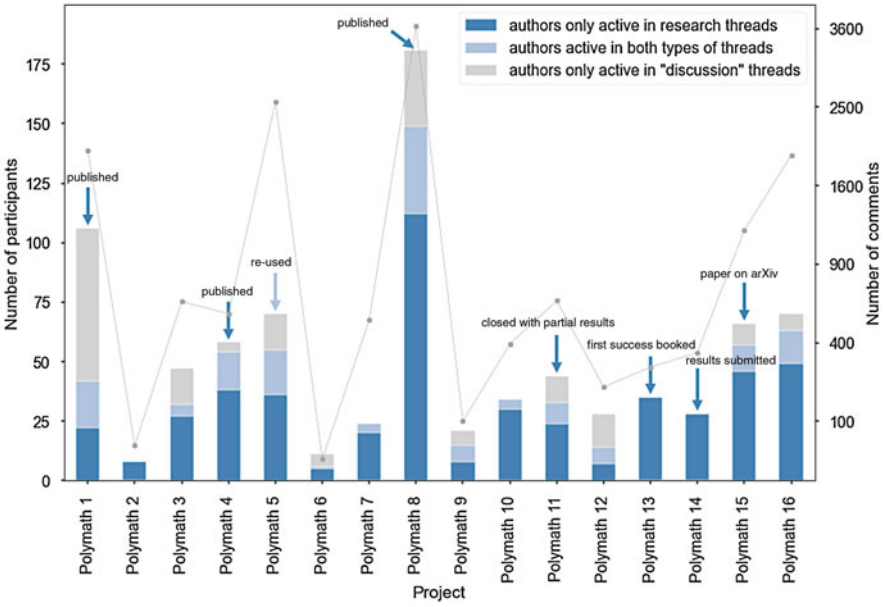

Fig. 2 Number of participants/comments for all projects

the five most recent projects were. The intermediate 6-year period led to fewer projects but was dominated by the largest Polymath project (to date), Polymath 8. For this chapter, we processed all commenting activity up to May 2020. Note, again, that we here do not consider the "mini" Polymath projects, dedicated to Maths Olympiad-final problems.

Polymath projects have had between 8 (Polymath 2) and 181 participants (Polymath 8). In terms of the number of interventions, the smallest project (Polymath 6) only had 27 comments, whereas the largest project (Polymath 8) had 3633. Across all projects, 622 distinct participants were identified (623 if "Anonymous" is included), and more than 14,000 comments were posted.

The distribution of the number of comments per participant appears to be extremely unequal. Across all projects, the average number of comments per participants is just below 24, with only 29 participants (less than 5%) commenting more than 100 times. Most notably, over 40% of all participants commented only once, and the two top contributors (Timothy Gowers and Terence Tao) wrote more than 25% of all comments. Data from the latest projects suggest, however, that the relative influence of Gowers and Tao has decreased in time.

To compare the inequality with results about Zooniverse from Franzoni and Sauermann (2014), we have plotted Lorenz-curves (not depicted to save space) and computed Gini-indices to quantify how unequal the Polymath projects are.

$$\text{Gini} = \frac{2\sum_i^n i \times y_i}{n\sum_i^n y_i} - \frac{n+1}{n}$$

with $[y_1, \ldots, y_n]$ a sorted vector of y_i 's. The range of this index is [0, 1], where the minimum value 0 corresponds to absolute distribution, while the maximum value 1 means absolute centralization. Hence, a high value of this index, approaching 1, means that a small proportion of participants is responsible for a high proportion of contributions.

The Gini-index for all comments across all projects is 0.88. This result is comparable to what was found for seven Zooniverse-projects (see Table S2 of the supplementary material from Franzoni and Sauermann (2014) at http://www.pnas.org/content/pnas/suppl/2015/01/02/1408907112.DCSupplemental/pnas.201408907SI.pdf), where a Gini-index of 0.85 is given as an average across all projects. In that sense, the value we find here is very high, but not exceptional. When we separate all projects, we find more variation. In general, larger projects tend to be more unequal in the sense that attracting more participants primarily means attracting more less active participants. This is to be expected since as projects go on, the relative impact of the most prominent participants increases.

In the specific context of Polymath, such a level of inequality may be more problematic than it is for other forms of crowd science. First, it may signal an extreme imbalance in the distribution of the cognitive labor that is at odds with the goal to engage in genuine collaborative problem-solving. Second, it may suggest that Polymath turns out to be less open than it has aspired to be. When we only count comments, we cannot settle this issue. We should therefore, minimally, try to gain a

better understanding of the nature of the inequality, by considering how it emerges, and what it may tell us about the role of prominent participants. We believe that the adoption of a network-perspective, as currently developed, is a fruitful approach to that end.

The distribution of comments can be described by a "heavy-tailed" distribution (Fig. 3). We have used the library described in Alstott et al. (2014) to fit the distribution and plot the results. The best fit is a Truncated Power Law (red line), but we cannot conclusively exclude alternative heavy-tailed distributions such as a Stretched Exponential or LogNormal distribution.
