This distribution should not be seen as evidence for a *rich gets richer* dynamics. High values are the result of time and energy invested. This is obvious in this context, where we only look at the number of comments, but it is crucial to also keep this in mind when we study relational data below. Being affiliated to many projects, threads and episodes require substantial efforts; consequently, joint affiliations with many participants do also. Moreover, when we simultaneously take into account the numbers of comments and the numbers of affiliations (not depicted to save space), we can understand how this distribution emerges. The key insight is that participants who contribute just a few comments almost exclusively do so in only one project, while participants who contribute more comments are also more likely to be returning participants in other projects. As a consequence, the growth of the Polymath community has been such that the number of comments by the most active participants and the number of participants with very few comments have increased hand in hand.

In addition to the already highlighted fact that a very small fraction of the participants is responsible for the majority of the contributions, we also note that

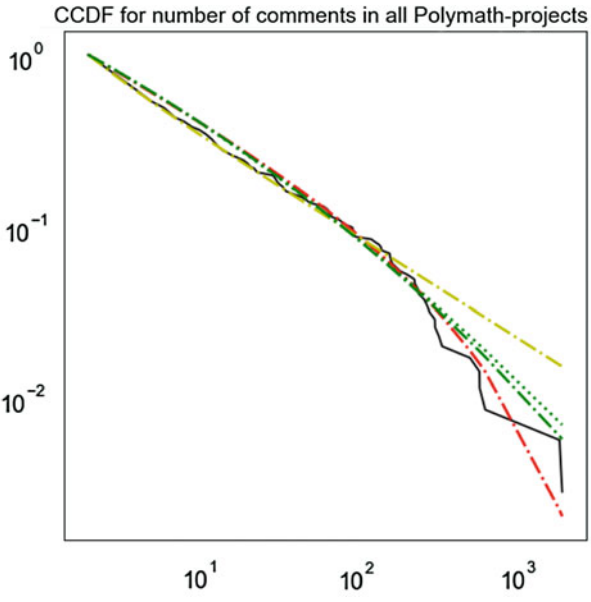

Fig. 3 Cumulative distribution of number of comments per participant

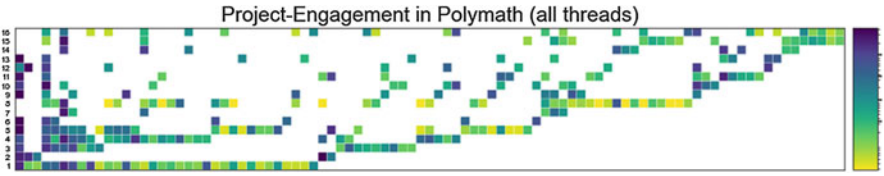

Fig. 4 Project affiliations of core participants based on the relative contribution to each project. This plot uses a logarithmic scale. The darkest blue depicts a relative contribution of over 40%; yellow and green depict relative contributions below 1%

only few participants have become long-term contributors: 529 of the 622 participants contributed to only one project, and as few as 11 contributed to at least five. We will henceforth refer to the 529 single-project participants as *peripheral* participants, and to the remaining 93 as *core* participants (Fig. 4). This terminology slightly diverges from the standard one which uses "core actors" (resp. "peripheral actors") to refer to actors affiliated to "core events" (resp. "peripheral events"), which would result in a larger core and smaller periphery (Borgatti et al. 2018: §13.6). A similar pattern, with the exception of Polymath 8 (marked by the presence of highly active single-project contributors), is found at the level of thread-affiliations: 90% of all participants participated in at most seven threads, and contributed at most six comments to each thread they participated in. Further analysis of the affiliation data moreover reveals that the weighted contribution to previous projects is a good (partial) predictor of future participation. This increases the plausibility of the hypothesised mechanism that produces the extreme inequality of the total sizes of contributions.

7 Affiliations and Joint Affiliations

We consider the affiliations of participants to projects and to threads by constructing bipartite networks with connections between participant-nodes and project- or thread-nodes. From these networks, we deduce joint-affiliation networks. Recall that the vast majority of Polymath participants we refer to as *peripheral* participants are only affiliated to a single project, and therefore only have joint affiliations that are based on a single project. As a consequence, joint-affiliation networks are characterized by the overwhelming presence of clusters of maximally connected participant-nodes that are all affiliated to the same project (Fig. 5 (left)). The connections between core participants, with affiliations to several projects, represent only a small fragment of all connections. Networks based on joint affiliations to threads (Fig. 5 (right)) share most of these features but can in addition be used to study more fine-grained patterns within projects.

With these caveats in mind, we can deduce a number of readily discernible features of the relevant networks. If we restrict our attention to the core participants, we find that a large proportion of them, about a quarter, were "early joiners," in that they joined already during the first project, and almost all had participated in more than one project by Polymath 5. Additionally, since the union of the affiliations of the two most active

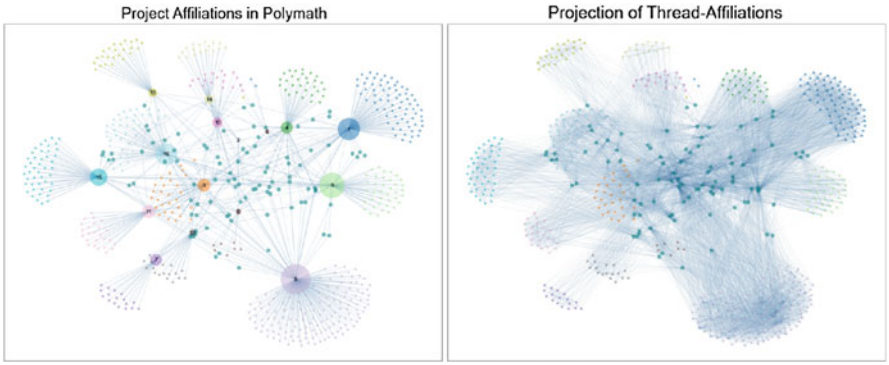

Fig. 5 Project affiliations (left) and joint affiliations to threads (right)

participants (Gowers and Tao) covers all projects *and* since their affiliations also overlap (with five common projects), we can conclude that the distance between the participants in the network based on joint project-affiliations is at most 3.

To further develop this analysis, we were in need of relying on a more systematic approach. We first give a precise description of the method that has been used to construct the joint-affiliation network and to assign *weights* to their connections between participants. The most common approach taken for generating coaffiliation networks is indeed to generate a weighted network from an unweighted bipartite network. One consideration is that joint affiliations to large entities (such as events that many people have attended) create weaker ties than joint affiliations to smaller entities. Another consideration is that having a joint affiliation to someone with many affiliations creates a weaker tie than having a joint affiliation with someone with fewer affiliations. Several approaches based on these types of considerations are reviewed in Borgatti and Halgin (2011). So if we want to take the strength of affiliations into account as well, we need a more elaborate approach, one that can be based on the following principles (explained relative to project-affiliations, but readily generalizable to thread-affiliations).

1. For every pair of participants l and k, let the vectors of weights $w_l = \left[w_l^1, \ldots, w_l^{16}\right]$, $w_k = \left[w_k^1, \ldots, w_k^{16}\right]$ correspond to the number of comments contributed to each project. This corresponds to a list of the weights between l (resp. k) and the neighbors of l (k) in the project-affiliation network; with zeros filled in to have fixed-length vectors and ensuring that the n th element of w_l is the number of comments of l contributed to the n th Polymath project. The sum of a vector w_l corresponds to the weighted degree of l in the project-affiliation network.
2. Let the vector $w = [\widehat{w}_1, \ldots, \widehat{w}_{16}]$ be the average number of comments contributed to each project.

We define the strength or weight of the tie beteween l and k as $\sum_{i=1}^{16} \frac{w_l^i \times w_k^i}{\widehat{w}^i}$

By multiplying weights, we ensure that the tie between two participants with few contributions is weak, and becomes stronger as either or both have more contributions. The normalizing factor ensures that the weights remain within the range of the original weights (based on absolute counts of comments). The results capture the idea that two highly active participants of a given project are more likely to have directly interacted. Moreover, the choice for absolute values (edge-weights as number of comments rather than project-relative proportions of comments) implies that stronger ties can in principle be created during larger projects.

Given what is known about the project- and thread-affiliations, and taking into account how coaffiliation networks are constructed, there are a number of notable properties of the resulting networks that we found unsurprising. They could also be deduced from our earlier considerations about project affiliations, and by observing the structural properties of coaffiliation relations. (Note that joint affiliations are symmetric or reciprocal, and affiliations to a specific project or thread are also transitive.)

1. Both project-level and thread-level joint affiliation networks are connected: There is a path between any two participants.
2. At the level of joint project-affiliations, path-lengths are very short: The distance between any two participants is at most 3.
3. The average clustering and transitivity of the network is very high. For joint project-affiliations, we found that the average clustering and the transitivity are twice as high as for a randomized network with the same degree-distribution.

   As such, these properties do not require further analysis or explanation. We can complement this with a few more specific observations.
4. When we consider the path-lengths for joint affiliations to projects, we see that 16 participants are within a distance of at most 1 of the majority of all participants. Given the variation in the project-sizes, these results do not entirely coincide with bare numbers in project-participation: Affiliations to a few of the larger projects place a participant close to many others.
5. When we make the same comparison for joint thread-affiliations, we only find two participants that are within a distance of at most 1 of the majority of all participants, namely Terence Tao and Gil Kalai. These are not the two original central figures of Polymath (and the two most active commenters), as it notably does not include Timothy Gowers. (In view of results obtained at earlier stages, where Gowers figured as a third, and indeed more prominent, central figure, it should be pointed out that Gowers' absence in Polymaths 14 through 16 tilted the balance.) This reminds us that joint affiliations to projects are rather loose ties. In this case, the central participants are exactly those who (by a substantial margin) participated in most threads.
6. Even when we look at joint affiliations to threads, we see that all but one participant are within a distance of at most 2 of the majority of other participants.

Jointly, these observations indicate that, given the specific position of the top participants, the size of the network is relatively small and that even single-project

participants (those we refer to as peripheral) are not peripheral in the more standard uses of the term. To better understand the role of the core participants, we will now engage in a still more sophisticated analysis.

8 The Relative Weight of Participants

Recall that the *degree* of a node is the number of links it has to other nodes, and that the *weighted degree* of a node is the sum of the weight of its links to other nodes. Note also that in the unweighted case the maximum degree of a node is bounded by the number of nodes in the network. When we consider the distribution of degrees, we compare the number of nodes with small degrees to the number of nodes with high or very high degrees. This type of analysis complements what we said about the distribution of the numbers of comments per participant.

We take the (unweighted) degrees of participants in the network based on joint thread-affiliations as our starting point. This is the most fine-grained and most extensive data set we have: There is a large number of participants and edges (≈9400), but there are also many (180) stages in the growth of this network. The purpose of this analysis is to characterize the emergence of nodes with very high degrees (so-called hubs), and to decide whether we have a regular (small- or ultrasmall-world) network or a network that is in the anomalous regime, where one central hub remains directly connected to all other nodes. We consider three aspects of the degree-distribution: (i) We fit the empirical distribution to a theoretical distribution to find whether it is heavy-tailed, (ii) we consider the evolution of the average shortest-path between nodes relative to the growth of the network, and (iii) we consider the evolution of the maximum degree relative to the growth of the network. The result can be found in Fig. 6.

As before, we can rule out that the degree-distribution is exponential. The best fit is a Log-Normal Distribution (blue line). As before, other heavy-tailed distributions such as the stretched exponential cannot be excluded. The dotted green line is the exponential distribution. (We refer again to Alstott et al. (2014) for a discussion of the fitting-method and the comparison of two competing distributions.) As we prefer to remain cautious, we postpone answering the question whether we have a small- or ultrasmall-world network, since we cannot straightforwardly consider the exponent of a fitted Power Law. (See Barabási (2016: Chap. 4) for an extended discussion.)

The analysis of the evolution turns out to be more informative (Fig. 7). We can see that the average shortest path-length grows linearly in ln ln (N), and that the maximum-degree almost keeps track with the number of nodes. From this, we may conclude that we have an ultrasmall network, which means that the presence of hubs substantially reduces the path-lengths in the network. However, note that with smaller network-sizes like these the difference between small-world and ultrasmall-world networks is not extremely well marked (Barabási 2016: p.132).

It is useful to note that this network is not in the so-called anomalous regime, where the degree of the largest hub is identical with the size of the network. The direct examination of the affiliations already revealed that this was not the case: No

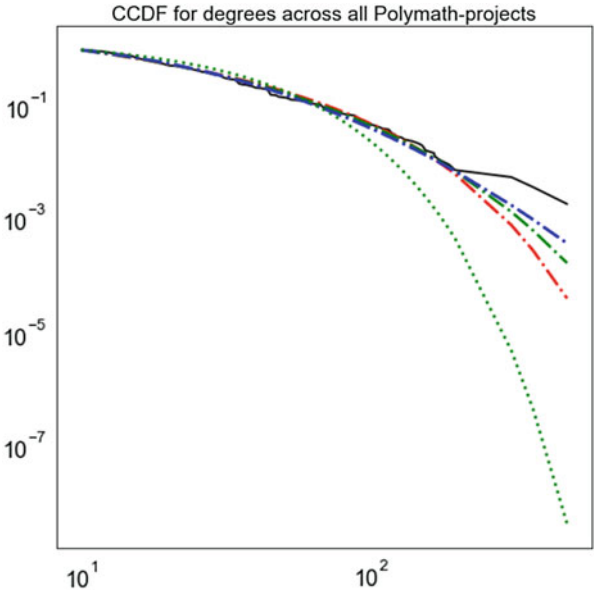

Fig. 6 Cumulative distribution of the degrees

participant is affiliated to all projects (and *a fortiori* to all threads), although the two core participants are sufficient to tie the entire network together.

It is insightful, at this point, to reflect on the mechanism that generates a specific degree-distribution. This can tell us how hubs emerge, and perhaps also shed light on the social role of the central participants. Traditionally, the presence of Power Law (or other heavy-tailed) degree-distributions is seen as the consequence of *preferential attachment*, which means that if new nodes are more likely to link to already well-connected nodes, then even a small preference for better-connected nodes will lead to the emergence of hubs (Barabási 2016: §5.3). Since we study a network based on joint affiliations, we cannot straightforwardly transpose this analysis to the present case. There are however at least two salient differences. First, new as well as already present nodes create links (or reinforce links). And second, participants do not directly link to other participants but link instead to projects or threads. In that sense, the emergence of hubs cannot be the direct result of preferential attachment.

But there is an additional complication, as participants cannot even freely choose their affiliations. At most stages, the number of available choices remains limited. With only one recent exception during Polymath 15 and 16 (which have proceeded simultaneously), there has always been at most one project to affiliate to. Additionally, during most projects (with Polymath 1 as a notable exception), there has only been one active thread to affiliate to. As such, the "choice" faced by a participant is binary: whether or not to affiliate to the current option. Moreover, every project or thread to affiliate to comes with preexisting affiliations that have to be taken as a given. These general features are slightly relaxed when we look at more fine-grained affiliations

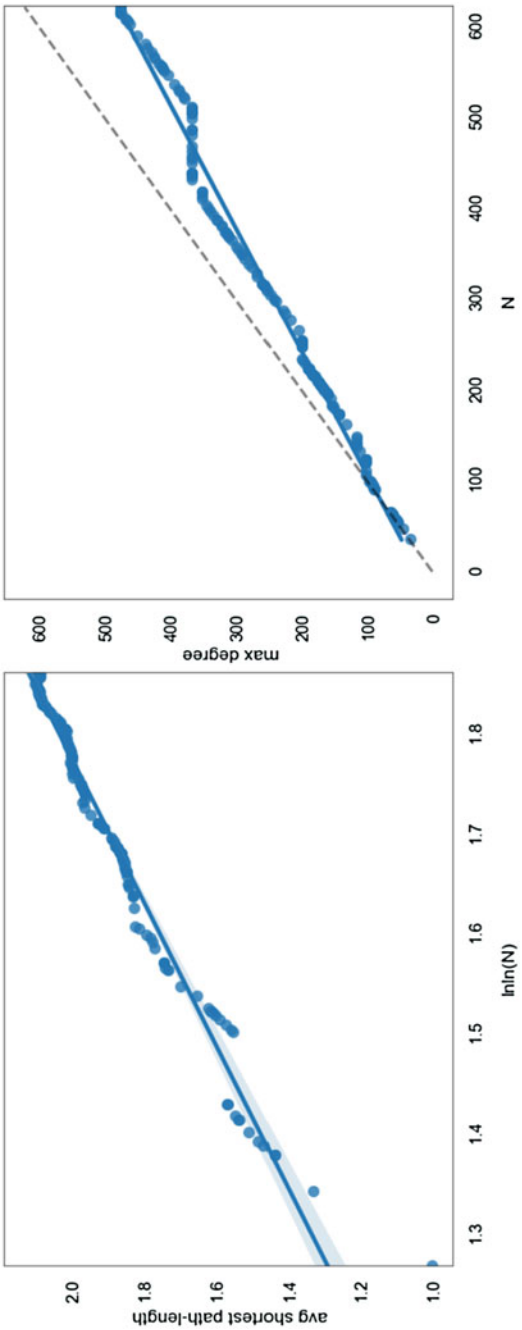

Fig. 7 Evolution of joint affiliations to threads

such as episodes, but they do not disappear. The discussion is always happening in a very small number of places.

This allows us to highlight two features of highly connected nodes:

1. They are omnipresent, in that they are always or almost always affiliated to the current option. This corresponds to a role for highly connected participants as *available* moderators or leaders.
2. They make the events they are affiliated to more attractive and thus increase the chance that other participants will affiliate rather than not affiliate. This corresponds to a role for highly connected participants as *attractive* moderators or leaders.

The first feature appears uncontroversial and squares with an earlier point we made about central participants: There is no lazy road to becoming a highly central participant, but centrality is due to extensive and sustained effort. The second feature is potentially problematic, for it may indicate that not every highly active participant can actually become a central participant, in the sense that only previously attractive participants can create a context in which they can become highly active in the presence of others. Contributing the majority of all comments does not, after all, make one highly connected. This only becomes possible if a sufficiently large pool of other contributors are willing to contribute the rest of the comments.

This worry connects to broader concern regarding the ability of Polymath to create the open environment it has aspired to. We cannot do full justice to this issue here but only reiterate the consequences of our two earlier insights. First, since centrality comes with effort, it is only within reach of those who are able and willing to spare that effort. And second, since the potential to spare the effort alone is presumably not sufficient to reach centrality, it may also not be within reach of those who are not already sufficiently attractive. Based on the self-reporting of the participants to Polymath 8, we should also stress that much effort remains hidden in the present analysis. Even just following without actively contributing requires a substantial investment given the high pace and level of most of the discussions (Polymath 2014).

The present analysis can unfortunately not shed any further light on the practical and institutional obstacles to reaching Polymath-prominence and cannot directly reveal anything about hidden investments to (or, indeed, the hidden returns of) the Polymath Project either. Nevertheless, the displayed method of precisely quantifiying the centrality of the most prominent participants can be of additional value, in that it will point to the relative centrality of less visible participants (something that cannot be inferred by merely reading the threads, but that surfaces by inspecting path-lengths), and can even give indications about the potential of newly emerging hubs (indeed, the largely inconclusive attempts to find subcommunities in the entire Polymath-community revealed that at any point there were apparent "runners-up" to the two major centers of attraction). In sum, by reasoning explicitly about the mechanisms that generate connections, nuance is added to how we evaluate the significance of centrality.

Granted, this type of highly abstracted analysis leaves many questions unanswered. Despite several attempts to decompose the entire Polymath community into

smaller subcommunities, and relate these communities to either the presence and influence of certain participants or to common interests and/or competences in certain types of mathematical problems, we could not draw any stable and convincing conclusions at this level. An examination of the types of mathematical problems that are proposed and actually accepted as Polymath projects did reveal that there are "typical" Polymath-problems, and newly proposed problems are often similar to earlier projects. Important differences between the types of problems that are tackled can be found as well though. One noteworthy instance are those projects that, such as Polymath 8 and more recently Polymath 16, depend on computational methods. Indeed, Polymath 16 quickly revealed close connections with Polymath 8 participants. What remains out of reach for now is the discovery of comparable, but less readily recognizable or predictable connections.

9 Specific Project Communities

In this final section, we take a closer look at the fine structure of the networks associated with specific projects. We shall do this by considering three types of networks for individual projects:

1. Directed (weighted) networks based on direct interactions
2. Undirected (weighted) networks based on joint affiliations to episodes
3. Directed (weighted) networks based on joint affiliations to episodes

Networks of the first type are directly extracted from the shape of the discussion-threads. In a directed weighted network, there is a directed edge with weight n from one participant to another *iff* there are n comments authored by the first participant that are a direct reply to comments of the second participant.

Networks of the second and third type are extracted from an intermediate affiliation-network between participants and episodes of intense interaction. Episodes are ordered collections of comments that, in view of their timestamps, supposedly belong together. As they are intuitively part of the same conversation, it is reasonable to presume that participants to a given episode have read all the comments belonging to it. We identified the episodes with the help of a clustering algorithm. A word on the latter. After initial tests with the `MeanShift` algorithm (Comaniciu and Meer 2002), we settled on the use of `DBSCAN` (Ester et al. 1996). Both are unsupervised algorithms that have the benefit of not requiring one to set a number of clusters in advance, but the latter algorithm also allows one to exclude single isolated data-points (or small numbers of points) from the clustering. This possibility is essential if we want to avoid the unpredictable and uninformative attribution of isolated comments to the closest cluster.

Undirected weighted networks based on the joint affiliation to episodes are defined as follows: There is an undirected edge with weight n between two participants *iff* the sum of the number of comments of the episodes both are jointly affiliated to is equal to n. Here, the individual contributions of the respective

participants do not play a role: only the sizes of the common episodes (a rough measure of how much information was exchanged in those episodes) matter.

Directed weighted networks based on the joint affiliation to episodes, in their turn, are defined as follows: There is a directed edge with weight n between one participant and another *iff* the sum of the number of comments contributed by the first participant in the common episodes is equal to n. Here, it is the size of the contribution in the common episodes of the source node that determines the weight; we look at how much information flowed from the first participant to the second.

Note that these approaches are distinct from those used at the level of project- and thread-affiliations in Sect. 6. There, we devised a method where only pairs of highly active participants could create strong ties, since the joint affiliation of two barely active participants to a large collection of comments could only indicate a weak connection. In the case of episodes, effective interaction is the norm, and it is the strength of the interaction (the amount of information exchanged or the number of actual interactions) that has to be quantified.

When weights are ignored, the second type of network is just an undirected variant of the third type. As such, it does not encode additional information and can therefore safely be left out of our analysis. Additionally, even if the third type of network is directed, all its relations are reciprocal (though potentially of a different weight).

In the remainder, we focus our attention on the third type, and provide a brief comparison of what can be learned from the first and third type to support this choice. Here are some general considerations in favor of the third type:

- The presence or absence of direct reply-to relations between comments is in general unreliable. Such relations were absent during the first few threads of Polymath 1 and exhibit substantially different patterns throughout later projects.
  - In Polymath 1, for instance, a separate ad hoc numbering was used for some time to explicitly and manually flag relations between comments. These relations were used by Cranshaw and Kittur (2011) to construct a comment reference-graph. The absence of such references during the subsequent projects rules out the extrapolation of that approach.
  - A comparison of the shape of the discussion-threads in Polymath 4 and 5 reveals a glaring discrepancy. Polymath 4 has comments of many levels (as shown in Fig. 1), but Polymath 5 has only level-1 and level-2 comments.
- As a means to track the flow of information between participants, a network extracted from explicit reply-to relations is exceedingly conservative. Taking into account the authors of "nearby comments" turns out to be a reasonable middle-ground between this conservative option and the liberal one of assuming that information is automatically shared with all participants. The latter option can readily be dismissed in view of the (reported) effort it takes to keep track of the discussion.
- Modeling information-flow relative to joint affiliations allows one to model comments as one-to-many communications. Correspondingly, we have limited our analysis to small, temporally dense episodes of interaction. There are good

reasons to believe that the discussion actually proceeds this way. There is not only the reported fact that the speed of the discussion is often high, but we also found indications of a diurnal pattern in the timestamps of the comments.
- More generally, the network obtained on the basis of affiliations to episodes appears to be a reliable guide to the structure of the community of a given project. We provide some evidence in favor of this below.

We now review a number of characteristic features of a selection of projects to compare them to the overall community. (Note that we had to exclude Polymath 1 from this analysis since the parallel development on two blogs turned out to be an obstacle to this type of direct comparison.) First a general remark: A comparison of the networks of type 1 and 3 for the Polymath 8 project reveals that when we only take into consideration the direct and explicit interactions between participants, the largest weakly connected component of this network only includes 93 from the total of 180 participants to the entire project, whereas when we look at joint affiliations to episodes, the largest weakly connected component includes 167 of these participants. As a consequence, the analysis of the interaction-graph will not convey any information about almost half of the participants. This seems unwarranted given that 30 of these isolated participants contributed more than 1 comment, and 6 of them contributed more than 5. It also turns out that some of these isolated participants are core participants of the global Polymath community. These observations suggests that, first, an exclusive focus on the interactions leaves out some potentially valuable information about the network, and, second, that it may also misrepresent how information is shared between participants.

A closer analysis of Polymath 4, 5, 8, and the first 6 threads of Polymath 16 (see Figs. 8 and 9 for illustration, others not depicted to save space) has revealed that:

- Distances in larger projects can be bigger, such as in Polymath 8, where the longest path within the main weakly connected component is 4, a very small number (6) of participants are within a distance of 1 of most other participants, but

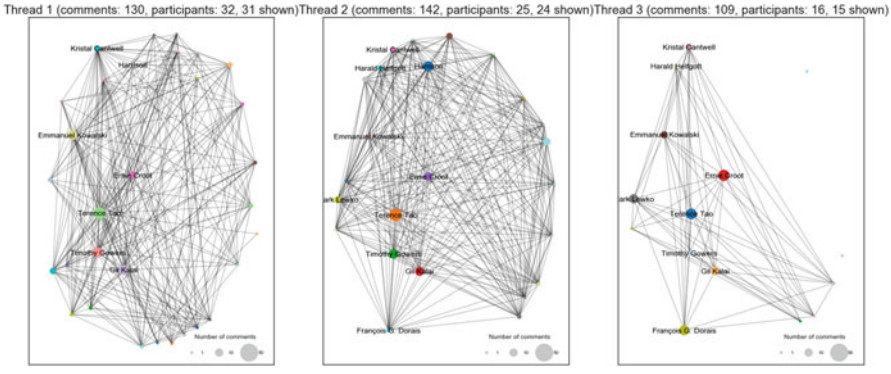

Fig. 8 Active network in Polymath 4 discussion-threads

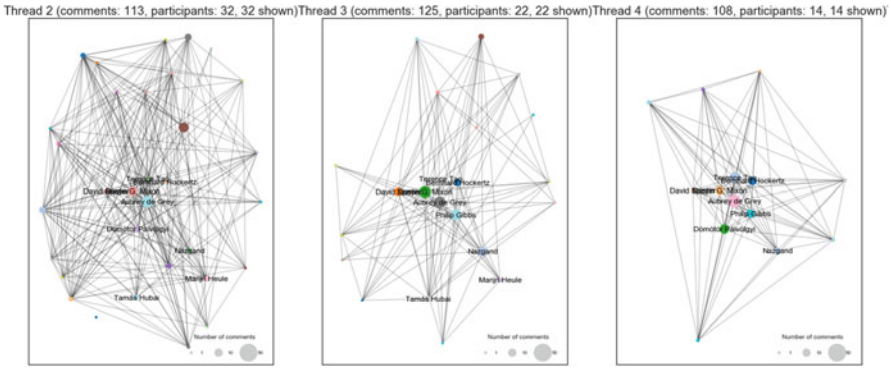

Fig. 9 Active network in Polymath 16 discussion-threads

almost all participants are within a distance of at most 2 of most other participants (We also found that the degree of the most connected participant sticks close to the number of nodes in the network.).

- A smaller project such as Polymath 4 is also based on a smaller network (longest path of 2), with a larger proportion of participants (13 out of 48) within a distance of 1 of most other participants. What is more remarkable is that the Polymath 4 community (presumably due to its small size, with only four research threads) evolved totally differently, and in fact did not visibly grow.
- Projects such as Polymath 5 and Polymath 16 that have a comparable number of participants, but more threads and comments, have again different features. The second has a larger proportion of small distances between participants, whereas the distances between participants are generally larger in the first one.

To understand how differences in the structure of project-networks emerge, it is instructive to consider the active part of the network during each thread. As it turns out, the evolutions we find are extremely different and highly remarkable. The Polymath 8 network, for instance, is best seen as a superposition of minor variations of the same collaborative network. Polymath 4, by contrast, seems to be the result of narrowing down the community to its barest essentials. In Polymath 5, then, the resulting evolution is perhaps best described with Terence Tao's comment that by 2012 Polymath 5 "petered out" (Klarreich 2015). Finally, the development of Polymath 16, reveals an evolution that (at least initially) resembles the development in Polymath 8.

10 Conclusion

For this first overarching quantitative analysis of the 16 Polymath projects, we chose to focus on the scientific community or communities that emerged during these collaborations. In the first sections, we have situated and motivated this endeavor in

general and our approach in particular. We then provided a detailed description of the methodology we developed and carefully laid out the modeling choices we relied on to distil a social network from the traces of the online interactions. For our actual analysis, we subsequently focused on the overarching community that emerged across all projects and the subcommunities associated with specific projects.

Our main findings about the global community concern the distances between participants, and the role of the most active participants. We could conclude that this community is to be situated in the ultrasmall-world regime, where the influence of the hubs is important. We pointed out that this pattern could not be explained by a mechanism of preferential attachment, but that it rather indicated the omnipresence or continuous involvement and availability of the leading participants.

Our main finding about the smaller project communities concerns the evolution of the patterns of interaction throughout the development of a particular project. We observed that there was a substantial variation between projects, with some projects evolving to a very small-scale collaboration and others continually varying around a more permanent core. Further research will have to reveal more detailed typologies for both the structure of the communities and the specific problems they aim to solve.

Abstract

Modern mathematics has been shaped by the process of secularization of science. Yet even some present-day mathematicians use religious terms behind the (mathematical) scenes. How essential this is remains debatable. Before modernity, everything, including mathematics, was perceived from a religious perspective. Deeper connections existed for Pythagoreans, and nowadays there is a revival of Pythagoreanism. Mathematics was used by medieval theologians, and even the founders of modern science – for instance, Newton, Leibniz, Boole, Cantor – referred to religion. From the present perspective, those theological aspects seem mostly irrelevant. The concept of actual infinity had a fundamentally religious meaning before the nineteenth century. Now, only a few see mathematical infinity as a notion common to mathematics and theology.

Religious origins of some mathematical concepts can be detected, for example, Indian origins of zero, possible Christian sources of the initiation of the

algebraic approach, the creative function of naming applied to infinite entities. On the other hand, mathematical illustrations of theological concepts are possible, even though genuine mathematical models do not seem to be essential or testable. Generally, religious needs and motivations played a role in the development of mathematics, and mathematical metaphors helped theologians. To perceive this connection as relevant now requires sensitivity to the realm of the religious.

Keywords

Philosophy of mathematics · Theological mathematics · God's mind · Religious metaphors · Religious inspirations · Mathematical models in theology · Infinite sets · God's point of view · Pythagoreans · Cantor

ἀεὶ ὁ θεὸς γεωμετρεῖ
God always geometrizes. (Attributed to Plato)

Mathematica est inimicissima omnino theologiae.
Mathematics is theology's greatest enemy of all. (Martin Luther)

Das Leben der Götter ist Mathematik. . . . Reine Mathematik ist Religion.
The life of the Gods is mathematics. . . . Pure mathematics is religion. (Novalis)

To consider relations of mathematics and religion we must assume we know what these two entities are. It is not easy to define mathematics but in the present Handbook familiarity with this field is presumed. What about religion, or rather religions, and theology, a faith-based rational study of religious issues? It seems hopeless to define religion. The best way to illustrate this difficulty is to quote Wilfred Cantwell Smith: "the question 'Is Confucianism a religion?' is one that the West has never been able to answer, and China never able to ask" (Smith 1964, p. 66). We have no choice but to assume familiarity with religious functioning and thinking about divine matters. The main reference points are the Abrahamic religions: Judaism, Christianity, and Islam; the religions that developed in India; and the legacy of Greek theological philosophy.

1 On the Approach to the Problem

While it may be true that everything is connected to everything else, mathematics–especially the practice of mathematics as we see it nowadays – seems unrelated, indeed totally opposite, to religion and theology. To modern eyes there exist no other two fields as unrelated as numbers and formal structures on the one hand, and God and divine matters on the other; or as calculating and proving on the one hand and praying and prostrating on the other. Yet to premodern eyes the connection was obviously there. The first task in the attempt to answer the question of whether mathematics is connected to religious matters should be to indicate the old

understanding of the relationship and, as a part of it, to indicate those who were both: mathematicians and theologians or passionately religious men. This task can be fulfilled only partially, by giving a few examples (in Sect. 3), since a full presentation would be close to a comprehensive history of the entirety of human thought.

Modern mathematics is the result of a process of secularization of science in general and mathematics in particular. The process took place mainly in the nineteenth century. It would be a mistake, however, to assume that the establishment of modern branches of mathematics was always done in the secular spirit.

It is of special interest to note that even present-day mathematicians use religious terms. To say that mathematics is for us "a divine language" constitutes a standard, if certainly metaphoric, idiom. The presence of such links is illustrated in Sect. 2. The most important (allegedly) common concept is, of course, infinity. It is treated at the end of Sect. 3, but it is also present at almost every point since some reference to infinity appears in most cases where we can observe connections of the mathematical to the religious.

Among more specific connections that can link mathematics and religion are the allegedly religious origins of some principal mathematical concepts (Sect. 4) and attempts to apply mathematics in theology (Sect. 5).

Comprehensive treatment of the subject seems hardly possible at this stage of research. According to Ivor Grattan-Guinness, the "secularization of mathematics has led historians to ignore religious factors in the development of mathematics, and even more of mathematical elements in religion" (Grattan-Guinness 2009, p. 278). To be sure, there are many publications researching aspects of the problem. Noteworthy recent books include the comprehensive volume edited by Teun Koetsier and Luc Bergmans 2005, the collection on infinity edited by Michał Heller and Hugh Woodin 2011, special issue on mathematics of the journal *Theology and Science* vol. 9, No 1, 2011, edited by James Bradley, and the issue of *Studies in Logic, Grammar and Rhetoric* 44 (57), 2016, subtitled "Theology in Mathematics?", edited by Stanisław Krajewski and Kazimierz Trzęsicki. A more popular collection was edited by Lawrence and McCartney (2015). Book length studies include Albertson 2014 dealing with medieval history, Cohen 2007 treating Victorian Britain, and Graham and Kantor (2009), describing the role of Orthodox Christian heresy "Imiaslavie" (see Sect. 4).

1.1 What This Chapter Is Not

The present chapter attempts to avoid prejudgments. The approach is cautious: some connections of mathematics and religion are indicated but no claim is made that they are very deep or absolutely essential unless this can be demonstrated. It is important to distinguish this relatively inconclusive approach from the essentially faith-based position adopted by some authors, especially in the USA, who advocate the religious impact of mathematics or a religious dimension of it. While publications under the rubric "Christian mathematics" can include valuable works, they are all written with the presumption that mathematics is religiously relevant. And this assumption is a

corollary to a more basic belief: everything is God's creation so we can perceive him everywhere, including in mathematics. This approach easily leads to doubtful claims. One can state that "the truth $2 + 2 = 4$ has the attributes of God, such as omnipresence, eternity, omnipotence, and truthfulness. God spoke the world into existence" (Poythress 2015, p. 42). This characterization is not without interest, but it brings no insight when the conclusion is that "when we analyze what $2 + 2 = 4$ really is, we find that arithmetic constantly confronts us with God himself, the Trinitarian God" (p. 25). In addition, "in thinking about arithmetic, we are thinking God's thoughts after him" (p. 25). The image behind all those statements is a theological assumption that used to be standard and normative two or more centuries ago but is totally unconvincing to most scientists today.

To mention a much more serious achievement, Bradley and Howell 2011 present a competent popularization of several mathematical topics. They argue that mathematics is fascinating and beautiful, the points which will be approved by every mathematician, and end each chapter with a statement like "Isaiah 1:18 asks us to reason with God, and the logical structure of mathematics gives us a way to reason effectively" (Bradley and Howell 2011, p. 138). The authors offer a general conclusion saying that "the Christian students would realize that the philosophy of mathematics and Christian faith share a number of interesting touch points. Indeed all things exist and have their being through Christ, including mathematical objects" (p. 217). This does not seem illuminating, for it is just presumed. That is why such books, even when they contain good presentations of mathematics, do not answer the question about the relation of mathematics to religion asked by unprejudiced inquirers.

Rather than trying "to redeem" mathematics, the approach adopted in this chapter is critical, assuming no religious starting point, but at the same time, it is open to the realm of the religious. It is neither assumed that everything must be according to religious convictions nor that nothing religious can be essentially tied to mathematical practice.

2 Mathematicians Using Religious Metaphors

In 1883, Georg Cantor expressed a strikingly modern opinion: the essence of pure mathematics is its freedom (Cantor 1932, p. 182). He wanted to defend the meaningfulness and significance of his pioneering work; he felt that his theory of actually infinite sets was consistent and compatible with the existing mathematics. This opinion is today absolutely dominant among mathematicians. Cantor and David Hilbert were among its first spokesmen. It was Hilbert, who in 1925, made the famous remark on behalf of mathematicians: "No one shall drive us out of the paradise which Cantor has created for us" (Hilbert 1926; Benacerraf and Putnam 1983, p. 191). Is the religious terminology he used only a convenient and universally understandable rhetorical device or does it express something substantial? Even if he just wanted to use a nice metaphor one can still ask why religious metaphors are particularly satisfactory when we talk about mathematics (Krajewski 2016). This

question is naïve, perhaps too naïve, but the ease with which mathematicians utilize theological language must not be ignored. To be sure, this language does not appear inside proofs or definitions, but rather on the side, in informal speech when one wants to say why some topic is important or interesting, and what were one's motivations or associations. On such occasions it can be perfectly natural to talk about God, "God's standpoint," "God's mind." Occasionally traces of this way of talking can be retained in the "official" text. Thus, we can talk about performing infinitely many acts (for instance, acts of choice of an element from a set) as if we had an infinite, "divine" mind; we can refer to a complete knowledge (for instance, taking the set of all sentences true in a given interpretation) as if we were actually omniscient. We can also refer to paradise in Hilbert's sense.

One might say that all such figurative utterances using, directly or indirectly, theological terms are irrelevant and should be ignored in reflection about the nature of mathematics; they are mere chatting, present around mathematics, but not part of it. This loose conversation is, however, part of mathematics, says Reuben Hersh, who asks us to consider seriously the fact that mathematics, like any other area of human activity (as analyzed by Erving Goffman), has a front and a back, the chamber, and the kitchen. The back is of no small importance since the product is made there. The guests or customers enter the front door but the professionals use the back door. Cooks do not show the patrons of their restaurant how the meals are prepared. The same can be said about mathematicians, and for this reason, its mythology reigns supreme. It includes, says Hersh, such "myths" as the unity of mathematics, its objectivity, universality, and certainty (due to mathematical proofs). Hersh is not claiming that those features are false. He reminds us, however, that each has been questioned by someone who knows mathematics from the perspective of its kitchen. Real mathematics is fragmented, it relies on esthetic criteria, which are subjective, proofs can be highly incomplete, and some of them have been understood in their entirety by nobody. Seen from the back mathematics is "fragmentary, informal, intuitive, tentative. We try this or that, we say 'maybe' or 'it looks like'" (Hersh 1991, p. 128; also in 2006). And we do borrow from the religious language. Perhaps the most telling example is the joking contention of Paul Erdös, the famous author of some 1500 mathematical papers (more than anyone else), according to which there exists "The Book" in which God (who else?) has gathered the most elegant proofs of mathematical theorems. Erdös was far from standard religiosity, but he reportedly said, "You don't have to believe in God, but you should believe in The Book" (Aigner and Ziegler 2001, Preface). If in the kitchen of mathematics people use religious language, does it mean the two fields are related?

Probably the most famous example of direct use of the term "theology" in relation to mathematics can be found in the reaction of Paul Gordan, in 1888, to Hilbert's non-constructive proof of the theorem on the existence of finite bases in some spaces. Gordan said, „*Das ist nicht Mathematik. Das ist Theologie.*" Later, having witnessed further accomplishments of Hilbert, he would admit that even "theology" can be useful (Reid 1996, p. 34, 37).

One should not miss the expressions that seem to point to an overlap of the contents of mathematics and theology or at least of the presence of common features.

This possibility is mentioned in some official statements, made for the "front" public. When Hilbert mentioned "the paradise" he could have meant only a rhetorical effect, but in another classic exposition of "Hilbert's Program," in 1930, Rudolf Carnap, while talking about logicism, used the phrase "theological mathematics." According to him, Ramsey's assumption of the existence of the totality of all properties should be called theological mathematics in contradistinction to "anthropological mathematics" of intuitionists; in the latter, all operations, definitions, and demonstrations must be finite. Ramsey "elevates himself above the actually knowable and definable and in certain respects reasons from the standpoint of an infinite mind which is not bound by the wretched necessity of building every structure step by step" (Benacerraf and Putnam 1983, p. 50). Clearly, when infinity is considered, theology is most easily invoked. Or, at any rate, this was happening in the late nineteenth and the early twentieth centuries. Back then it was still far from obvious that we could act as if we could fully control infinite structures, perform infinite sequences of operations, and consider as given the results of an infinite number of acts. By now, such capacities are commonly seen as unproblematic. On a mathematical level, the opposition to infinitistic mathematics seems virtually non-understandable for a contemporary university student. For example, the rejection of the Axiom of Choice by French "semi-intuitionists" was explained, in 1908, by Emile Borel: "the legitimacy of a non-denumerable infinity of choices (successive or simultaneous) . . . appears to me . . . entirely meaningless" (after Moore 1982, p. 102). Nowadays, only the rare species of committed constructivists can express such objections.

The present situation resulted from an exceptional, total victory of Cantor's ideas. Infinitistic mathematics is now hardly seen as connected to theology. Almost always, the theological connection is completely ignored. It is only deep at "the back" that we could say that only God knows the entire decimal representation of the number π. If we were to say that "at the front," we would stress it is just a joke, as did Erdös.

3 Historical Interrelations

Through the eighteenth century nearly everyone was religious, so no wonder mathematicians also were; and later there existed professional mathematicians who were deeply religious; this is still the case. It seems, however, that for many of them the two dimensions of their lives are not genuinely connected but rather just present side by side. The point is whether for some of them the two components could be in harmony. What this can possibly mean in general is hard to say. It is possible, however, to present telling examples.

3.1 Pythagoreans and Their Legacy

The best known and most highly consequential ancient case is that of the Pythagoreans whose founder was both a mathematician and a religious leader. Around 530 B.C.E., Pythagoras began to attract disciples in southern Italy. The Pythagoreans

saw (natural and rational) numbers as the essence of everything – things, relations, musical harmonies, and the celestial harmony, produced by the spheres containing heavenly bodies; at the same time they discovered – to their alarm – incommensurables, or realized that there existed irrational numbers. (For details see Fritz 1945) The most directly religious aspect of their views can be seen in their veneration of the tetractys, or the number 10 represented by the points arranged in an equilateral triangle formed by rows of 1, 2, 3, and 4 points. The upper point represented the essence of all numbers, the two below symbolized the line, the next three symbolized the two-dimensional triangle, and the last four stood for a pyramid. The tetractys was seen as revealing the structure of reality. It was considered holy, and the Pythagoreans swore by it. (Fritz 1981, p. 221.) One of the prayers was, "Bless us, divine number, thou who generates gods and men! O holy, holy tetraktys, thou that containest the root and source of eternally flowing creation!" (Dantzig 1954, p. 42).

The Pythagorean view of the role of numbers sounds far too mystical for present-day scientists and philosophers, yet not only did it remain extremely influential throughout centuries but it has reemerged in a new format in our own time. A century ago, Bertrand Russell wrote that "perhaps the oddest thing about modern science is its return to Pythagoreanism" (Russell 1924, p. 252). He meant, for example, quantum physics allowing only a finite number of states, which brings back the idea that everything is composed of definite units. This idea is further developed in modern physics. For example, Max Tegmark (2014) claims that reality is a mathematical structure. Russell also referred to modern genetics and to the arithmetization of the calculus, leaving only natural numbers as the basis of the continuous. For us, the arithmetization of syntax and especially the ubiquitous presence within our world of the digital realm, which is fundamentally a configuration of numbers, has opened up a new reality that deserves the name of "modern Neopythagoreanism" (Krajewski 2011). Its climax can be seen in the thesis presented by Stephen Wolfram, the author of the widely used program *Mathematica*. In his 2002 book *A New Kind of Science*, he claims that linear automata can code the most complex calculations including the universal Turing machine. (For a critique, for instance of the issue of the complexity of de-coding, see Baldwin 2004.) This claim makes possible the vision of the universe being a computer or even a computer program. Thus, as had been claimed by Pythagoras, literally everything would consist of numbers. To be sure, most of us see no directly religious aspect in such pancomputationalism. Yet for the ancients the interplay of the religious and the mathematical was obvious.

Plato extended Pythagorean ideas, ascribing to mathematical concepts a special role (see, for example, Baum 1973). Plato's philosophy has been at the center of Western thought and mathematics plays an important role in his thought as an example of certain knowledge and also as an educational tool required in his Academy, established at the beginning of the fifth century B.C.E., the first institution of higher learning. According to (later) tradition, the famous inscription at the entrance to the Academy read: "Let no one ignorant of geometry enter." Mathematical examples are presented in *Meno* to prove both the existence of immaterial Forms, which is a central point in Plato's philosophy, and the preexistence of the soul, a religious claim. In the late dialog *Timaeus* the divine "demiurge" is presented

as using mathematics to form the material world. And it is mathematical entities that are in between the ideal Forms in the "divine" realm and the visible objects in our material world. Mueller says, "Plato did have a comprehensive picture of the cosmos divided into a higher divine, intelligible world and a lower human, sensible world . . . A, and I suspect the, crucial link between these worlds is mathematics" (Mueller 2005, p. 117).

Theological presentation of the Platonic vision became common. In pre-Christian Rome, Seneca wrote that numbers existed in the divine mind: "God has these models of all things within himself, and has embraced the numbers and measure of all things which are to be accomplished in his mind. He is filled with those shapes which Plato calls 'Ideas': immortal, immutable, indefatigable" (after Albertson 2014, p. 56).

Around 100 C.E. Nicomachus of Gerasa wrote *Introduction to Arithmetic*, soon translated into Latin. "Nicomachus's works represents the fruition of Pythagoreanizing Platonism in Greek antiquity and the realization of what we can call a mathematical theology" (Albertson 2014, p. 51). It became highly influential: "the continued use throughout Europe of the arithmetic of Nicomachus, as translated by Boethius, are typical of the period from the tenth to the sixteenth century," state Robbins and Karpinski (Nicomachus 1926, p. 145). According to them, "the philosophical arithmetic of the Greeks, of which the arithmetic of Nicomachus is a specimen" includes number theory as we understand it now and at the same time "we have a mystical development, ascribing even magical powers and life properties to numbers" (Nicomachus 1926, p. 4). Indeed, such numerology was present in many cultures as was "sacred geometry," especially insights used in the design and building of religious constructions. In the ancient world also gematria was used, ascribing numbers to words, which is possible due to the fixed numerical values of letters. It was applied primarily to religious texts and is still mentioned in traditional Judaism (Cf. Grattan-Guinness 2009, Chap. 14).

3.2 Medieval Developments

Another Pythagorean achievement, not appreciated today, reigned supreme for centuries. It is the classification of mathematics into the discrete and the continuous with the former involving arithmetic and music, and the latter geometry and astronomy. This was the basis for the famous quadrivium of knowledge, which structured education, religious and nonreligious, in Europe until the early modern era. Its religious significance is stressed by Albertson: "the quadrivium as originally conceived for Latin Christianity by Boethius named the universal principles of first philosophy, or fundamental theology" (Albertson 2014, p. 10). In the fifth century C. E., in the prologue to his commentary on Euclid's *Elements*, Proclus explained that "mathematicals" are "projections of higher principles within soul, just as soul itself is a projection of the divine Mind." Hence mathematics is secondary to theology, and "the highest bond of the quadrivial arts is the divine Mind itself" (Albertson 2014, p. 66). Proclus also believed that "mathematics is the best conceptual language for

expressing the ineffable" (Albertson 2014, p. 66). The connection of theology to mathematics was very strong.

And it remained so for many centuries, although not for everyone. In the fourteenth century, Nicole Oresme, who was a scientist, philosopher, and theologian, presented the first proof of the divergence of the harmonic series. His mathematical work was separate from theology, unlike the scholarly work of Nicolas of Cusa in the fifteenth century. "Cusanus viewed his theological and mathematical explorations as belonging to the same integrated intellectual enterprise." He was praised in surprisingly strong words: "how is even Aristotle comparable to this Cusanus?" wrote Giordano Bruno, and added, "I would readily acknowledge his mind to be not just the equal of Pythagoras, but far superior" (Albertson 2014, p. 1).

Nicolas continued the earlier idea that the proofs of arithmetic, music, geometry, and astronomy lead to knowledge of the Creator. In particular, "mathematicals provide the surest pathway to contemplating God" (Albertson 2014, p. 171). For example, his book *De docta ignorantia*, or "On Learned Ignorance," of 1440, contains a presentation of geometrical figures as tools helping in contemplation, based on the idea that "mathematical knowledge is a *via negativa* to God" (Albertson 2014, p. 181). Thus, given a sequence of circles tangent to a given line in the same point, when their radii grow indefinitely the limit is a line, the common asymptote. And similarly with other figures, for instance indefinitely growing triangles. Therefore, "if there were an infinite line, it would be a straight line, a circle, and a sphere" (Nicholas of Cusa 1985, p. 20). In another work, he describes the game of a spinning top. "If the top spins with 'infinite velocity,' then any two points on the circumference of the top's surface would be co-present with any given point on the fixed circle" (Albertson 2014, p. 259). All the examples show that infinity is not present in our world, and cannot be reached from the domain of the finite. Even potential infinity is impossible. Yet it can be grasped conceptually. The reason for this is the presence of infinity in God. It involves *coincidentia oppositorum*. And since infinity is never reached via approximations by finite objects, it is infinity that is primary: "the one and only Absolute Eternity is Infinity itself, which is without beginning. Consequently, everything finite is originated from the Infinite Beginning" (Nicholas of Cusa 1996, p. 538). And mathematics can reflect God's mind: "we give our name 'number' to number from the Divine Mind" (Nicholas of Cusa 1996, p. 552).

All such considerations strike us now as rather naïve mathematically. Perhaps the most appealing image, also discussed by Cusanus but present since at least the twelfth century, and perhaps much earlier, is offered by the concept of the infinite sphere, whose center is everywhere and whose circumference nowhere. This Latin statement "*Deus est sphaera infinita cuius centrum est ubique, circumferentia nusquam*" (Liber XXIV philosophorum II 1989) can evoke the concept of the circle at infinity in the projective plane. (See Sect. 5 below for a contemporary insight.) The picture can have far-reaching consequences. According to Counet, "Nicholas's universe, which is actually neither infinite nor finite, whose centre is at once everywhere and nowhere, which is not exactly describable through mathematical notions, although mathematics can give an ever more precise account of it . . . the revolution initiated by Nicholas of Cusa is far more radical than that of Copernicus" (Counet 2005, p. 284–5).

This infinite circle was meant as one of the definitions of God. Cusanus also tried to present various mathematically conceived names of God, for example, "infinite Angle" and "infinite Number." He claimed that "an infinite angle would enfold all opposing angles, maxima and minima" (Albertson 2014, p. 247).

3.3 (Early) Modernity

Galileo's famous dictum that the Book of Nature is "written in the language of mathematics" did show the scientific way independent of religion. It is common to treat Galileo as the initiator of modern secular science who was silenced for his anti-Church position. Yet he remained a believer and did not think his views were heretical. In his letter of 1615, he wrote that "the true meaning of the sacred texts . . . will undoubtedly agree with those physical conclusions of which we are already certain and sure enough through clear observations or necessary demonstrations" (after Remmert 2005, p. 353). What is more, Galileo wanted to convince everyone that the mathematical approach is necessary and, according to Remmert, he referred to "the metaphysical legitimation he constructed for the mathematical sciences by eventually taking recourse to God and the divine" (Remmert 2005, p. 349). Similarly, Johannes Kepler "even considered the mathematical way as a kind of divine service" (Remmert 2005, p. 356). And the celebrated founder of mathematical physics, Isaac Newton, was not only deeply involved in theological research, but he should be seen as someone working not in modern science but still in the field of natural philosophy that "considers God and His creation. This orientation towards God was taken for granted" (Pater 2005, p. 463).

Another giant of that era, Leibniz, seems to indicate a much more specific connection of mathematics and theology. His dictum, "As God calculates and executes thought, the world comes into being" (after Breger 2005, p. 489), presents God as a mathematician. Again, he employs theological language to indicate the role of mathematics in the scientific account of the world. Leibniz believed that the same mathematical approach can be applied in theology. By that, he meant the need to use precise logical arguments rather than mathematics as such. One can still ask whether Leibniz applies mathematics in his theological considerations, that is, if it is possible to connect Leibniz's mathematical achievements, such as the creation of contemporary infinitesimal calculus, with his theodicy. An attempt to establish a link has been made. Namely, the idea of our world being the best of possible worlds is an expression of the belief in the applicability of an optimization principle. According to Emil du Bois-Reymond, Leibniz "conceives God in the creation of the world like a mathematician who is solving a minimum problem, or rather, in our modern phraseology, a problem in the calculus of variations – the question being to determine among an infinite number of possible worlds, that for which the sum of necessary evil is a minimum" (du Bois-Reymond 1870, p. 36). Max Planck liked this interpretation, and actually, this approach can be generalized since it is known that many physical theories can be seen as applications of the principle of the least action. Leibniz can be perceived as a forerunner of this approach not just with regard

to physical theories but also in the realm of theology. Yet, one can ask, how essential is mathematics here? The mathematical terminology does not seem to add anything essential to the general idea that our world is the best of all possible worlds. To express this idea no mathematics is needed. Thus, while it is possible that Leibniz was motivated by ideas similar to his mathematical concepts, the connection appears to be primarily psychological. Possibly important in the context of discovery, the connection plays no role in the context of justification.

Similarly, Blaise Pascal who made great contributions to mathematics devoted a lot of attention to religious matters. He emphasized the opposition and the lack of continuity between these areas: the reasons of the mind are opposed to the reasons of the heart, *esprit de géometrie* is opposed to *esprit de finesse*, and, even more important, he knew since his mystical experience of 1654, that the God of Abraham, Isaac, and Jacob is to be distinguished from the God of philosophers. A mathematical mind and the experience of a man who created the calculus of probabilities can be seen in his famous theological argument, the wager, *le paris de Pascal*. While some mathematical inspiration might have been important for Pascal in his theological considerations, this was a general, nonspecific encouragement. The formulation of it does not require mathematics, even if strict mathematical formulation can be helpful. Actually, "probability theory does not seem to have been invoked to elaborate" the high probability of the existence of a Designer, notes Grattan-Guinness (2009, p. 305).

George Boole was a founder of modern symbolic logic that became the foundation for the epitome of our era, computers and the digital realm. Yet, again, writes Daniel Cohen, "it is wrong to assume that the purpose of nineteenth-century pure mathematics and the symbolic logic that arose out of it was to construct a completely scientific, secular realm of philosophy" (Cohen 2007, p. 11). According to his wife, for Boole mathematics and logic was of secondary interest; primary was "the cause of what he deemed pure religion" (Cohen 2007, p. 77). He "seemed never tired of reading what are called 'religious books.' . . . The pursuit of scientific truth was also a religious act" (Cohen 2007, p. 92–93).

Another key logician of that time Augustus De Morgan shared much of Boole's religious approach, yet in the late nineteenth century he "provided a secular approach to those issues that would become increasingly alluring to the growing ranks of professional mathematicians. In a charged cultural environment, De Morgan realized it would be best for everyone if religion and mathematics did not mix" (Cohen 2007, p. 136). In England, Russell completed the divorce, and in France, it was the influence of the Enlightenment that had a strong anti-religious impact. Yet for the creators of the *Encyclopédie* both theology and mathematics were seen as marginal branches of the tree of knowledge. Perhaps the reason was that "both mathematics and theology moved beyond the reach of experience into realms of the perfect and the infinite" (Richards 1992, p. 54).

Some mathematicians are also theologians. Some theologians use mathematical concepts or expressions with mathematical connotations. How deep is the connection of theological discourse with mathematics? Often it seems superficial and inessential, but sporadically the suspicion can arise that a serious relation of contents or method can be detected.

Pascal, Newton, Leibniz, and Boole were leading mathematicians and scientists and at the same time men of faith who, in addition, were devoting a lot of efforts to theology. They all thought that the search for mathematical truths makes it possible to uncover God's thoughts. However, one can doubt if they revealed a genuinely essential connection between the two fields. Can we find a stronger connection between mathematics and religion? In the next Section some examples of possible religious inspirations are presented, and in Sect. 5 mathematical models in theology. Before this, the most important case of an interplay of religion and modern mathematics is presented, that of Cantor.

3.4 Cantor and Infinity

Infinity, understood as a completed entity, was for a long time seen as representing the nature of God. It was basically a theological concept. Mathematicians used potentially infinite processes: extending lines, adding numbers, dividing geometrical objects. The proposals that actual infinities could be studied by mathematicians were not accepted. In the early nineteenth century Gauss, the prince of mathematicians, rejected infinite collections. And then came Georg Cantor. At first, he was a regular mathematician. Studying the sets of convergence of trigonometric series, he introduced the notion of a derivative of a set – that is, the collection of the limit points of sequences with members belonging to the given set – and he noticed that we can consider the intersection of the infinite sequence of subsequent derivatives. What is more, one can take the derivative of the intersection, then the derivative of the derivative, etc. This led him to the notion of a transfinite sequence and transfinite ordinal number. Soon, a whole theory of infinite sets was developed by him and later by others. For several decades, however, mathematicians were against the new theory. The strongest criticism was voiced by the highly influential Leopold Kronecker who was defending the traditional finitism, that is, the view that only finite objects really exist. Cantor claimed that his infinite numbers are of the same nature as the irrational numbers, since both kinds of numbers are the limits of infinite sequences. And both can be accepted because they satisfy certain conditions, which, according to Joseph Dauben, should be interpreted as consistency (Dauben 1977, p. 88). In addition, Cantor had deeper reasons to believe in the reality of his infinite numbers. Deeper means theological. In an 1895 letter to Hermite, Cantor referred to St. Augustine stating that natural numbers "exist at the highest level of reality as eternal ideas in the Divine Intellect" (Dauben 1977, p. 94; also Dauben 1990). Having adopted this view, it is easy to accept the existence of arbitrary infinite objects; after all, there is no reason to impose any limitations on the "divine intellect."

Cantor faced a wall: his approach was rejected not only by Kronecker or by Charles Dodgson, better known as Lewis Caroll, the author of *Alice in Wonderland*, who derided the "bewildering region of Infinities and Infinitesimals" (Cohen 2007, p. 174); even one of Cantor's allies, who had popularized his mathematical results, Magnus Mittag-Leffler advised him, in 1885, not to publish a paper on order types.

As a result, Cantor was pondering withdrawal, abandonment of mathematics. What he did instead was to start an intensive correspondence with theologians. He wrote to Mittag-Leffler that his ideas about infinity were inspired by God. He also stated that by his work he wanted to serve the Catholic Church. His approach was met with interest by some neo-Thomist theologians. For example, Constantin Gutberlet used Cantor's set to argue that actual infinity exists. In correspondence with him, Cantor argued that his infinite numbers make God greater, not smaller. Cantor was able to gain the acceptance of Cardinal Johann Franzelin, a leading theologian of the First Vatican Council, who was satisfied by the Cantorian distinction between absolute infinity and actual infinity. According to Cantor, some infinite structures are so infinite that they are not sets, that is, they cannot be subjected to set-theoretic operations. Due to this distinction, antinomies could be avoided. For instance, the ordinal number ω and the set of natural numbers are actually infinite, but there is no set of all ordinal numbers, because as a "multiplicity" it is "absolutely" infinite. Franzelin accepted the idea that the Absolute Infinite is reserved for God and the (mere) actual infinity is present in the creation. He wrote to Cantor: "there is no danger to religious truths in your concept of the Transfinitum" (Cantor 1932, p. 386).

Cantor firmly believed in the existence of infinite sets. At the same time, he categorically rejected infinitesimals, the infinitely small quantities. He alleged that "the atoms of our physical world form an actually infinite set with cardinality $\aleph_0$ and he believed that the set of the atoms of the universal ether is essentially bigger and possesses the power $\aleph 1$ of the continuum" (Thiele 2005, p. 535). (He assumed the continuum hypothesis.) He was not only deeply interested in theology – for example, he wrote a pamphlet rejecting the immaculate conception – but also was convinced that he was "merely the tool of a higher power" (Thiele 2005, p. 546).

It is apparent that Cantor not only used theological arguments to support his theory, but he also found consolation among Catholic theologians. Granting this, one can still ask whether theologians and mathematicians speak about the same realities. This is unclear (see Oppy 2011; Tapp 2011). Did Cantor use the theological notions in his mathematical considerations? It is doubtful that his religious considerations were necessary or even essential.

The Cantorian distinction between the "regular" and the "absolute" infinity was mathematically right. It gave rise to the mathematical distinction between sets and proper classes, or collections that may not be elements of other classes. However, Cantor's theological-philosophical justification of the distinction did not stay. For him, any set, finite or infinite, could be treated as unity (*Einheit*), or one completed whole, whereas those absolutely infinite collections could not be treated as completed unities. Yet von Neumann, Bernays, Gödel formulated axiomatic theories of classes in which both sets and proper classes, like the totality of all sets, are treated as objects in the same way; they all can equally be treated as unities.

The story does not end here. One can imagine the Cantorian-style procedure continuing. Christopher Menzel invokes this possibility as a comment upon one proof of the existence of God proposed by Alvin Plantinga 2007. The proof takes for granted a later development of the Cantorian vision, that is, the generally accepted cumulative hierarchy of sets: they are formed iteratively by collecting sets, and

possibly other objects, formed at previous stages; the sequence of stages is transfinite. Incidentally, this hierarchy uncovers the role of theological categories: the void and infinite power. Namely, from the empty set one can create "everything," or rather the universe of "pure" sets sufficient for the foundations of mathematics. Nothing, emptiness, is combined with infinite power and a kind of unrestricted will to continue the construction ad infinitum. Terms like "infinite power," "all-powerful will" are unmistakably theological. If Leibniz had known modern set theory, he would have rejoiced, both as a theologian and as a mathematician. He claimed that "all creatures derive from God and nothing" (Breger 2005, p. 491). When he introduced the binary notation, he gave theological significance to zero and one: "It is true that as the empty voids and the dismal wilderness belong to zero, so the spirit of God and His light belong to the all-powerful One" (after Barrow 2000, p. 33).

Now, if idealized "collecting" is treated as executed by an infinite mind, the process can be extended: all sets form the universal class and beginning with it one could consider classes of classes, and form a superhierarchy, and then to continue it further into the transfinite. As Menzel notes, for the realist who believes in the existence of sets (as most mathematicians seem to do) it is unclear "why the cumulative hierarchy is necessarily only as "high" as it is in fact and could not be extended. Call this the realist's impasse" (Menzel 2018, p. 44). His solution would surprise mathematicians: "a satisfying explanation for the existence of the sets in any given world: they are the ones whose members God in fact chose to collect. . . . given that God knows all of the large cardinal properties – certainly at least those we are in principle capable of formulating – it is reasonable to suppose that God does enough collecting to satisfy all of them" (Menzel 2018, p. 49–50). This discussion shows a lasting religious potential in the Cantorian vision.

4 Religious Sources of Mathematical Concepts

There are examples of mathematical concepts that according to some authors have been developed due to religion. None of these instances gives an undoubted exemplification of fundamentally religious origins. Yet each of the cases mentioned below – Indian origins of mathematics and zero, Christian sources of the initiation of the algebraic approach, Maxwell's stress on relations, Grassman's theological inspirations, the creative function of naming – does provide a vista on something religious.

Basic religious behavior involves ritual. Often such rituals are ancient and their sources are of mythic character. Abraham Seidenberg in (1961, 1962), and later papers (e.g., 1978) presented the theory that religious rituals were the source of mathematics. The need to perform ceremonies, for instance, those presenting myths of the origin, led to both the art of calculation and basic geometric notions. Independently of this idea, Seidenberg advocated the diffusion theory: fundamental mathematical concepts were introduced once and gradually migrated to other places to eventually reach the whole globe. In this way, he opposed those historians who believe that basic notions were discovered independently in several places. The

diffusion claim was approved by Bartel van der Waerden: "if we find quite similar ideas about the ritual importance of geometrical constructions in Greece and India, . . . the conclusion that these religious and mathematical ideas have a common Indo-European origin is highly probable" (Van der Waerden 1983, p. 35).

In addition, Seidenberg claims that it was ancient India that was the hypothetical source of basic arithmetic and geometric concepts. This is claimed with reference to interpretations of some old Vedic writings. To give one illustration, "most mathematical problems considered in the Śulba Sūtras spring from a single ritual requirement; namely that of constructing altars that have different shapes but occupy the same area" (Rogers 2015, p. 272). From India, the mathematical knowledge was brought to Babylonia. Seidenberg, a distinguished algebraist, was a major scholar so his proposals should be treated with attention, even though they met with serious criticism. Yet, more recently, further research of ancient mathematics has shown that "some of Seidenberg's opinions may have been justified," says Leo Rogers (2015, p. 269).

While ritual applications could stimulate research, it is less than clear that they were the source of mathematical ideas. A great example of the religious source of concepts, and an Indian one at that, is provided by the invention of zero. Zero as a full-fledged number – a more substantial idea than just an indication of absence in notation systems – emerged in India, not later than fifth century CE. In 628 Brahmagupta presented the rules of using zero in addition and multiplication. And from there it migrated to the Islamic centers and to Europe. The term "zero" was derived from the Arabic *assifr*, meaning void, the translation of Hindu *sunya* (see Barrow 2000).

It is impossible to overstate the importance of zero. It is necessary for the full treatment of arithmetic, for the mature functioning of the decimal notation of numbers, for the operations like binary arithmetic that made computers conceivable. According to John Barrow, "the Indian system of counting is probably the most successful intellectual innovation ever devised by human beings" (Barrow 2000, p. 69). It is so essential and seems to us so simple. Why did the introduction of the number zero take place in India and the brilliant Greek mathematicians not have the idea? One might say that it just so happened, for no special reason. It is much more illuminating to detect cultural circumstances that enabled the innovation, more specifically, the features of Indian culture that were absent in Greece, and helped develop the notion of zero. The relevant difference can be seen in the treatment of nothingness. Zero symbolizes nothing. For Greek philosophers, nothing can result from nothingness, one cannot reasonably state about non-being anything more than its nonexistence. Against that logic, the Indian "religions accepted the concept of non-being on an equal footing with that of being. Like many other Eastern religions, the Indian culture regarded Nothing as a state from which one might have come and to which one might return – indeed these transitions might occur many times, without beginning and without end" (Barrow 2000, p. 65). To have the concept of zero one needs to treat nothing as something, absence and presence at the same time. The Hindu idea of a "positive nothing" indicates a complex notion involving various phenomena, from an empty container to a mystical void. This concept is expressed by the term *sunya*. It is a consistent idea, and despite its contradictory description as non-being and being at the same time, it can be represented by a symbol, zero.

Barrow's account is echoed by William Byers (2007) who treats it as an instance of a more general rule. He argues that some contradictions play a constructive role in mathematics. In particular, new concepts are introduced to overcome incompatible frames of reference. He states, "our culture has tamed the concept of zero by removing its contradictory aspects and incorporating it into a logically coherent mathematical system." Of course, he does not deny the need to have consistent theories. Yet he adds, "reality in general and mathematics in particular are greater than logical consistency" (Byers 2007, p. 109.)

The above account of the history of zero seems to be the best available. The role of religion, Hinduism, has turned out to be essential and non-trivial. A conscious effort of discovering vital Christian sources was undertaken by Gene Chase. He proposed a few examples "wherein Christian theology potentially provided specific insights and motivations for the development of specific new branches of mathematics" (Chase 1996, p. 193). One of them is Cantor, another Boole, both treated as unproblematic cases. Two other stories are of special interest since specifically Christian motives are invoked.

First, William of Ockham (fourteenth century) "wanted to be faithful to the doctrine of transubstantiation but to be consistent with observation. He argued, therefore, for a philosophy which allows the substance to change from bread to body, while the attributes (accidental properties) do not change" (Chase 1996, p. 198). And "his views on the Eucharist were a theological catalyst for his algebra" (Chase 1996, p. 197). Ockhamm "freed mathematics from being about specific concrete objects, or even about specific objects in Plato's heaven" (Chase 1996, p. 198). This is the initial source, claims Chase, of our contemporary mathematics dealing with abstractions, independent of substance.

The second example is provided by the bold move made by James Clerk Maxwell who introduced the concept of field. In the 1860s, he wrote "that an electromagnetic field acts through all space and all time, not just where matter is present. Lord Kelvin called Maxwell's view 'mysticism,' for in it even time and space were contingent upon God's continual sustaining" (Chase 1996, p. 206). Today we think of physical fields as material. Maxwell's view was understood as being non-materialistic, because it was against the mechanist reading of materialism. It was possible for him to make that move, claims Chase, because "in the Calvinistic tradition, God is the author not only of the material universe but also of the laws governing that universe. . . . [Maxwell's approach] has completely reversed the roles of things and their relations" (Chase 1996, p. 206).

In mid-nineteenth century, another development took place, important for later mathematics and related to theology, as has been recently pointed out (Lewis 2011; Achtner 2016). Hermann Grassman in *Ausdehnungslehre* of 1844 introduced revolutionary concepts that, albeit not immediately, initiated vector and tensor calculus and modern linear algebra. "Ernst Cassirer contended, . . . that it was Grassmann who changed the understanding of modern mathematics as a science of magnitudes to a science of structures, functions or relations" (Achtner 2016, p. 112). The point is that Grassmann was primarily a theologian. What is more, he credited the possibility of introducing his new concepts to his teacher Friedrich Schleiermacher, a leading

German theologian of that time, who taught the right approach, and provided his students with the appropriate method. This sounds like a confirmation of the theological source of multidimensional structures, but unfortunately, Grassmann's specific explanations are very general. According to Achtner's summary, "New knowledge is found by constructive abstraction from diversity to the complexity of unity going through different levels of abstraction leaving behind perturbations at a particular level" (Achtner 2016, p. 117). The theological aspects of such statements are unclear, and a scholarly debate continues with regard to the claim that Schleiermacher had a genuine influence on Grassmann.

Two more examples come from the beginning of the twentieth century. Intuitionistic mathematics, created by Luitzen E. J. Brouwer, denies non-constructive entities and even the logical law of excluded middle. At the origin of this vision, there were mystical considerations, important for Brouwer himself. His doctoral dissertation was purged of those thoughts since his advisor did not count them as mathematics. Almost all mathematicians would agree. Yet, the most authoritative study of Brouwer, van Dalen (1999), is entitled "Mystic, Geometer, and Intuitionist," in this order. The story is even more ambiguous. Brouwer was pressed by his mysticism to abandon mathematics as "evil," but his attraction was too strong. In the words of his biographer, "the genesis of the dissertation is a story of temptation, as experienced by all hermits and saints. No matter how much Brouwer fought the evil influence of the world, the fascination of mathematics proved stronger than his Spartan views" (van Dalen 1999, p. 84). It can be said that his research was conducted despite his religious views rather than because of them. At the same time, his mystical predilections could play a role in devising mathematical constructions: "Brouwer's view of the continuum shows a suggestive similarity to the mystic experience of the initial chaotic state of the individual. In this state, also, there are no sharp bounds, everything is flowing and amorphous" (van Dalen 1999, p. 114).

Sources of inspiration should not be ignored, but if they are religious, it is indeed unclear how to account for them, be it in the case of Grassmann or Brouwer. An especially clear case, although much less familiar, is that of Russian mathematicians who about one hundred years ago were developing the so-called descriptive set theory. Some of the scholars of that group, in particular its founder, Nicolas Luzin, were inspired by a heretical (for the Christian Orthodox Church) theology *Imiaslavie* (name worshipping). The story is now known due to the book Graham and Kantor 2009. The theology of name worshipping was heretical because it involved the readiness to identify God with God's name. Luzin, later the head of the Moscow school of mathematics, was influenced by theologian Pavel Florensky who noticed that making God present by an appropriate uttering of God's name is similar to Cantor's claim that a proper naming of an infinite set is sufficient to ensure the set's existence. At the beginning of the twentieth century, it was highly problematic to claim that the naming of an infinite ordinal number is enough, no other proof of its existence is needed. Now, this claim is widely accepted. One of the ways to its acceptance was Luzin's conviction that university stress on logical and empirical sources of knowledge should be supplemented with "intuitive-mystical understanding" (Graham 2011, p. 161). This religious approach made possible the development

of a major mathematical school. While also in this case one can claim that the same research could have developed without that mystical background, the fact is that a hundred years ago some religious ideas and practices encouraged new mathematical constructions.

A more recent parallel has been proposed: Alexandre Grothendieck, the creator of a massive framework that has deeply influenced modern mathematics, was also using the method of creative naming and, at the same time, spoke of a mystical vision of the mathematical universe. "Grothendieck, like Luzin, placed a heavy emphasis on 'naming,' seeing it as a way to grasp objects even before they have been understood" (Graham and Kantor 2009, 200).

Finally, a famous case must be mentioned, that of Indian genius Srinivasa Ramanujan who, a hundred years ago, produced unbelievably complicated theorems, claiming that they were revealed to him by goddess Namagiri. She "would write the equations on his tongue. Namagiri would bestow mathematical insights in his dreams" (Kanigel 1992, p. 36). Ramanujan's story is so exceptional that it is impossible to generalize it.

5 Mathematical Models in Theology

Mathematical illustrations of theological concepts are possible. Those of Cusanus or Leibniz (see Sect. 3) look rather naïve from the present-day perspective. The same can be said about explaining the Trinity by $\aleph_0 + \aleph_0 + \aleph_0 = \aleph_0$, where the symbol "aleph-zero" stands for the first infinite cardinality. (After all, $\aleph_0 + \aleph_0 + \aleph_0 + \aleph_0 = \aleph_0$ also holds, which means that the concept of a "Quadrity" would be equally well justified.) Moreover, it is doubtful that it makes sense to refer to mathematical addition of numbers, finite or infinite, as corresponding to the "addition" of the persons of the Trinity. Perhaps it would be better to refer to the operation of the Boolean union: in Boolean algebras adding the (Boolean) one to itself results in the same one. In addition, it is the only element (of the algebra) that is greater than each of the remaining ones. It has, therefore, a "divine" quality, and since it is unique, it can be seen as modeling monotheism. Yet, obviously, this model is as shallow as it is arbitrary. It is no better than Cusanus's reverence for "the equation $1 \times 1 = 1$ as a sublime name of God" (Albertson 2014, p. 1). Nowadays, mathematical models are so rare that in the monumental volume Diller and Kasher 2013, presenting dozens of models of divinity, they do not appear at all. Yet, mathematical models are sometimes invoked by modern theologians. A notable example appeared in the Victorian era: *Flatland* (Abbott 1952) is a tale about geometric creatures living in a flat world. A three-dimensional being has divine properties from the flatlanders' perspective: it can perceive the whole flat world and when it interferes with the plane this is perceived by the flat figures as a miraculous happening. In this way, the recently discovered multidimensional geometry is presented as not a threat but rather an aid to religious faith. The words of Boethius (sixth century) become understandable: "God abides for ever in an eternal present, . . . and, embracing the whole infinite sweep of the past and

of the future, contemplates all that falls within its simple cognition as if it were now taking place" (Boethius 1897, Book V, Song VI).

To give a contemporary example, James Miller 1998 presented a model, based on the normal (Gaussian) distribution, in order to explain the supposedly paradoxical belief that submission to God's will provides more freedom than does disobedience. While this is difficult to explain in everyday language, it becomes understandable when the Gaussian curve is considered in the space of all options available at a given moment of one's life. On the y-axis the number of options is indicated and on the x-axis their quality. Miller assumes that the most agreeable to God are the options belonging to the "middle way." The acceptable options are not much different from those in the middle, distant no more than one standard deviation. As a result, we model free will, since there are many possible options to choose from. At the same time, since the columns near the middle position are relatively larger, the way that pleases God offers more opportunities. The submission provides more freedom. Furthermore, sin can be illustrated as a deformation and dislocation of the Gaussian curve: then what the sinner takes to be the middle way is in reality distant from the genuine "divine" middle way.

The value of the model is debatable. It is commendable if it helps someone to grasp some theological ideas.

Another proposal has been made, in a way opposite to the well-known idea that the set of true sentences is part of the "divine" knowledge. Making use of logical and set-theoretical notions one can try to express "divinity" as ... the set of all true sentences. John Post (1974) does it in the spirit of Quine's minimalism in order to express the foundations of theism, avoiding "metaphorical, analogical, symbolic, mythical" (Post 1974, p. 736–7) talk about God. He tries to paraphrase the statements about God in a possibly restricted language so that one can get sentences that are "literally true." Thus "Godhead" is defined as the smallest set G, whose transitive closure (that is, its elements, elements' elements, etc.) includes the set of all true sentences about sets, the set of true sentences about justice, virtues, religious experience (whatever it may mean for us), etc. The set G is mysterious, it "combines transcendence with immanence" (Post 1974, p. 740), it contains complete knowledge, and the "mythic" personal God is its "intended object." Even this short summary suggests that this construction can be easily criticized as contributing nothing essential to theology. The model can be easily undermined by asking, e.g., whether devout people really pray to a set.

Another model is presented in Krajewski (2019) (and mentioned in 2011). It illustrates Martin Buber's vision of God who is revealed in interhuman relations. In 1923, he wrote, "The extended lines of relations meet in the eternal Thou" (Buber 1937, p. 75). To anyone acquainted with projective geometry, this picture would seem familiar. In the system of plane geometry, the direction of each straight line constitutes a point of a new type, and this point at infinity is common to all parallel lines. Thus, every pair of straight lines (in the plane) intersects in exactly one point, with no exceptions. For parallel lines this point of intersection is at infinity, but in projective geometry, these infinitely far located points have the same status as do the usual points of the plane. What is more, the totality of the points at infinity constitutes one "straight line at infinity." This line can be seen to correspond to

God in Buber's vision: the line of the relation between two arbitrary individuals always reaches the same God.

The use of this picture can be extended. The well-known model of the projective plane in the Euclidean (three-dimensional) geometry is given by a hemisphere. If the Northern hemisphere together with the equator is imagined all the points above the equator constitute the proper (finite) points of our model, and the points on the equator constitute the points at infinity. Straight lines are the semicircles with the center coinciding with the center of the ball (the Earth). (They form the shortest way between two points, and are called great circles.) One more move must be made. In order to have only one point corresponding to the direction of a line, the opposite points of the equator must be identified. The resulting objects cannot be easily imagined, but it is also possible to assume that the whole line segment joining two opposite points constitutes, *ex definitione*, one "improper point." The totality of these improper points forms a plane figure, or a disc determined by the equator. In our model, this object is the basis of the hemisphere. Thus, God is here the fundament of our world, unattainable directly, but, being the direction of every line joining two points, it is present in every relation between the beings of this world. In addition, the model can be used as a visualization assisting prayer (Krajewski 2019, p. 1014–1015).

The emerging picture is attractive, but mathematical research on the projective plane includes many more deep theorems than what was used in the model. They seem to have no theological parallels. If the geometrical model is seen as an adequate description of the philosophico-theological idea, philosophy and theology look meager compared to mathematics. If, on the other hand, one believes that it is philosophy and theology that deals with important problems of humankind and the world, then the mathematical model becomes no more than an illustration – a suggestive one, but meager and fundamentally irrelevant.

None of the presented examples of applications of mathematics to theology seems truly fundamental. If they help pondering some theological ideas, they are useful. However, they are only metaphorical and lack the features that make mathematical models so powerful in science, especially in physics, where they are creative; in particular, they suggest new concepts, and have predictive power, that is, enable us to foresee events or experimental results, and thereby check the model's adequacy. In theology, nothing so essential seems to be added by mathematical modeling.

6 Conclusion

Relations between mathematics and religion are seen by some as friendly, by others as antithetical – see the mottos to the present chapter. While modern mathematicians usually disregard the connection, some philosophers try to detect it. This can be done by affirming faith, as does Roy Clouser (1991), who argues that the right Biblical approach takes everything as dependent on God, therefore to attribute absolutely independent existence to numbers constitutes paganism. On the other hand, the criticism of Platonic assumptions can be done from an anti-religious position: "the actual Platonic infinity seems to invoke some version of the Greek–Hebraic divinity," states Brian Rotman (1993, p. 49). Any belief in the existence of mathematical

objects leads to the "unstated theism – implicit and unacknowledged – of twentieth-century mathematical infinitism" (Rotman 1993, p. 157). This, one could add, seems to be a major reason for the attractiveness of mathematics. According to Vladislav Shaposhnikov, at the turn of the twentieth century "some key mathematicians of the period made an attempt (perhaps partially unconscious) to substitute pure mathematics for departed theology" (Shaposhnikov 2016, p. 48).

Up to modern times, the relation of mathematics to religion was close. According to Ivor Grattan-Guinness, "the main contexts lay in numerology, sacred geometry, and mechanics" (Grattan-Guinness 2011, p. 144). They are now of historical interest only. With the advent of modernity, the interplay of mathematics and theology continued. Ultimately, modernizing did mean secularization. Yet the process of getting to the present fundamentally irreligious science, including mathematics, was long and slow.

The examples mentioned in this chapter do not provide an indisputable proof that religion was indispensable for mathematical developments or that mathematical modeling was essential for theology. There is no doubt, however, that religious needs and motivations played a role in the development of mathematics, and mathematical metaphors helped theologians. Perhaps to have genuine mathematical models of divine matters another mathematics, still to be developed, is needed?

Is mathematics still connected to religion(s)? The present-day answer depends on how open is one's attitude to the realm of the religious. For those sensitive enough to religion the connection can be perceived.

In addition to possible mutual influences, there exists another method of relating mathematics to theology. It seems that in both disciplines a central role is played by mystery: the more we know the more we realize the limitations of our knowledge. While such limitations are present in all sciences they are particularly prominent in apophatic theology and in mathematical incompleteness phenomena. Some of the main assumptions must be accepted for no other reason than faith. Again, this may be true about knowledge in every field because we often function within a paradigm, chosen without sufficient reasons – which does not mean irrationally. Yet mathematics and theology seem to be more arbitrary than other fields, which is due to the fact that both are more distant from the empirical world than are the other disciplines. Mathematics and theology are controlled by internal consistency requirements, fruitfulness, esthetic values, intuitive appeal. Even though intuition is shaped by empirical and cultural factors, they do not fully determine mathematical or theological assumptions. Positions in the philosophy of mathematics differ as widely as they do in theology.

Acknowledgment The author is grateful to Andrew Aberdein for several suggestions that have helped correct and improve this chapter.

Abstract

In this short Introduction to the present section, I will first briefly point out the reasons why the chapters collected here present original research in the context of the philosophy of the practice of mathematics, and open even newer perspectives. It is important to note that one crucial issue for future research will be to explore the connections within these chapters and with other chapters included in other sections – in particular, but not exclusively, the sections on Proof, on "Experimental" mathematics, and on the Semiology of Mathematical Practice. Second, I will present a short – and not exhaustive – summary of the themes that are tackled in the chapters. There will be overlaps and common threads: These chapters are indeed the final product of several discussions and exchanges within the community of the philosophers of the mathematical practice, which is extending toward other regions of philosophy thus blurring standard boundaries.

1 New Perspectives: Where Do They Come From?

As it is well known – and the number of pages of this Handbook proves it – the attention to the practice of mathematics has extensively grown in the past years, thus becoming a trend that has gained more and more momentum in philosophy as well as in other neighboring disciplines.

Now that the philosophical interest in considering the more dynamic aspects of mathematics has been settled, it is time to ask for more details and in particular to clarify the implications for the study of mathematics, possibly opening new research perspectives. It should be noted that the interdisciplinary nature of the attention to the practice of mathematics has been emphasized at many occasions, from the beginning; however, there is a sense in which, at least in the case of philosophy, such an approach can also be seen as "intradisciplinary": As it is evident from the chapters collected in this section, the notions that have emerged in the context of the philosophy of the practice of mathematics can be connected to and enriched by the consideration of lively debates in other territories of philosophy, such as philosophy of science, social ontology, epistemology, and philosophy of action. Indeed, the aim of this section is to see whether examining the research in other fields of philosophical inquiry can reply to questions emerged in the philosophy of the practice of mathematics and open even newer perspectives, which might also imply the application of new methods.

All chapters present very recent and original work, as testified in the lists of suggestions for further research that are found in the conclusions of each of them. Moreover, despite the fact that the chapters seem to go in different directions, they are not necessarily incompatible and many of the topics that are touched upon can be related to one another. Before summing up the contents of the chapters, I will highlight three themes that seem to me to be recurrent in the characterization of new perspectives for the philosophical approach to the practice of mathematics. I will leave to the reader the challenge of finishing "connecting the dots" and finding these and other relevant links among the chapters of the section.

The first theme is the relation between a form of knowledge that is recognized as *knowing-how* and the traditional definition of knowledge as *knowing-that*. If the philosophy of mathematical practice has been stressing the "procedural" aspect of mathematical expertise, some authors – for example, Ferreiros and De Toffoli in this section – propose a framework where mathematical knowledge is still intended as a form of knowing-that, where beliefs do not lose their central place; however, this is done in a renovated fashion, so as to emphasize as well the processes – the knowing-how – that have brought to it.

A second theme is the focus on the social aspects of mathematics: What does it mean precisely that mathematics is a collective enterprise? This social element comes to the fore in all chapters, for example, in connection with social ontology or social epistemology. In particular, Cantù discusses at length the growth and the development of mathematical knowledge in a social context, with its repercussions on traditional notions such as objectivity, while Hamami stresses the role for mathematical knowledge of the actions that are learnt and performed – collectively – by

the mathematical subjects. An approach focused on the social aspects of the practice of mathematics can also make a difference in considering mathematics education, as shown in Tanswell and Inglis' chapter.

A third theme that appears in the background of the chapters is the tension between formal and informal methods in mathematics, in particular in relation to the notion of proofs.

2 Summary of the Chapters in the Section

The first two chapters in the section, Ferreiros and van Bendegem's, present innovative and more general frameworks to account for the practice of mathematics. It is important to note that both Ferreiros and van Bendegem are among the founding fathers of the *Association for the Philosophy of Mathematical Practice,*[1] which was created in 2009 – the first conference took place in Brussels in 2010.

In his chapter, Ferreiros comes back to his very influential book from 2016, and to his picture of mathematics as based on an interplay of practices. At the time, Ferreiros' book had surely the merit of putting forward an exhaustive account of mathematical knowledge as requiring a "web of practices." In this chapter, he outlines some of the ideas presented in the book and makes them even more explicit. First, he clarifies that his framework presupposes that mathematical knowledge is knowing-that: Mathematics has for him a specific theoretical orientation besides mathematical research. However, it is clear that an approach directed to the practice of mathematics will attend to the process of mathematics and look for epistemic values and goals. At the forefront, there are indeed the dynamics of knowledge; for example, we might look at the prehistory of concepts and therefore go also beyond mathematics. However, mathematics is not a natural product of the brain but involves the reference to external representations: writing, notations, and geometrical figures; this symbolic part of mathematics is important not only for reasoning but also for communication. It should be pointed out that mathematics is not a symbolic practice as any other, but a specific one where the contents involved are the notions of number and form; in general, it is the study of patterns – an idea that we will find also in van Bendegem's chapter. Ferreiros also points out that his interplay of practice does not entail a form of social constructivism. Such interplay is in fact characterized by many constraints at different levels, our biology for a start but also the several symbols that are introduced in the practice; moreover, mathematics has cultural preconditions and requires social institutions. We will come back to this point when presenting Cantù's paper.

Another interesting element in Ferreiros' approach is that it allows for the study of other proper practices that are interested in knowing-that beside Western mathematics: This is the case of Chinese or Indian mathematics, even if they do not have a notion of "theorem proving." For this reason, Ferreiros distinguishes his view from

[1] For more information about the Association, see http://www.philmathpractice.org

ethnomathematics. Interestingly, according to him, cognitive science and ethnomatematics share the inclination to identify something as innate or panhuman in mathematics; in contrast to this idea, Ferreiros reminds that there is a danger in retroprojection, that is, in looking with modern eyes at practices that are in fact not the same as ours. This may happen, for example, in the case of the concept of "function," which he discusses in detail, that cannot be thought as a simple extension of previous number concepts. In presenting the case of function, Ferreiros introduces Cavaillès' *thematization* and Piaget's *reflecting abstraction* as having an important role in accounting for the historical emergence of this notion, but also for the way students grasp this concept. It looks like there is some kind of "meta" element that is very important for Ferreiros in considering the development and the stabilization of mathematical concepts, and their emancipation from other previous more technical notions. This opens a new perspective in the history of mathematics.

van Bendegem's chapter considers mathematics as an experimental science and refers to some of the studies presented in the section of the Handbook on "experimental" mathematics. According to van Bendegem, experiments in mathematics are far from being a fiction, because they are a fact, and a fact that will keep being a part of the practice of mathematics for long; for this reason, they deserve philosophical attention. He invites the reader to think "within" his framework, which he calls a "scheme," and possibly to individuate new questions and solutions, hoping for what he calls a "*Mendelejev-effect.*" The framework presents a list of elements that characterize what can be called an experiment and is a sort of working grid that is discussed and modified throughout the chapter, following the analysis of concrete examples and the comparison of them to what is found in the empirical sciences. van Bendegem's strategy is in fact to start from a scheme that can be proposed for scientific experiments, and proceed by analogy to formulate the corresponding one to talk about experiments in mathematics. Of course, the notion of experiment is a matter of debate also in philosophy of science; however, for the sake of the argument, van Bendegem does not go into details of these discussions and simplifies them in order to focus on the case of mathematics. He specifies that his schema is just the beginning of the story, as it is plainly first order; new research might be able to provide a second-order version of it.

The connection with philosophy of science is thus made and presents frictions. In fact, if in science to make a statement and to make an observation seem to imply different things, in mathematics to make a conjecture and to acknowledge some specific instance of it look like they are of the same kind, that is, they give two mathematical statements as a result. A second problem is that while an experiment in science needs to be performed, how can we perform a mathematical experiment? In fact, it seems that in mathematics we simply prove (or disprove) a statement. Another difference is that there seem to be far more surprises in the universe that science is concerned with than in the world of mathematics. For van Bendegem, the only way of resolving these tensions is to open a new perspective, which will not focus on confirmation in mathematics but on insights and on the generation of ideas and concepts, something similar to what happens when we explore new territories. One possibility is to come back to the old notion of "probing" instead of proving,

where the mathematician looks for patterns to show up, and to consider tacit knowledge – knowing-how – as well.

van Bendegem offers several examples of experiments and introduces possible extensions starting from his schema. Among others, one possible new direction of research would be to ask whether given a mathematical theory and a scientific theory, there exist experiments that are related to the scientific theory but are also relevant for the mathematical theory. If this were the case, then such an experiment should be considered at least in part a mathematical experiment. Further research concerns the role of thought experiments in mathematics, and their relation to mathematical proofs.[2] In van Bendegem's view, a "grander" scheme should be envisaged so as to account for empiricism in the philosophy of mathematics – getting rid of the Lakatosian "quasi." He concludes his chapter by claiming that mathematical experiments are an essential ingredient of the activity of mathematicians to the same extent that understanding the path that brings to a proof is as important as obtaining the proof.

The next three chapters in the section discuss more specifically debates in three particular areas of philosophy – social ontology, epistemology, and philosophy of action – in relation to notions that have emerged in the philosophy of the practice of mathematics. In all three cases, the aim is to capitalize on these discussions to clarify notions that are still understudied in the philosophy of the mathematical practice, and conversely to evaluate whether the research about the practice of mathematics can shed a new light on them.

Cantù's very rich chapter opens up the new perspective of considering concepts from social ontology as relevant to explain the social constitution of mathematics. In her view, a philosophical-normative framework is necessary to guide the discussion on the objectivity of mathematics and on the kinds of semantics that are introduced when the attention is focused on the practice. It is only once such a framework is specified that we can look back at episodes in the history and philosophy of mathematics and see what an approach based on the practice of mathematics can teach us that we did not know already – starting from more standard pictures of mathematics – about them. As an example, Cantù takes the case of the axiomatic practice; if mathematics is assumed as having crucial informal elements, what does it remain to say about its more formal aspects, such as axiomatics or formal derivations? Is it the case that a sharp distinction between formal and informal methods in mathematics cannot be drawn? In a sense, Cantù's chapter resonates with Ferreiros', as she insists on the need to specify more what is intended by practice or practices and why they should still be subject of philosophy.

The chapter starts with a brief introduction to social ontology, which is undoubtedly very useful for the reader of this Handbook who is not necessarily acquainted with it. She discusses at length the philosophy of John Searle, who was not interested in mathematical phenomena as social facts but in social phenomena such as money,

[2] See Starikova's article in this volume and Giardino (2022), where I distinguish between thought experiments, real experiments, and quasi-experiments in mathematics.

property, or marriage; however, a lot of social ontology developed in reaction to his views. Francesco Guala criticizes Searle and claims that the focus should shift from theories about the mind to the sociohistorical study of institutions: Social ontology can be naturalized, and the dependence of social phenomena on representation can be explained in purely causal terms, without the need to introduce collective intentionality.

The point is then to compare social facts and mathematical objects, and to do that Cantù considers the views of Feferman, Ferreiros, and Cole. Feferman considered mathematical objectivity as a special case of intersubjective social objectivity, and his view, according to Cantù, can be integrated by looking at Lorenzen's research. Ferreiros – as we know it from his book and from his chapter in this section – bases his notion of practices on the presence of agents and of symbolic frameworks; however, he does not agree with Cole, who claims that mathematical objects are institutional facts, since he believes that mathematical objects are more stable than institutions. Carter, Giardino, and Pantsar's proposals on how to intend mathematical objectivity are then introduced; Cantù highlights that three different guiding principles emerge from the literature: naturalization, historicization, and normatization of mathematical practices and mathematical agents. For what regards the forms of semantics that are introduced when considering mathematical objects in this new perspective, according to Cantù's reconstruction, the semantics is representational when the focus is on mental states, and nonrepresentational when the focus is on the practice. Finally, as mentioned above, Cantù takes the example of axiomatics conceived as an institution along the lines of Guala's social theory: Axiomatics can be considered as a coordination tool and not necessarily as having a justificatory role.

Some of the elements already discussed in Cantù's chapter will be taken up again in the next two chapters, opening other complementary new perspectives. De Toffoli's objective is to reconcile analytic epistemology and the philosophy of the mathematical practice, and to this aim she introduces a fallible conception of mathematical justification.[3] In her view, beliefs, which are the main topic of epistemology, are still central to the consideration of the practice of mathematics, no matter if mathematicians are recognized as embodied, fallible and embedded in a specific context. In line with Ferreiros' insistence on mathematics as theoretical knowledge, she argues in favor of a *human* epistemology of mathematics, where subjects should not be considered in isolation. She also offers some points of contact between the mathematical subject and the characterization of subjects in social and feminist epistemologies: Knowledge can in fact be indexed to groups rather than to individuals.

Furthermore, De Toffoli shows how traditional topics in epistemology can be applied in mathematics – notably, there are Gettier cases also in mathematics – provided that we substitute the traditional infallible notion of mathematical justification that is standardly associated with proofs with its fallible counterpart; at the

[3] On this point, she draws on previous work. See De Toffoli (2021).

center of our epistemological inquiry, there are fallible human subjects and not anymore highly idealized ones. In her view, justification is fallible and therefore there is a gap between justification and truth: Whether a subject is justified is not only a matter of logic but depends also on social considerations, which does not mean that we have to endorse a form of relativism. De Toffoli's knowing subject is obviously related to Ferreiros and Hamami's agents; however, she defends the idea that it is crucial to keep separate the subjects of epistemology from the agents of ethics and opts for the use of "subject" as the appropriate term.

Hamami's chapter aims at making sense of the claim that mathematics is an activity, which has been one of the "mottos" of the philosophy of the mathematical practice from the start. It is evident that such a claim goes against standard philosophy of mathematics, which is agentless; however, what does it mean really? What is agency in mathematics? According to Hamami, it is not enough to acknowledge that mathematics has an active dimension, but we should figure out how to study it. Ferreiros is always on the background, since also for Hamami there is no practice without practitioners; closely to De Toffoli's project, he wants to account for what a subject needs to do to acquire knowledge.

Hamami surveys several themes that have emerged in the literature concerning mathematical activities and their relation to artifacts, proofs, and texts. Mathematical knowledge has been considered as rooted or grounded into elementary human activities: Kitcher has followed this line of thought as based on an ideal agent, while Ferreiros has chosen to talk about the interplay of practices. Several new perspectives are now open: the consideration of what it means to do things with artifacts such as diagrams, symbols, or graphs – referring to the notion of epistemic action, or of mathematical cognition. An important point of the chapter is the interaction of an agent with mathematical informal proofs. In his reconstruction based on previous work (see Hamami and Morris 2021), proof activity refers to the sequence of deductive inferences that correspond to a mathematical proof, which is in turn the result of the execution of a plan that is produced by a mathematical agent – what Poincaré described as the proof's *architecture* or *unity*. Moreover, proof plans can be related to proof understanding.

Hamami discusses also the question of how mathematical agents can realize mathematical actions based on mathematical texts, which directly brings to the subject of the last chapter in the section. Finally, he stresses how the most obvious areas for future research are social agency, computer agency, and extended agency. This new perspective raises questions that are both theoretical and methodological in an interdisciplinary fashion, in line with the characterization of the philosophy of the mathematical practice.

In the last chapter in the section, Tanswell and Inglis apply methods from corpus linguistics to look for empirical evidence for the prevalence of imperatives and instructions in mathematical preprints. Their focus, as highlighted by Hamami, is on the relation between agency and texts. In previous publications, Tanswell has argued for a *recipe model* of proofs (Tanswell forthcoming): In his view, proofs are like recipes, that is, they give instructions for mathematical actions to be carried out. In this chapter, together with Inglis, he offers a systematic, large-scale,

computational analysis of mathematical texts, so as to focus on the relationship between the language used in written, textual mathematics, and the way in which we should understand what proofs are. Another merit of the chapter is that it surveys interesting studies in mathematics education on the use of instructions. Methodologically, the chapter is very careful in making the hypotheses explicit before presenting the analysis in detail, and in pointing out the limits of the particular study, thus paving the way for new quantitative analyses.

As evoked above, all the chapters in this section end with a list of suggestions for further research, so as to prepare the ground for even newer perspectives. From the discussions in the chapters, we see that the interdisciplinary nature of the philosophy of the mathematical practice is confirmed today, in line with the pioneering works published at the beginning of the 2000s; furthermore, the chapters collected here also show that assuming an "intradisciplinary" approach within the regions of philosophy can enrich the debates and raise new questions. I cannot but encourage the reader to dive into them.

Abstract

This chapter can be considered as made up of two parts, a general discussion of the notion of mathematical practice and the limits of its use, comprised by the first three sections, and a particular case study that is presented in order to exemplify the idea of the web of practices, which occupies the remaining three. The presentation of my approach to the notion of mathematical practice is brief and synthetic but more articulated theoretically than in a previous book (Ferreirós 2016). Considerations in Sect. 3 about mathematical cognition and ethnomathematics have to do with the "limits" of mathematical practice, i.e., with practices that do not fall under that rubric.

The case study concerns the evolution of the function concept, which offers a complex example of the web-of-practices approach. We start with early Modern developments that led to the eighteenth-century idea of function (as "analytical expression") and the nineteenth-century "logical" idea of function, showing how complex is the spiderweb of interrelated mathematical and scientific practices

knotted around the function concept. In the last section, I consider the difficult question of the most basic practices and cognitive experiences that form the basis of the idea of function. I propose that two conceptions – a dynamic and an algebraic or operational one – coalesced to give rise to the early Modern idea of function.

Mathematical cognition · Ethnomathematics · History of mathematics · Function concept · Pragmatism about mathematics · Agent-based approach

The line of studies called *philosophy of mathematical practice* has been very active during the last 20 years. It is a lively community of research, including not only philosophers but also other relevant disciplines. Here is how it is described in the webpage of the APMP:

> Over the last few years, approaches to the philosophy of mathematics that focus on mathematical practice have been thriving. Such approaches include the study of a wide variety of issues concerned with the way mathematics is done, evaluated, and applied, and in addition, or in connection therewith, with historical episodes or traditions, applications, educational problems, cognitive questions, etc. We suggest using the label "philosophy of mathematical practice" as a general term for this gamut of approaches, open to interdisciplinary work.[1]

The aim of this Association was to stimulate research in philosophy of mathematics "related to mathematical activity, past and present." From this statement of goals, it should be clear already that historical studies, cognitive studies, and educational research, among others, together with philosophical and foundational studies, are relevant lines of research and analysis for people in the field.

Traditional philosophy of mathematics has been described as focused on problems of ontology and epistemology of mathematics, with a tendency to see mathematics as a fixed body of theory – usually either arithmetic (PA) or set theory (ZFC and extensions). Ontological and epistemological problems keep occupying philosophers of mathematical practice seriously, but they argue for the need to expand "the epistemology of mathematics . . . well beyond its present confines" (Mancosu 2008, p. 1) and, often, also for the need to relax ontological concerns.[2] The idea is that the more traditional questions and analytical tools leave out some highly relevant epistemological issues. As a result, careful attention has been paid to questions of evidence, fruitfulness, visualization, explanation, purity, etc., sometimes employing similar tools to those that were being exploited already in the analytical literature (see Mancosu's collection *The Philosophy of Mathematical Practice*, 2008) but sometimes using also quite different tools.

[1] See http://www.philmathpractice.org/

[2] However, this is a rather prominent trend nowadays, arguing for minimalist or "thin" ontology. See, e.g., Linnebo (2018).

As should be expected, the field is not free of disagreements. In an overview paper, Jessica Carter (2019) identifies three different (albeit in some cases overlapping) "strands" in the philosophy of mathematical practice: (1) an *agent-based* strand, with two different orientations, (2) the *historical* strand, and (3) the *epistemological* strand (so-called for lack of a better term) perceived as closer to traditional philosophy of mathematics. Here is an example of tensions: some proponents of the agent-based orientation have emphasized sociological questions, to be studied with the empirical methods of the social sciences, while some proponents of the "epistemological" strand object and argue against giving such prominence to sociological factors. In many other cases, of course, there is cooperation and/or complementarity, rather than disagreement.

One obvious, but deep, problem facing this thriving field – which is actually underscored by the wide variety of perspectives and research methodologies – is the lack of a clear definition of its intended object of study. What is meant by mathematical practice? And, by the way, singular or plural, practice or practi*ces*? Some critics argue (Salanskis 2014, p. 44) that, if the program of the practice turn is to be significant, it must recommend looking at science or mathematics in a specific way, which can be contrasted with other ways: "This absolutely requires that we have at our disposal a non-universally encompassing notion of practice." Indeed, if anything and everything, from perceiving corners in a room and counting coconuts to doing statistical analysis of big data, is "mathematical practice," then this notion says almost nothing and will be of no use.

The three strands identified by Carter, with their various sub-strands, may actually have different implicit conceptions of mathematical practice. At the very least, they have very different methodological orientations, regardless of whether they study past case studies or present-day material. In another overview, Giardino (2017, pp. 24–25) has called attention to four different "replies" to the question about mathematical practice. One suggests that maths is a *historically situated* human activity, another focuses on its being a *semiotic* practice, the third calls for an *expanded epistemology*, and the fourth understands itself as a *pragmatist* approach.

In fact, the main example of a pragmatist approach offered by Giardino is my own proposal in *Mathematical Knowledge and the Interplay of Practices* (2016), which also happens to be agent-based and historical.[3] That book constitutes an attempt to articulate an *epistemology* of mathematics, in a sense of the word that is perhaps broader than usual in the analytical tradition. Some of the claims are that understanding mathematical knowledge requires careful attention not only to its cognitive roots but also to its semiotic and cultural roots, in ways that can be illuminated by the ideas of pragmatism, with the result that one must follow or accompany (epistemologically) the historical dynamics of this form of knowledge.

Here I would like to revisit some general aspects of the proposal I made for the analysis of practices, in particular the characterization of mathematical practices and the idea of an intricate spiderweb that extends from "technical"

[3] Carter (2019) distinguishes two kinds of agent-based approach: the sociological and the pragmatist; my orientation is along the latter line.

(non-mathematical) practices to high-level mathematical ones, also including links to scientific practices of modeling, data control, etc. We shall (i) reconsider and refine the working definition of what a mathematical practice is; (ii) analyze the relations and differences between mathematical practices and other kinds of cultural practices, e.g., those studied in ethnomathematics; and (iii) consider a particular case study, the web of practices and theory related with the central concept of function, which articulated a large portion of the mathematics developed in the last 300 years.

The reader can profitably consider the chapter as made up of two parts, a general discussion of the notion of mathematical practice (hereafter MP) and the limits of its use, comprised by Sects. 1, 2, and 3, and a particular case study that is presented schematically in order to exemplify the idea of the web of practices, which occupies Sects. 4, 5 and 6 – this concerns the evolution of the concept of *function*, which, to be sure, is very complex. The presentation of my approach to the notion of mathematical practice intends to be brief and synthetic but more articulated theoretically than in the book (Ferreirós 2016). The considerations in Sect. 3 about mathematical cognition and ethnomathematics have to do with the "limits" of MPs, i.e., with what does not fall under that rubric.

1 Defining Mathematical Practices: Cognitive Aspects

Chapter 2 of Ferreirós (2016, p. 33) proposed a "working definition" of mathematical practice, restricted to the limited purposes of an epistemological analysis. This was meant to acknowledge that studies of mathematical practice may have goals different from the philosophical ones – not the case here, – and that for those purposes it may be useful to characterize mathematical practice differently. (It also meant to emphasize that I preferred to keep the "definition" simple, in order to employ it as a tool for analysis; it would have been possible, but probably of little use, to present things in a much more sophisticated way.) Here we aim to revise and update that definition, making it a bit more precise and self-contained. In any event, I should warn the reader that this first part of the chapter is a kind of précis and clarification of aspects of the book, but some important elements cannot be elaborated upon in detail. Thus I'll be referring you to the book itself for elaboration and details.

By a "practice" in general we mean a recognizable type of activity that is *done*, and can be *taught* and *learned*, by human agents. We always associate mastery of a practice with one or more particular ways of solving some problems, and we only acknowledge that somebody knows or masters a practice when some *success conditions* are met – they know *how to* do it. In many cases there will be explicit norms and rules associated with a practice, but in *all* cases, there are implicit norms.[4]

[4] Think of the practice of riding a bike or sailing a boat: we have explicit rules in the form of traffic regulations and also rules for competitions, but, even at the most basic level, there are success conditions and associated norms (the ability to maintain control and balance, to brake at or negotiate a curve, and so on).

In relation to such implicit norms, and how a given agent may learn them, other agents typically act as regulators – the community is most relevant to an individual's attainment of proficiency. Any reasonable analysis of the factors that regulate mathematical practice, making mathematical knowledge possible, must include the resources and abilities of the single mathematician and her or his interaction with others in the community. So,

First, reference to the community of mathematicians is essential, and one can state briefly the main reason: there is no practice without practitioners.

But next,

Second, each mathematical practice is linked with a recognizable type of symbolic framework—formulas or diagrams or signs of a certain kind—employed by the agents to solve problems in the pursuit of particular goals and to share information.

The symbols we are considering here are external representations, and it is important to keep in mind that diagrams are counted among them.[5] Mathematics is public and shared; it is "common knowledge" (see the Liu Hui quotation below).

At this point, it's relevant to introduce an aside, a note of warning that will accompany our reflection in what follows. Notice that, in retrospect, it will always be possible to link such mathematical practices with particular mathematical theories and thus to *reconceive* them from a theoretical standpoint, given that we, today, possess a large body of mathematics. But in fact, for our purposes, the adequate thing is to keep separate, at the level of analysis, the practice of mathematics and its products (see Sects. 4 and 6). This implies also to be careful distinguishing a given practice from any possible (and, in the chronological order, future) theoretical reconstruction. We come back to this below with remarks on retroprojection (Sect. 4), but let's continue with the exposition.

Since our notion of practice aims to help understand mathematical knowledge, i.e., developing an epistemology of mathematics, it is important to underscore that mathematics, as we understand it here, is not just practical knowledge but has at its core theoretical knowledge. Thus,

Third, we understand by mathematical practice one that is oriented to the production of knowledge, with a bias toward *know-that* rather than know-how at the level of goals.[6]

Mathematical practices incorporate a theoretical orientation, which is characteristically linked with attention to some epistemic *values*, such as accuracy or precision, consistency, and simplicity, and with the *goals* of the practice, such as generality, understanding, and certainty. As an example, consider the gou-gu rule (this is the ancient Chinese name for what we call the Pythagorean theorem – when three lengths form a right-angled triangle, they stand in the relation $a^2 = b^2 + c^2$): for practical purposes of building and the like, *particular* instances are most useful, e.g.,

[5] Diagrams are not just figures; there ought to be rules of construction and/or rules of operation on the elements of the diagram (see De Toffoli and Giardino 2014). On the symbolic component of mathematical practices, see Ferreirós (2016, pp. 46–50).

[6] Jessica Carter comments here that know-how and know-that are intertwined. Granted. They are interconnected, but what we call mathematics gives pride of place to some theoretical goals, to know-that and associated values (examples are given immediately in the text above).

the fact that triangles of sides 3-4-5 or 8-15-17, which comply with the rule, are right-angled. From a theoretical standpoint, however, the theorem as proved by Euclid or by Liu Hui is most valuable due to the great *generality* of the result. This is akin to the difference between approximative procedures, aimed at practical solutions, and perfectly exact or precise results.[7]

Attention to *processes*, and not merely to more or less perfect results, is characteristic of studies of mathematical practice. From the standpoint of practice, theories are one and *only one* of the products created by the mathematical community (besides, any given theory is in a dynamic process of reconception and changes in presentation). Other highly relevant products put forward by mathematicians are problems, conjectures, and methods, and so:

Fourth, we shall consider *problems* and *proofs* (including proof-*methods*) and *theories* as central elements of mathematics, or if you wish as the central products of the processes that conform mathematical practices.

Problem-solving, theorem proving, and theory shaping are some of the most important aspects of mathematical activity. Conjectures and methods can be made sense of as revolving around those key goals, e.g., in the process of solving a problem, some conjecture may be proposed and subsequently refined (see Lakatos 1976; on conjectures, Mazur 1997). Or take what we just called *theory shaping*, a very important activity: it aims to select those methods that are judged most appropriate and relevant for a given subject matter and to rework systematically a theoretical corpus so as to develop it in accordance with that approach. The theory will be reconceived and the proofs of theorems will be fine-tuned accordingly; often the process will lead to decisions about the principles and methods that are to be employed preferentially, about the assumptions that are decisive for establishing what one regards as the central results in the field or about the axiomatic basis on which the theory is to be erected. Value judgments are of great importance in such cases – judgments about the most adequate conceptual framework; about the "purity" of the methods employed with respect to the subject matter; about which methods or ways of proving theorems are more fruitful and more explanatory; and so on.[8]

Summing up: we have proposed that it is adequate for our purposes to concentrate on theoretical approaches to methods and results, clearly setting the mark above the so-called practical mathematics, which allows us to make a difference between mathematical practices and their prerequisites, among which we prominently find (i) basic cognitive skills and (ii) technical practices.[9] What I call "technical practices" are *techniques* such as counting, or practical measuring: practices in the general sense, which may involve the use of instruments (a rod, a knotted cord of rope, a vessel) but which do not depend on external representations or especial

[7] More on this topic in Ferreirós (2016, pp. 115–117, 119–122). On the question of generality, see Chemla, Chorlay and Rabouin (2016).

[8] There's a lot of literature on these issues, see, e.g., Mancosu (2008) and other chapters in this Handbook.

[9] Meant are cognitive skills having to do with number (or rather, the "feeling" for numerosity) and with visuospatial abilities of orientation in the environment, and of identification of shapes, see, e.g., Hohol (2020), Van der Ham et al. (2017) and Dehaene (2011).

symbolic components – oral language is involved, of course, but writing is not needed. They have to do with practical problems such as measuring fields or creating a building with right-angled corners.[10]

There are also *constraints* associated with the role of agents, with the cultural level at which we shall locate practices (in connection with symbolic frameworks, problems, results, methods, and their justification), with our interest in know-that (not just know-how), and with the main goals of practice that will be our concern. For our limited epistemological purposes, then:

(I) *Mathematical practice is what a community of agents do when, on the basis of their cognitive abilities and cultural techniques, they employ the resources of symbolic frameworks and methods* (perhaps together with other instruments) *to solve problems, justify results and procedures, shape theories, and eventually elaborate new frameworks*.

Let me insist that problem-solving, theorem proving (or perhaps better, to avoid the Western notion of *theorem*: the justification of results and procedures),[11] and theory shaping are some of the most important goals of mathematical activity.

One possible objection is that my definition does not single out *mathematical* practices. There are other kinds of symbolic practice – especially writing, but also the employment of musical notation – that comply with that definition. By writing we solve certain problems (e.g., communication between people or the storage of relevant information), sometimes we justify certain results and ideas (e.g., by logical argument and critique), and we may even articulate and develop theories (say, philosophical theories). I accept this objection. In fact, I don't think it is possible to characterize mathematics without reference to some of the *contents* involved. Mathematical practices have to do with number and form (i.e., spatial figures) or at least with results and patterns that can be linked with numbers and forms or instantiated in numerical and figural instances (e.g., geometric configurations).

Notice that concepts of number and concepts of geometric form are articulated prior to the introduction of mathematical practices in the proper sense: one can say that they belong to proto-mathematics.[12] So we add to the previous clause (I) the following:

(II) *those practices are recognized as* mathematical *due to their links with the notions of number and form* (i.e., spatial figures)*, which may be explicit or implicit;*

[10] This notion of a "technical" practice, applied to measuring and to drawing (geometric) designs, is discussed in Ferreirós (2016, pp. 38–42, 113–114). See also Sect. 6. Counting may involve instruments (like a stick and a tool to mark tallies) or may just involve fingers or other body parts.

[11] This ought to make room for including ancient Chinese maths, and Indian maths, as proper practices; Liu Hui (see Chemla and Shuchun 2005) or Bhaskara (see Plofker 2009) were clearly interested in know-that, far beyond the realm of know-how.

[12] For this idea of proto-mathematics elaborated in the case of geometry, see Ferreirós and García-Pérez (2020); interestingly, we agree on many points – including the use of this expression, proto-geometry – with Schemmel (2016), a work that only came to my attention recently.

generally speaking, mathematics has to do with the study of patterns*, numerical and geometric patterns being prominent*.

Please take note, then, that the definition of mathematical practice should include both clauses, (I) and (II).

The ancient Chinese classic of mathematics, *Nine Chapters of mathematical procedures* (*Jiŭzhāng Suànshù,* 九章算术), may serve as a paradigm example of a mathematical practice defined as per (I) and (II). We find there the symbolic ingredients; procedures for the solution of problems, which are formulaic and explicitly recorded; mathematical instruments like the try square and compass;[13] the search for patterns and interconnections between those procedures; and the systematic organization of knowledge into nine "branches" of the tree of mathematical knowledge.

This is how the great Chinese mathematician Liu Hui (in the third century) writes about mathematical training, as it existed around 200 BCE, in the preface he wrote to the *Nine Chapters*:

> Mathematics (*suan*) is part of the six arts: the ancients employed them to select people of talent, to instruct the children of high dignitaries. . . . As regards the transmission of methods, one can certainly make common knowledge, as with the trysquare (*ju*), the compass (*gui*), the numbers, and measurement; there is nothing there particularly difficult. (My translation, following Chemla and Shuchun 2005, p. 127)[14]

In the Chinese tradition, as in the Greek one of Euclid, problems of drawing figures and measurement problems were considered in one sweep, and they were approached using traditional methods based on compass and ruler, a most noteworthy coincidence.[15] This underscores commonalities linked with the above condition (II). You may think that the theoretical orientation is not sufficiently explicit in the *Nine Chapters*; nevertheless the work of Liu Hui (in his commentaries) has an undeniable theoretical bias – an explicit interest in justifications, in knowing what is *precise* and what is not, an orientation toward know-that.

Notice too that, in the definition given before, we have not required a focus on mathematical innovation or research, the elaboration of new problems, or new results. In Ferreirós (2016) I intentionally did *not* adopt the position that only

[13] The trysquare is an L-shaped instrument, a *gnomon* in Greek terminology, used to draw straight segments and right angles and to find distances. For further details about the *Nine Chapters*, see Chemla and Shuchun (2005).

[14] The above translation does not coincide with Shen et al. (1999, p. 53), where the last sentence reads: "The course of [the arithmetical arts] is not particularly difficult using the methods handed down from generation to generation, just like the compass and trysquare in measurement, with which we draw figures."

[15] This is not so different from early Modern views: D'Alembert in Vol. 7 (1757), p. 629 of the *Encyclopèdie* says: "Geometry is the study of the properties of area, inasmuch as one considers this simply as extent and form." And Legendre started his classic *Éléments de Géométrie* saying that "La géométrie est une science qui a pour objet la mesure de l'étendue," the measurement of extension.

research mathematicians do mathematics, properly speaking, since we should be interested in how individuals attain knowledge of mathematics. Doing research and developing new mathematics is certainly of enormous interest, but the question is also how aspiring members of the community learn to do mathematics and mathematical research and how they obtain their professional know-how.

2 Defining Mathematical Practices: Sociocultural Aspects

We emphasized that mathematics is the collective work of a community of agents. It should be a truism that mathematical knowledge is a collective product: no single individual could have developed the cumulative knowledge that was mastered by Liu Hui (or by Archimedes), which can only be amassed due to the existence of social institutions making it possible. To emphasize this point is by no means to argue for any strong form of social constructivism – that would imply to forget the role of biological conditions, cognitive abilities, semiotic components, logical aspects, and so on. However, it has to be made clear that mathematics has cultural preconditions and requires social institutions.

Mathematicians are a group of learned practitioners; they are erudites, *savants*, philosophers in the ancient sense of the word; and one can always see that their collective work is possible, thanks to the existence of some institutions. That is, their practices are made possible by the stratification of societies and the emergence of division of labor: Babylonian mathematics was made possible by the institution of the scribes, just like Greek mathematics was made possible by the institution of schools like the Academy in Athens and the Museion in Alexandria. The reinvention of mathematics in the nineteenth century was intimately connected with the emergence of a strictly professional class of mathematicians within industrialized societies. Fermat was an amateur, and Gauss was still (professionally) an astronomer, but these kinds of situations increasingly disappeared as the nineteenth century advanced, leaving the scene to professionals.[16]

As regards the cultural preconditions, we have assumed that mathematical practices are, at core, semiotic practices – this is why symbolic frameworks have been emphasized. Thus they depend *inherently* on forms of *external representation*, such as writing, numerical notations, and figural designs such as those usually called geometric.[17] Of course, the cultural existence, development, and preservation of such symbol systems have further preconditions in material culture, such as the development of writing media: cuneiform tablets made of clay and worked with a stylus c. 3200 BCE at Uruk in Sumer; the Egyptian papyri and the scrolls preserved in ancient libraries like the famous one of Alexandria; modern printed books, together

[16] See, e.g., C. Goldstein's chapter in *Eléments d'histoire des sciences*, ed. Michel Serres (Paris: Bordas, 1989; English version Oxford: Blackwell, 1995).

[17] On this matter, see the papers by Giardino in the Proof section and by Waszek in the Semiology of Mathematical Practice section of this Handbook. On the last topic, see Schemmel (2016).

with the book commerce and the organized libraries that accompanied them; or systems of digital archives in our computerized internet age.

Semiotic components, what I've called *symbolic frameworks*, belong among the cognitive preconditions of mathematical thinking, which by no means is merely a "natural" product of the brain. But there is more. The semiotic component is central to the emergence of communication, to the sharing of information and the interconnection of cognitive processes among agents, and thus to the intersubjective character of mathematics that turns it into true knowledge. For those reasons, mathematical cognition depends on sociocultural niches like the educational ("paidological") niches that I talked about in Ferreirós (2016, pp. 19–22); see Menary (2015).

Babylonian mathematics was made possible by the institution of the scribes, which in turn depended on the invention of writing and numbers. Notice also that the "appearance of texts clearly representative of theoretical thinking is a markedly uncommon phenomenon in the ancient world" (Boltz & Schemmel, in Schemmel ed. 2016a, p. 142), and the presence of external representations of knowledge does not lead by itself to theoretical knowledge. For instance, we find "no sources from ancient Egypt or Mesopotamia that document a theoretical reflection on spatial language" (*op. cit*., 123), which however we find in ancient Greece and ancient China, during the Warring States period.

It would be of little use to enter more deeply here into such components of cultural and mathematical history, which are well studied in a number of works.[18] Let us now turn to another question, about the lower reaches of MPs.

3 The Limits of Mathematical Practices

The previous working definition of MP may be perceived by some as too restrictive. Wouldn't it be advisable to work with a more inclusive approach that opens the way to acknowledge the mathematical aspects present in *all* human cultures? Many contributions of the last decades, to the history of non-Western mathematics, the study of mathematical cognition, and not least ethnomathematics, have adopted such a stance. Let us briefly review their perspectives.

A. *Cognitive science of mathematics* (*mathematical cognition*): according to some authors, the number concept has been wired into our brains by evolution (and into the brains of rats, pigeons, dogs too); the same is true of the space concept, Euclidean space. This means that the basic notions that we have underscored in (II) as definitory of the contents of mathematics are, one may say, "natural" and "universal" (see, e.g., Izard et al. 2011). At most, then, there could be cultural novelties having to do with the methods for dealing with such notions and

[18] See, among others, Netz (2000), Hoyrup (2002), Chemla and Shuchun (2005), Robson and Stedall (2009), Schemmel (2016), and Overmann (2019).

developing them. But mathematics is in essence, according to these authors, pan-human and innate. (Cultural elements are often acknowledged as contributing to the emergence of elaborate concepts, e.g., by Carey (2009), although the role of the cultural in cognition is mostly ignored; see Beller et al. (2018).) Such claims are in conflict with traditional philosophy of mathematics.

The crucial point for many experts in mathematical cognition is that there exist specific numerical (and spatial) capabilities in our basic cognitive setup and that they are independent from other cognitive capabilities, especially linguistic ones.[19] Yet we should make clear that speaking of an innate "number sense" is ungranted by the available data or at the very least misleading: the number concept, in a minimally precise rendering of this notion, goes beyond the basic cognitive abilities of subitizing and of judging size (what is sometimes called the AMS or "analogue magnitude system").[20] So, what should the philosophy of mathematics answer to the claims of cognitive scientists?

B. *Ethnomathematics*: experts in this field have found "mathematics" in basically all cultures: the famous *quipu* of the Incas, string games of Papua New Guinea, the patterns of Arabic geometric decoration, polyrhythmic music from the pygmies, and so on (see Ascher 1991; Eglash 2000; Gerdes 2004). Often these experts suspect ethnocentrism whenever more restrictive conceptions of "mathematics" are defended:

> Ethnomathematics holds that mathematical ideas are pan-human and are developed within cultures. ... The imposition of order on space, for example, is universal, but its particular expression varies with and within culture and may change over time. (Ascher and Ascher 1994, p. 1545)

Notice also that an important part of ethnomathematics deals in effect with applications of modern mathematics (formal languages, graph theory, knot theory, combinatorics) to the study of non-Western cultural products. The mathematical nature of string games (Vandendriessche 2015) or polyrhythmic music (Arom 1985; Chemillier 2002) is gauged by applying modern mathematical tools. There is here an intriguing combination of the opposition to ethnocentrism and the imposition of math-centrism.

C. *History of non-Western mathematics*: one finds very significant bodies of mathematical information in cultures that did not develop the famous "Greek" or Euclidean notion of proof and systematic deductive organization. Cultures and civilizations that have carefully elaborated mathematical notions and methods, to solve problems in ways that can be compared with so-called "Western" mathematical practices: Babylonian or Egyptian mathematics many centuries before the common era, Chinese mathematics from before C.E., Indian mathematics long

[19] See, among others, Dehaene et al. (2006) and Izard et al. (2011). For discussion and criticism of such views, see Núñez (2009), Overmann (2011, 2019), and Ferreirós and García-Pérez (2020).

[20] These concepts are abundantly discussed in the literature on mathematical cognition. More on the argument outlined above, in Ferreirós (2016, sections 3.4 and 3.5, and Chap. 7).

before 1300, and so on. In fact, this body of work can be analyzed with the approach to PM that I outlined in the previous two sections – for it does not presuppose a given way of proving, neither the Euclidean nor what one might call the "Hilbertian" one.

In all of these cases, we find results or ideas *comparable* to results in the mathematics of the West, but not always commensurate with them. In all of them, the old wisdom of hermeneutics applies: we can only interpret other languages, other cultures by analogy with our own; even historians, in the midst of all their sophisticated attempts to break the hermeneutic circle, cannot avoid to relate the ideas and techniques of other times or spaces with our own. But also, hermeneutics has always emphasized the need to make a conscious effort to question one's own cultural assumptions while developing an acquaintance with the foreign. If you study a non-urban, unstratified society with oral culture, it would not be wise to assume that they will display marked differences between, say, the areas of religion and sports, like the ones we may be accustomed to. I assume it wouldn't be polemical to say that some cultures do not have "sports,"[21] and so one may ask why would it be polemical to say that some cultures do not have "mathematics." A matter of cultural pride, there's little doubt.

In the historical and ethnographical cases, we find ideas or practices that can be profitably compared to mathematical results, or studied with mathematical methods, but of course the possibility to interpret something with mathematics does not imply that such a thing is mathematics. The classical example of this is music. Django Reinhardt was not like Bach. Is the musician who plays by rote learning, with no erudite knowledge of musical notation, counterpoint, and the like, still unknowingly a mathematician?

If we wanted to embrace the approach of ethnomathematics, we would have to revise the previous notion of mathematical practice. Notice, by the way, how the ethnomathematical perspective may also be seen as a natural by-product of the nativist ideas of some cognitive scientists. Both trends are inclined to emphasize that there is something innate or pan-human in mathematics. But to make room for this, one would have to modify the basic definition of mathematical practice. Not only should the emphasis on knowledge – on know-that, the theoretical – be avoided, but also we'd have to cease requiring that there exist semiotic components, formulas or diagrams, or some kind of external means of representation, as a basic element of the practice.

However, one can offer rather robust arguments for the view that the abovementioned experts in mathematical cognition are wrong: there are no concepts

[21] *Sport* describes a category of activities that only coalesced in the West in the nineteenth century and was then carried around the globe by Western colonialism and imperialism and later globalization (Guttmann 1994). One may find it wise to broaden the notion of sport so as to include Greek Olympic games, Roman gladiator games and chariot races, and Mesoamerican ball court games, even though this must be done rather carefully. But it would be uninformative to adopt such a broad notion of sport that one would *ipso facto* find them in all cultures.

of number, nor concepts of spatial configurations, without cultural practices involving external representations. The case has been made by experts such as Overmann and Núñez as regards number or Schemmel for space (see also Ferreirós and García-Pérez 2020).

Adopting the views of these experts, coming from fields as diverse as cognitive psychology, archeology, and historical epistemology – so that their views are based on careful consideration of cognitive science, anthropology, and history – it's natural to argue that one should differentiate three levels of cognition:[22]

- **Basic cognition**, of the kind that is developed from innate cognitive abilities, "naturally," by exposal to typical phenomenal experiences[23]
- **Proto-mathematics** based on basic cognition amplified by external representations, which requires some sociocultural conditions, including a certain degree of organizational and material complexity[24]
- **Mathematics** properly speaking, which is the product of theoretical reflection on certain forms of proto-mathematics, made possible by the creation of specialized external representations.

Let me give an example. The "sense of numerosity" (to use Dehaene's phrase) is pan-human, available at the level of basic cognition, and it *must be* distinguished from the possession of a concept of number; the latter emerges at the second level,[25] not in all cultures but in many of them, often in relation to measuring practices (measuring with concrete tools requires counting and thus presupposes number). Mathematics properly speaking begins when there is not only methods for the resolution of concrete problems, practical problems like counting or creating a building with right-angled corners, but also a next-higher interest in reflection about such methods and the patterns that emerge in them – questions such as whether a given method can be extended further, the exact limits of their validity, their degree of precision, etc.[26] These seem to have always required systems of writing, the elaboration of technical vocabulary, and in many cases special symbol systems for the practice of mathematics.

I claim that the distinction of those three levels is highly informative and even necessary. The labels may be judged more or less felicitous, and perhaps the expert

[22] See also Giardino (2016).

[23] Here we mean experiences characteristic of human life on earth, such as walking or running, regardless of cultural environment.

[24] On those preconditions, see, e.g., Overmann (2011, 2019).

[25] The so-called number sense is precise only at the range of subitizing but is fuzzy in general; external representations (counting with sticks, words, or body parts) make it possible to obtain a crisp general concept of number. Instead of the "number sense," one should perhaps speak of a *quantic sense*, making a contrast of crisp concept (number) with imprecise intuition (of quantity).

[26] For instance, the *gou-gu* rule is valid for certain triangles, like the 3-4-5 or the 5-12-13 triangle, but is it valid more generally for any right-angled triangle? The ratio of circumference to radius is close to 157/50, is this result fully precise?

in ethnomathematics will prefer to label 2. as "mathematics" and 3. as "theoretical mathematics." I have nothing to object to such a terminological option, provided the relevant preconditions and presuppositions are made clear. Of course, a change in the definition implies a change in the content and the conditions of applicability.

4 The Web of Mathematical Practices: The Case of Functions

In Ferreirós (2016), I presented and discussed the thesis that mathematical knowledge typically requires a web of practices, interconnected by systematic links. The meaning and function of mathematical statements can be linked with a plurality of practices, starting from what I called "technical practices" (see Sect. 1) and going all the way to sophisticated scientific practices. This can be easily seen for any of the core concepts of mathematical knowledge, such as the notions of natural number, of real number, of geometric form (in the plane), or of function. Intentionally left aside in Ferreirós (2016) were more complex notions such as function, but it may be useful to elucidate the thesis of the web of practices with this case in view.

4.1 The Web-of-Practices Approach

Let me first present a few of the basic tenets of this approach. There is a multiplicity of coexisting practices, i.e., different levels of practice, and associated knowledge, that coexist and are systematically linked in an intersubjective way (as shown by the fact that all this is taught and learned, collectively shared). To summarize the main theses, they are:

Coexistence: several different levels of practice and knowledge coexist; this means coexistence both historically in a given period and "cognitively" so to speak.[27]

Interplay: the interconnections between practices are central, i.e., their *systematic* links;[28] analysis of one practice requires to consider its relations to other MPs.

Symbolic nature: mathematical practices, properly speaking, elaborate on symbolic frameworks (semiotic components) and conceptual frameworks.

Roots in techniques: at the roots of the web of practices lie "technical" practices; also, in due course, there arise links of MPs with scientific practices.

Notice also that the web-of-practices approach *requires* an agent-based perspective: since the links between different strata (or levels of practice) are not abstractly given,

[27] A single agent usually masters many different practices; consider the examples given in the text.

[28] I will not give details about the idea of systematic links here, but it is central to my analysis; see Ferreirós (2016, pp. 83–88, 34–43) and *passim*. For details about frameworks, see Ferreirós (2016, Chap. 3).

but concretely and "cognitively" in a broad sense of this word (see Ferreirós 2016, p. 59), the whole web of interconnected practices can only be sustained by agents.[29]

I presented elementary examples of three different levels of practice interconnected, in cases such as the natural numbers, geometry, and proportion theory (see Ferreirós 2016, pp. 38–39). But of course there usually are more levels involved, as happens with core mathematical ideas such as the real numbers.

The concept of real number, even in its formative stages, links back to measuring practices (an example of a "technical" practice) and to the calculus of fractions and plane geometry (properly MPs); in its subsequent evolution, it connects with many more levels of mathematics and science. The web-of-practices approach underscores the idea that an adequate epistemological analysis of our knowledge of the real numbers should consider those practices separately but must also analyze their systematic interconnections.

Notice that this goes against some traditional tendencies in the philosophy of mathematics: from foundational studies we inherited a tendency to adopt a single mathematical system (e.g., axiomatic set theory) as a reductive basis for all of mathematics. I claim that such a reductionist perspective makes it *impossible* to properly analyze the cognitive bases of mathematical knowledge and its historical development, i.e., the dynamics of knowledge.

With a view to the configuration of mathematical knowledge prior to the seventeenth century, one can mention schematically the following three practices (Ferreirós 2016, p. 39):

> Measuring practices / fraction arithmetic / proportion theory.[30]

This interconnected web became a basis for introducing a new layer of practice and knowledge, the real numbers. Some mathematicians, notably Stevin and Newton, proposed to *define* number as "that by which the quantity of any thing is explained" (Stevin in 1585), which linked the idea of number with proportion theory; with Newton (in 1720) this became explicit, since number is for him "the abstracted ratio [proportion] of any quantity, to another quantity of the same kind" (see Ferreirós 2016, Chap. 8). Notice that this represents an enormous shift from some ancient conceptions of number, in particular the Greek conception. The arithmetic of fractions is subsumed here, the system has the classical algebraic properties, and the underlying assumption that some domains of quantities – to which the theory of ratios is applied – are perfectly continuous implies the continuity of the real number system.

[29] This applies to typical cases up to twentieth-century mathematics, but this does not preclude the possibility of higher-level interrelations (e.g., between structures) being explicitly thematized (see Ferreirós 2023).

[30] The reader can probably reconstruct on her own the systematic links involved here: to give only an example, measuring practices lead to a system of fractions as soon as we consider the idea of using submultiples of the basic measuring unit, in order to refine measurements (an example being aliquot parts of the unit). For proportion theory and the reals, see, e.g., Stein (1990).

The real numbers **R** are a veritable knot linked with all kinds of MPs. When we examine the real numbers, a complex spiderweb should have to be considered, linking number and geometry, the discrete and the continuous, algebra and analysis, and topology and more. But this is not all: one can (and should?) always consider the "applications" of those ideas in scientific or engineering contexts,[31] with astronomical models usually leading the way (in the historical order of development). There are always connections with one or more "technical" practices but also with the so-called "applications," i.e., with scientific practices (Ferreirós 2016, pp. 39–43).

When dealing with advanced mathematical concepts, the emerging picture can be truly complicated and difficult to explore. The situation with functions is correspondingly complex, but let's try to offer a survey.

4.2 The Function Concept

It should be obvious that the notion of function is central to modern mathematics as developed from the eighteenth century onward, until the beginning of the twentieth century. A very large amount of advanced mathematics can be explained and justified in terms of this central notion, which has also been at the core of innovative ways of understanding physical reality. If a great many mathematical theories can be considered as "extensions of the general theory of sets" (Bourbaki 1949, p. 7), exactly the same can be said about the theory of functions.[32] However, complex cases like that of the emergence and development of the function concept are truly defying for historical-philosophical analysis.

In a highly commendable paper, offering a general overview, Israel Kleiner wrote:

> Mathematical concepts usually develop gradually, in response to mathematical needs. While the function concept dates back about 300 years, the "instinct for functionality" may be said to be about 4000 years old. (Kleiner 1993, p. 184)

I wholeheartedly agree that mathematical concepts develop historically, and the function concept is an excellent example. But the last part of Kleiner's statement is far from being clear; indeed it is far from a formulation of "fact" – at most it should be regarded as the formulation of a problem. How far back can we follow the idea of function? Maybe the "instinct for correlation" that appears to be extremely ancient could be regarded already as an "instinct for functionality"? Or perhaps not. How do you know? How *can* you know?

[31] I use scare quotes around the word applications, because at the time those were not *external* to the mathematics, but rather perfectly natural and internal. Only with the advent of "pure mathematics" in the nineteenth and twentieth century did it make sense to regard the applications as something else, a novel addition, so to say.

[32] Set and function are interdefinable concepts: to see the point fully clear at a technical level, consider von Neumann's original version of the NBG axiomatic system (von Neumann 1925) or else the system ETCS (see Leinster 2014). After all, axiomatic set theory is, to a large extent, just a basis for developing the number systems and the theory of functions.

Fig. 1 Tablet #92698 in the British Museum (Old Babylonian period), featuring squares of the numbers up to 59. Here we find a record of calculations, but no functional thinking. . . (Neugebauer, *Mathematische Keilschrifttexte* I, pp. 68–73 (especially p. 71 n. 2). Budge, *Guide to the Babylonian and Assyrian antiquities* (London, 1922), p. 161)

Notice that in such cases there is a great danger involved in what I have called retroprojection. It's easy to see "functional thinking" when we look with modern eyes into documents that come from practices of which (very likely) that thinking was *not* part. Say, a Mesopotamian table of squares (Fig. 1; we come back to this example in the last section). The phenomenon of retroprojection is familiar from studies of mathematical cognition, where some authors go so far as to speak of the "number sense" as a system for "set detection."[33] The phenomenon is also familiar from studies of ethnomathematics, many of which adopt the methodology of analyzing cultural practices with modern mathematical tools (here retroprojection is an explicit part of the methodology, which makes it admissible, but this also invalidates some possible conclusions or extrapolations from the case studies). In our case, since we aim at analyzing the historical dynamics of mathematical concepts, we must be especially aware of retroprojection and regard it as damaging to our aims.

[33] Spelke et al. (2010, pp. 874–875) Unlike the notion of class, which in its early stages was vague and imprecise, the idea of set is very modern; it didn't exist before 1860, and of course there are no sets in the environment with which we might interact (for details, see Ferreirós 2007, especially the Epilogue).

In sharp contrast with the sentiment expressed by Kleiner, math educator W. L. Schaaf wrote in 1930:

> The keynote of Western culture is the function concept, a notion not even remotely hinted at by any earlier culture. And the function concept is anything but an extension or elaboration of previous number concepts—it is rather a complete emancipation from such notions. (Schaaf 1930, p. 500)

The idea expressed here may also be exaggerated, but as far as I know, there is no evidence that the concept of function can be found early and in particular not in the so-called origins of Western culture – ancient Greece or the Hellenistic period.

In the next two sections, I will develop some ideas about the web of practices that is knotted around the function concept. We start with Early Modern developments that led to the eighteenth-century idea of function (as "analytical expression") and the nineteenth-century "logical" idea of function. Then, in the last section, I'll enter into the difficult question of the most basic practices and cognitive experiences that form the basis of the idea of function. In the end I propose that two old conceptions – a dynamic and an algebraic or operational one – coalesced to give rise to the early Modern idea of function, but this was only the start of a longer process.

5 1600 Onward: A Mixture of Mathematical and Scientific Practices

As concerns the historical evolution of the function concept, from my perspective one should differentiate four phases: (1) the *prehistory* of the concept, up to about 1650 (I leave open the question when does it begin, but perhaps in the Middle Ages); (2) the *early history* in analytical geometry and infinitesimal analysis, leading up to the explicit formulations of the concept in the eighteenth century;[34] (3) the *classical period* that can be located in the nineteenth century, marked by the debate around Dirichlet's proposal of "arbitrary functions" and characterized by progressive expansion of the field investigated by mathematicians (e.g., discontinuous functions); and (4) the "modern" or *contemporary period*, including full extensionalization of the function concept but also featuring a series of innovative structural conceptions (e.g., function spaces).[35] However, it's not my purpose here to write a history of functions, but to investigate the web of practices that surrounds this crucial mathematical idea.

To speak about the prehistory, I surmise, there has to be a more or less explicit conceptual understanding of notions that can be recognized as leading to the idea of function. But let us for the moment ignore the difficult question of the most

[34] By Bernoulli (1718), quoted below. It is well known that, at this point, functions were mostly conceived to be (or defined as) analytical expressions; for details, see the expositions by Luzin (1936), Youschkevitch (1976), and Kleiner (1989).

[35] The evolution of the function concept has not stopped, but it falls outside the scope of this chapter to try to analyze its development during the twentieth century.

elementary practices that are linked with our conceptions of function (I come back to this in Sect. 6). We will assume that the prehistory of the function concept saw the emergence of a *dynamic* conception of the interrelation between variable magnitudes,[36] under the impulse of the study of models in astronomy and mechanics.

Such models had to do with the understanding of physical phenomena in terms of functional dependence, where *time* figures prominently and rises to the status of independent variable par excellence. If this is right, the emergence of an idea of function didn't just occur in connection with any calculation or correspondence of values, but was crucially linked to a conceptual understanding of *dynamic interrelations*. And thus the rise of functional thinking would have been inextricably linked with scientific topics in astronomy, optics, mechanics, and perhaps other fields of study.

An obvious example can be Galileo's study of accelerated motion, "the intimate relationship between time and motion" that he discovered (Galileio 1638, p. 197). Notice that we find here a clear conceptual understanding of dynamic interrelations between (physically significant) variable magnitudes, but without any explicit technical language for the concept of function. Let me quote from the Third Day of *Two New Sciences*:

> Some superficial observations have been made, as, for instance, that the free motion [*naturalem motum*] of a heavy falling body is continuously accelerated; but to just what extent this acceleration occurs has not yet been announced; for so far as I know, no one has yet pointed out that the distances traversed, during equal intervals of time, by a body falling from rest, stand to one another in the same ratio as the odd numbers beginning with unity. (Galileo 1638, p. 153)

Galileo manages to produce a precise mathematical correlation between times and spaces, expressed in the classical language of proportionality: if a mobile falls from rest, under gravity, in equal times the spaces are in the same proportion as the odd numbers 1, 3, 5… Thus he complements the idea of uniformity of motion (equal distances traversed during equal time intervals) with the picture of uniformly accelerated motion (during any equal intervals of time, equal increments of speed; see Galileo 1638, pp. 197–198).

His studies allowed him also to associate clear geometrical patterns with other physically significant phenomena: projectiles describe a curved path, which in fact is a parabola. The Galilean method is controlled by experiment but depends also on idealization; he relies on the hypothetical construction of analogical models (see Crombie 1994).

In the next phase of development, analytical geometry is formed by linking geometric practices with the general (still imprecise) idea of real numbers, and with algebraic equations, via the Cartesian way of representing and studying geometric curves by means of algebra. This adds a new layer to previous mathematical practices, incorporating innovative methods, and it also adds to the methodological

[36] Functional thinking was moving *beyond* causality, understood in the simple classical sense of basic causal schemes linked to "manipulative" causation.

tools available for the construction and study of mathematical models of astronomical systems, mechanical systems, optics, etc.[37]

The second generation of Cartesians will go beyond the finitary restrictions of the master, also deploying infinite series – a great conceptual and methodological innovation, in a context that continues to be a mixture of mathematical practices, mechanics, optics, and astronomical practices. Notice that the context is *non-mathematical* in the twentieth-century sense (i.e., not pure mathematics); this is where the crucial step of explicit introduction of the function concept will be prepared. It's an "impure" background of *mixed* mathematics: astronomy being the context for the introduction of trigonometrical operations, mechanical or astronomical systems and their evolution being the frame for emergence of the dynamic conception of how variable magnitudes are interrelated, and the dynamics of such systems being a key goal for those who introduced infinite series.

The dominant conception of functions, from their inception in the early eighteenth century, was as "analytical expressions." Bernoulli defined in 1718: "We call function of a variable magnitude, a quantity composed in any manner of this variable magnitude and of constants"; essentially similar definitions can be found in Euler and others, even in (Cauchy 1821).[38] The quantity so composed is again a "variable magnitude," whose variation can be computed from the variation of the independent magnitude. Thus, conceptually a function is just an interrelation of variable magnitudes, with one independent and one dependent variable. But the mathematical, operational aspect of things dominates the picture, leading authors to insist on "analytical" representability by means of some basic operations (still, this left room for broadening the conception by introducing new basic operations, e.g., sine and cosine).

Nevertheless, as is very well known, there was tension with alternative ideas inspired in physical images: the idea of free graph (to speak in later terms) is defended by Euler, against the ideas of D'Alembert and Bernoulli, in the celebrated controversy on the vibrating string.[39] The debate centered on admissible initial forms of the vibrating string, whether it had to be given by a single analytical expression; Euler argued that more than one law should be admitted, and even more, freely drawn curves should be admitted. This prepared the way for an extension of the function concept, a liberation from the viewpoint of explicit operations or expressions. Euler's intervention was saluted by Truesdell as "the greatest advance in scientific methodology in the entire [18th] century" (1957, p. 248).

[37] Perhaps we shouldn't forget engineering, artillery, and so on, which were branches of seventeenth- or eighteenth-century mathematics.

[38] See Euler (1748), Klügel (1803), and Cauchy (1821).

[39] See Truesdell (1957) and Bos (1980). The vibrating string controversy had to do with the problem of solving the wave equation, a partial differential equation employed to describe mathematically the vibrations of an elastic string (think of a violin). This is described in any good exposition of the evolution of the function concept, e.g., Luzin (1936), Youschkevitch (1976), and Kleiner (1989). Apparently the first time that this episode was emphasized, thanks to Dirichlet's advice, was in Riemann's exposition written in 1854 for his *Habilitation* thesis.

The mixed or impure context of physical and mathematical practices intermingled continues to be decisive in the subsequent evolution of the function concept. The next crucial steps came with the triumph of trigonometric series in the hands of Fourier and his followers. P. G. Lejeune Dirichlet, who studied in Paris and was a young member of Fourier's circle, made a decisive contribution with his rigorous study of the representation of functions by trigonometric series and his clear but challenging conception of "arbitrary functions." This was introduced in an 1829 paper published in Crelle's *Journal* but also (and the detail is worth notice) in a chapter of Dove's *Repertorium der Physik* (1837).[40] A function was now to be just any (many-to-one) correspondence of real values, which is exactly the idea expressed by the modern notation f: $\mathbf{R} \rightarrow \mathbf{R}$:

> it is not at all necessary that y depend on x in the whole interval according to the same law, indeed one does not need to think of a dependence that is expressible by mathematical operations. . . . This definition does not prescribe a common law to the different parts of the curve; one can think of it as composed of the most heterogeneous parts or even totally lawless [*gesetzlos*]. ... As long as one has determined a function for only a part of the interval, the manner of its continuation over the remaining interval will be totally left to arbitrariness [*ganz der Willkür überlassen*]. (Dirichlet 1837, pp. 152–153)

The idea of arbitrary function is meant seriously here.

One can say that this is a purely *logical* conception of functions. In effect, Dirichlet's 1829 result established that any arbitrary function that is piecewise continuous (and complies also with another condition) will be representable by a trigonometric series. Thus, a conceptual determination of the functions, by very general properties, leads to the existence of an analytical representation. That throws light on some of the deep reasons for the sharp *conceptual turn* that Dirichlet promoted, reasons behind his famous remark on "the ever more prominent tendency in modern analysis to replace calculations by thoughts."[41]

The history of the function concept continued with many ups and downs (Riemann, Weierstrass, and so on), but this is not the place to consider the details. To summarize, we have reviewed some of the main mathematical and scientific practices that were involved in the first explicit emergence of the function concept. They include on the "mathematical" side Euclidean geometry, proportion theory, real numerical magnitudes, and algebraic equations and on the side of "physics"[42]

[40] The only paper in the section Mathematical Physics: "On the representation of completely arbitrary functions by series of sinus and cosinus" (Dirichlet 1837).

[41] See Ferreirós (2007, pp. 28–31). Similar remarks were offered by Eisenstein in 1843, Riemann in 1851, Dedekind in 1871, Hilbert in 1897, and others. Riemann in particular (1851, Sect. 1) offered a very clear reflection on the import of Dirichlet's contribution. Eisenstein remarked on the strong contrast between the older school and the "fundamental principle of the new school, founded by Gauss, Jacobi, and Dirichlet" (full quote in Wussing 1984, p. 270).

[42] I place those words in quotes because they represent a categorization that is anachronistic; more or less they reflect our present conception, but this only emerged in the nineteenth century.

astronomical and mechanical models (e.g., the vibrating string) and the theory of heat (Fourier). More precisely, let us mention:

- Geometric models like those of Galileo for uniformly accelerated motion, which were interpreted in terms of proportion theory
- Other geometric models in astronomy (Kepler), in the study of the path of projectiles (Galileo), and many more
- Geometric models linked with the notion of real magnitudes and with algebraic equations and manipulations, in the "analytical geometry" of Descartes. (This was elaborated both at the level of pure geometry and at that of physical studies, optics, etc.)
- Further developments of those models (mixing geometry and algebra) with the introduction of new methods and ideas, such as infinite series, and in due course trigonometric series, and more.

Again, let us emphasize that all this is not separable from their uses in the study of astronomical phenomena, mechanical systems like the vibrating string, the theory of heat, etc.

All of these elements allowed for the articulation of a basic general conception of function, in the sense of a dynamic interconnection between variable magnitudes, that had been ripening in contexts such as astronomy and mechanics – e.g., in Galileo's work, where geometrically represented physical magnitudes appear as functions of time.[43] This underlays the earliest explicit definitions of "function" as analytical expressions (Bernoulli in 1718, Euler in 1748), which however emphasize algebraic features and which were already incorporating new ingredients from the emerging infinitesimal calculus (infinite series).

We have seen how the process starts with a "dynamic" conception, couched first in somewhat rigid algebraic language, which leads to an "analytical" notion of function. And also that this early conception evolved into the modern "logical" one of Dirichlet ("arbitrary" functions understood as relations between real numbers), again in connection with models of physical situations and with innovative mathematical methods such as the trigonometric series of Fourier.

6 Basic, Low-Level Practices in the Case of Functions

Leaving aside the further development of the function concept, I'd like to say a few more words on its early stages of development and its connections with very basic practices. In my view, the prehistory of this concept (from geometric models in astronomy, until about 1650) would be particularly interesting and promising as a field of future studies. But this prehistory is particularly understudied because it

[43] Even if lacking the conceptual and methodological resources that would be introduced along the following century, this is still expressed in the language of proportion theory.

requires us to go beyond "mathematical" history of mathematics: to analyze it in detail, we have to enter into transdisciplinary considerations. We will need to carefully explore cases in which the mathematical ideas are emerging in the context of astronomy, geometry of intensions (Oresme), the rise of mechanics (interrelations between inhomogeneous variable magnitudes, e.g., time and distance and speed), and so on.

Beyond that, there's still the question about the "technical" practices – in my sense of the word – and the most basic cognitive experiences at the basis of the idea of function. This is a fascinating topic, still awaiting careful exploration, although much material on it has been amassed by educationalists. Here I'd like to present only two hypotheses, which I will introduce with some remarks on Cavaillès and Piaget. A phenomenon that is often found in the development of mathematics is what Cavaillès called *thematization* (Benis Sinaceur 1994, p. 77), namely, progress by making explicit a notion that was implicit in a previous practice. This move takes place by reflection on that practice, making an aspect of it the thematic focus of a new symbolic framework and new methods (new concepts, a new kind of object). This is typically found in the "duality operation-object" (also "method-result") that Cavaillès emphasizes in the development of mathematics (Benis Sinaceur 1994, p. 81).

Let me offer two examples from nineteenth-century mathematics: at one stage we find groups of operations (e.g., permutations) as a method for the study of a certain body of mathematics; later we encounter a new generation of mathematicians studying groups themselves as their object, via higher-level methods. What was previously a tool in a particular theoretical setting has become a new thematic object. Second example: at one stage we find bijective correlations employed as a tool, be it in projective geometry or in Cantor's work; subsequently the general concept of mapping offers a thematic focus for a new theory that subsumes previous ideas of function, bijection, and so on. This idea of thematization seems to be intimately linked with that which Piaget called "abstraction réfléchissante," *reflecting abstraction*: some aspect of, say, action is projected onto a higher level of representation, which involves its reconstruction and reorganization on this higher plane.[44]

Thematization or reflecting abstraction seems to play an important role in the historical emergence of the notion of function but also in the way students of mathematics grasp the function concept. Paz and Leron (2009) argue that the formal function concept is intimately linked with "intuitions of actions on familiar objects." More particularly, they identify an "algebraic" conception of functions, which they present as based on the image of an input-output machine, and the "dynamic" conception that we discussed, based on the image of covariation of two magnitudes.[45] My first hypothesis is that the basis of this "algebraic" conception emerges from thematization of some aspects of basic practices of calculation or reckoning.

[44] See selected quotes in Montangero and Maurice-Naville (2013), citing the 1977 work: *Recherches sur l'abstraction réfléchissante*.

[45] There is a terminological problem, since Paz and Leron call this last the "analytical" conception, but as we've seen historically, the idea of function as an "analytical expression" is closer to their "algebraic" conception. I make my own terminological choice with a view to integrating history and cognitive analysis.

Children who learn mathematics are drilled into the practice of obtaining an output from a given input (e.g., to compute the square of a given number), in a kind of symbolic or semiotic action that, naturally, we regard as intimately connected with mathematics. It is a significant part of "the mathematical experience." Such input-output aspects of our conscious behavior can also be found in non-mathematical practices, to be sure – say, when a child is given a sentence and is assigned the task to parse it grammatically into its components. But usually, such situations are based on deployment of an explicit symbolic framework (be it numbers and calculation with them or letters and writing), and thus the basis for thematization is not just action on familiar objects, but actions on familiar symbolic systems – semiotic action. Another example could be the execution of the steps in the algorithm for solving a second-degree equation, with output the value of x.[46]

My second hypothesis would be that the historical emergence of the function concept was a product of the combination of the two conceptions of function just described. On the one hand, based on scientific practices of modeling (astronomy, optics), there emerged a conceptual understanding of dynamic interrelations, the "image of covariation of two magnitudes." On the other hand, the rise of algebra implied reflecting abstraction on reckoning operations, or their thematization, to become new focal concepts of algebraic practice. At some point, *cross-hybridization* of these two lines of development led to the idea of *representing dynamical interrelations by means of algebraic operations*, with geometric models as a background and with time as the independent variable. This was the birth of the function concept, and it is less interesting to know the "who" of this invention, than the "what" was involved. Perhaps several generations of mathematicians (from Galileo to Bernoulli, say) were needed to distil the idea and fully elaborate the new conception.

Notice that the situation is mixed or impure, as I have stressed, and also that both conceptions had ties with geometric thinking. The birth of the function concept *was not purely mathematical*, unlike, say, the concept of set in the late nineteenth century. The result was a decisive new idea of the early Modern "New science," which would be articulated around the technical terms: *function* and *variable magnitude*. (In the nineteenth century, linked with the rise of the Dirichlet conception of functions, the idea of a variable magnitude receded and was replaced by the conception of the system of real numbers. But again, let's not enter into the historical details too much.)

The subsequent development, guided by refined methods of expression and study of functional interrelations, such as infinite series and trigonometric series, led in due course to the rise of a third key conception – the "logical" conception of functions. This is a more abstract, static conception that came to be known as the "Dirichlet concept" of "arbitrary" function. Part of the complexity of the evolution of the concept of function, and the obstacles encountered by those who learn about functions (see, among many other works, Paz and Leron 2009), have to do with the conflicts between those different conceptions, which give rise to conflicting "intuitions" about functions, variables, and values.

[46] Also relevant may be intuitions of "technical" actions, such as a sequence of measuring actions (repetitive) and its output, a measured length or volume.

Abstract

In this chapter, the possibility of experiments in mathematics is examined. A general scheme is proposed as a tool to handle the different forms of experiments that are being used in mathematical practices: computations, "experimental mathematics" as a new research domain in mathematics and computer science, real-world experiments, and thought experiments. In a final section, extensions of the scheme are proposed that further support the conclusion that mathematical experiments are indeed facts and the future.

1 Introduction

At first sight, the idea of experiments in mathematics, from the philosophical point of view though not exclusively, does not seem to make a lot of sense. After all, so the argument goes, mathematicians do not have laboratories where experiments are performed and mathematical theories are not rejected because of real-world data that contradict the theory. In fact, there are still plenty of philosophers to be found who defend such a thesis, see, e.g., Brown (2022), Buzzoni (2011, 2022) and, as it happens,[1] Van Bendegem (2003). This lack of a bodily interaction with the real world is put forward as the crucial distinction between scientific experiments and mathematical "experiments." The latter can only claim a metaphorical status at best. So, if a choice has to be made between the three "f"'s in the title, surely, it should be a fiction with little or no future. However, at second sight, simply looking at the table of contents of this handbook, a different and complementary story must be told. There is in fact a separate section, edited by Jessica Carter and Henrik Kragh Sørensen, entitled "Experimental" Mathematics,"[2] containing chapters such as "Numerical calculations as experiments in 19th century mathematics" (C. Goldstein), "On computer simulations as experiments in the natural sciences" (A. Barberousse), and "Thought Experiments in Mathematics" (I. Starikova). So surely should we rather not conclude that it is clearly a fact and very likely to stay for the future. Or, in a weaker form, that there are a number of philosophers who do believe that genuine experimentation in mathematics is indeed a possibility. In fact, as I will try to show in this survey of what can count as an experiment in mathematics, the wealth and richness of available material needs some framework to understand the connections and relations between the different forms of such experiments.

To achieve this goal, the underlying strategy of this chapter is built on the following idea. From the point of view of mathematical practices, there definitely are practices, as the chapters just mentioned demonstrate. These practices are clearly not "purely" mathematical and they do seem to share at least some characteristics of what could be considered to be an experiment of some kind, commonly understood.[3] So, if we have a closer look at these practices, what can we say about their status as experiments? Are they in some sense "genuine" experiments, similar to scientific experiments, or are they "experiments" in some metaphorical or analogical sense, or are they a new brand of experiment in its own right? To be able to answer these questions, I propose in the next section a scheme that will structure the rest of the chapter and that will help to come to some kind of first-order classification of what mathematical experiments could be. Although I had hoped for a *Mendelejev effect* –

[1] To understand this turn of phrase, see note 30.

[2] Note that the editors themselves used quotation marks to indicate that the interpretation of "experimental" is not necessarily a standard one.

[3] At this introductory stage, this description should suffice. I am referring here to the standard view of experiments being performed by physicists, chemists, usually in laboratories or specialized spaces such as observatories. Or, to put it differently, the way experiments are standardly presented in scientific documentaries for lay audiences.

i.e., a classification usually has some blank spots that no one really expected but that may happen to be filled in later on[4] – this will not happen in this chapter, though there is no reason to assume that the classification is in some sense complete, since it is after all first-order. That being said, it does allow to accommodate many of the known examples of mathematical experiments and that is precisely what will be presented in the sections following the presentation of the scheme. At least the richness and diversity of the classification are very strong arguments to indeed drop the second "f" of the title of the chapter and to insist both on experiments in mathematics being a fact with great promises for the future. Many of these developments are quite recent, as they involve computing machinery, but it seems rather clear that in years to come these experimental practices will "solidify" within the more global structure of all mathematical practices.

2 A First-Order Scheme for Discussing Experiments

The scheme that is presented below should be seen as a first-order characterization of what an experiment could be in a quite general sense. There is of course in the philosophy of science an immense literature on the topic but in order to avoid a survey of this vast domain, I will restrict myself to a "skeleton" version or, if you like, a list of elements that need to be present whenever we talk about an experiment. I do realize that this way of presenting carries a rather strong "flavor" of standard logical empiricist jargon, preferably to be expressed in the language of some logical calculus, but that is not the aim here. The aim is not to arrive at a clear-cut definition but rather to look at what the idea of an experiment presupposes (or, if you prefer, to list conditions, necessary to qualify as an experiment). The skeleton suggestion, throughout this chapter, is that an experiment E presupposes at least the following elements:

- A theory T that is related to the experiment E,
- A "realm" outside of T, usually "nature" or "the world" W,
- (A) procedure(s) P on how to execute or perform E in W, possibly involving instruments M,
- A set of relations R between the outcomes of E and T (confirmation, falsification, a Bayesian evaluation method, or some kind of support in more general terms, . . .).

First one may consider this skeleton to be somewhat naïve. In fact, I believe that the opposite is the case. The reader must have noticed that ample use of quotation marks. The reason is simple. I do not want to enter here and now into discussions about how we should regard W, whether it is a world existing independent from us, whether the person or persons performing E are themselves part of the world W and

[4] I do realize that historians and philosophers of science will consider this description rather naive but it is the idea rather than the actual historical processes that I am considering here. Gaps occur in classifications all the time and that generates the interesting question what to do with them.

what the consequences are of that parthood[5] . . . I also do not want to be too specific about the relations R.[6] What, on the other hand, is important is that this scheme covers just as well elementary experiments – drop an object and measure the distance covered in function of time covered[7] – as experiments performed with the *Large Hadron Collider* as experiments in behavioral economics or experimental psychology.

Given this elementary and general description of an experiment E, the strategy I am proposing here is to see what happens when we perform a replacement, whereby the scientific theory T is replaced by a mathematical theory MT. Again, I want to emphasize that what distinguishes T from MT is itself a tricky business[8] (although in Sect. 5 of this Chap. I will have to address the matter in some more detail). In schematic form, the crux of the matter is this: given the scheme below, what can we fill in for the question marks?

- Scientific theory T → Mathematical theory MT
- The world W → ?
- Procedures P → ?
- Instruments M → ?
- Relations R → ?

At first sight, this does not look very promising. It is not helpful at all to simply add "mathematical" everywhere, although the possibility should be considered seriously that instead of the "real" world W, we consider a mathematical world MW, which somehow leads an existence, "independent" from any mathematician. If, instead of such a mathematical world MW, we use the expression "mathematical universe U," this should sound quite familiar to many mathematicians and philosophers. It corresponds to what might be called, "folk platonism." I use this term to

[5] So, at this point, the definition should be acceptable to a naive scientific realist, to a social constructivist, to a classical view or a one or other quantum-mechanical model, where the observer is implicated in the experiment itself, co-determining its outcome.

[6] Frankly, I would not know where to start to provide an overview of the possibilities for the relations R. The few examples listed such as confirmation and Bayesian updating . . . are mere illustrations, nothing more. For the same reason I do not provide here references but limit myself to direct the reader to the Stanford Encyclopedia of Philosophy, where lemmata such as "Experiments in physics," "Computer Simulations in Science," and "Theory and Observation in Science" can be consulted.

[7] Although we might discuss whether this is indeed an elementary experiment. It requires devices for measuring distances and, even more importantly, devices for measuring time (as Galileo knew very well).

[8] For one thing, it raises the issue what the relations are between "pure" and "applied" mathematics (and, from the historical perspective, one cannot ignore the importance of "mixed" mathematics), assuming that the labels "pure," "applied," and "mixed" are clearly understood, which they are not. Sufficient to note here that the very idea of "pure" mathematics has undergone some dramatic changes in time. Or, as Ian Hacking calls it in his [Hacking 2014]: "A very wobbly distinction" (164 ff.).

make the distinction with "sophisticated platonism," where all the philosophical and mathematical considerations have their part to play, leading to subtle distinctions between (forms of) platonisms and (forms of) present-day-platonisms, connected to just as subtle considerations related to the underlying logic(s).[9] "Folk platonism" is the way that most mathematicians and many philosophers understand the idea that the mathematical universe U is a kind of independent entity, existing somewhere, where not only all mathematical objects (though not always clear whether that includes mathematical structures as well) are to be found but also the famous *Book*, containing all the godly proofs.[10] Seen thus, there is a neat way to complete the scheme, namely as follows:

- Scientific theory T → Mathematical theory T
- The world W → Mathematical universe U
- Procedures P → Mathematical intuition
- Instruments M → Mental imagery
- Relations R → Establishing mathematical "facts"

The accessibility question for U is of course a well-known and deep problem, see Linnebo (2018) for an overview, but the reference to "mathematical intuition" is surely one of the preferred candidates for an experimental procedure. And in so far as instruments are involved, it seems reasonable to assume that "mental imagery" should do. Again, a wealth of issues are coming together here – can this (in)famous intuition be the result of educational training or not? Is it innate in some sense? To what extent are we talking here about "images"? Is it necessarily visual? . . . – but these need not be answered here. This also holds for the last item, namely the establishment of mathematical "facts." In what sense can we indeed talk about facts (keeping in mind that in the philosophy of science too, facts are not straightforward entities that scientists are supposed to deal with)? Granted that in a second-order version, this should all be taken into account, here it suffices to note that plenty of quotations can be offered from mathematicians, logicians, and philosophers, who support the scheme as it is filled in above. No doubt the most famous one being the Gödel statement:

> "But, despite their remoteness from sense experience, we do have something like a perception also of the objects of set theory, as is seen from the fact that the axioms force themselves

[9] As a special case, I mention Balaguer [1998] where so-called "full-blooded platonism" is defended, suggesting that, similar to quantum mechanics, we should better talk of mathematical multiverse U instead of single, unique universe. "Folk platonism" has little or nothing to do with such philosophically challenging theories.

[10] I am referring here, of course, to Aigner and Ziegler [2018]. The first edition appeared in 1998 and the number of pages has increased by almost 50%. This seems to suggest that the book is not all that difficult to read. Of course, the most interesting worry is whether the book is finite in size or rather something similar to the book Alpha in the Borges' story, counting a denumerably infinite number of pages.

> upon us as true. I don't see any reason why we should have less confidence in this kind of perception, i.e., in mathematical intuition, than in sense perception . . .." (Feferman et al. 1990, 268)

This analysis leads to a rather curious conclusion. If the question is asked whether experiments are possible in mathematics, then a "folk platonist" can, actually should answer with a clear yes. But that means that in that sense we have been experimenting in mathematics for centuries, ever since we had the idea that mathematical objects and structures have an independent existence in a separate universe. In that sense, mathematical experiments have been around all of the time. The question is therefore not whether experiments are possible, but rather whether the scheme can be completed in other ways than the one sketched above. As one might expect the answer, as mentioned in the introduction, is doubly positive. Firstly, yes, there exist other ways to fill in the scheme and, secondly, these ways are diverse and plentiful. To be a bit more specific, the two sections that follow suppose that we keep (something like) the mathematical universe U and explore what other choices there are for the procedures P, the instruments M, and the relations R. In Sect. 5 and, to a certain extent, also in Sect. 6. I will look at the scenario where mathematical experiments are performed in the real world W itself and investigate what the implications are of such a view.

3 To Compute = To Experiment?

Let me start with a well-known example, namely Goldbach's conjecture: for $n \geq 2$, there exist primes p_1 and p_2 such that $2n = p_1 + p_2$. As it is a statement that starts with a universal quantifier, we can always look at particular instantiations and check whether the conjecture holds for that particular instance. Taking, e.g., $n = 100$, then it is straightforward to check that $100 = 3 + 97$. Actually, if all possibilities are considered, then there are several solutions: $100 = 11 + 89 = 17 + 83 = 29 + 71 = 41 + 59 = 47 + 53$, six in total. In fact, at present the conjecture has been checked for values of n up to 4.10^{18}, this result dating from 2012. Here is the question to answer: can the computation that leads to 100 being equal to the sum of 3 and 97 be considered to be an experiment, testing Goldbach's conjecture.

At first sight, the answer seems to be yes. Take an example in the natural sciences, say biology. We have a hypothesis H and we perform an experiment E to check whether H is supported or not. If H states that all ravens are black and E is the observation of a black raven then we have support for H.[11] At second sight, however, a case can be made against this positive answer. First note that we are not in W but in U and all we seem to be dealing with are mathematical statements.[12] In the scientific

[11] Here I am actually using the analytical way of writing, though here too it carries no specific philosophical commitments. Terms such as "observation" and "support" are used here in their ordinary language (complex) meaning.

[12] That is, for all of us who are not endowed with such marvelous mathematical intuition as, e.g., Kurt Gödel.

case, we can make a distinction between H and E, the former one being a statement, the latter one an observation. But in U this is a different matter. The conjecture and the specific instance are of the same kind, they are both mathematical statements. The case is then further strengthened by an additional difficulty, namely we need not "perform" a mathematical experiment, in whatever sense of performance, we can actually *prove* that $100 = 3 + 97$. This means that the underlying strategy that is being followed here, is not that we perform an experiment for the special case $n = 100$ in support of the Goldbach conjecture/hypothesis. Rather we reason as follows: if there is proof for Goldbach's conjecture then there should also be a proof of the special case $n = 100$. Now, there is a proof for the latter, hence this supports the conjecture. So what we are really talking about here, are relations between proofs and that has little to do with experiments.[13] In summary, the answer to the question should be negative. Calculating special cases of a general statement cannot be considered as performing an experiment.[14]

This, however, need not be the end of the story. There is another way of looking at computations as experiments that, actually seems far more interesting. When we look at actual mathematical practices, as already indicated above, we note that mathematicians do not perform isolated computations, rather they check a range of cases. Of course, it seems plausible to assume that from the standard confirmation-falsification point this makes sense. A larger set of positive instances increases the likelihood of the conjecture, one negative instance and it can be rejected. Granted that a negative instance is indeed a counterexample, it does not seem to be the case that mathematicians think in terms of confirmation. The strongest argument why this is so, is the fact that there are too many examples around of universal statements that are "confirmed" up to "large" n, yet counterexamples do exist for higher values. A well-known example is Pólya's conjecture: more than half of the numbers less than n have an odd number of primes. The smallest counterexample is in the neighborhood of 1845×10^{361}. In terms of the worlds W and U, it seems that U behaves quite differently from W and holds far more surprises and therefore the confirmational approach is not really favored. Now, given the fact that mathematicians do perform these massive computations, this raises the unavoidable question: why then do they do these computations nevertheless?

The answer is that they are looking for patterns or structures to show up. A fine example is precisely Goldbach.[15] A derived function is the G-function, where

[13] I will come back to this matter near the end of this chapter.

[14] In a more elaborated version of this chapter, a comparison should be included with the ideas of Ludwig Wittgenstein on computation as an experiment, to be found in the *Remarks on the Foundations of Mathematics* (1956).

[15] There are plenty of other examples to be found in the mathematical literature. An example probably just as famous as Goldbach's conjecture is the Collatz conjecture, also known as the hailstone problem (see Van Bendegem 2005). Given a natural number n, if n is even, replace n by $n/2$, if n is odd, replace by $3n + 1$. The conjecture is that repeated applications of this transformation must produce 1 (and then go in a cycle, $1 \rightarrow 4 \rightarrow 2 \rightarrow 1$). Interesting graphs show, e.g., the number of steps needed to get to 1, or, the highest value reached during the process. These graphs are quite informative. Another famous example is Ulam's spiral representation of distribution of primes.

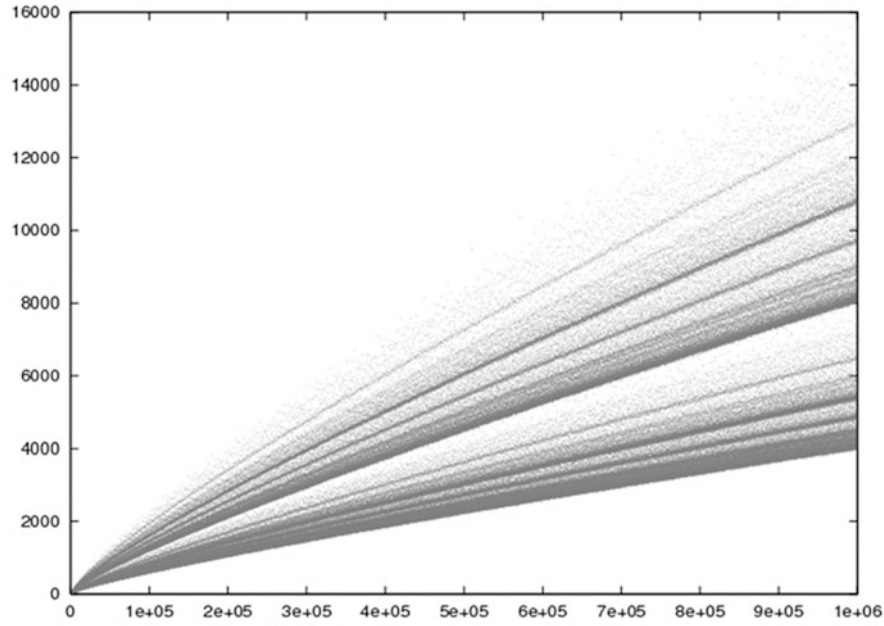

Fig. 1 Graph of the G-function

G($2n$) = number of ways of writing $2n$ as a sum of 2 primes. As mentioned above, G (10) = 6. Given this function, it is sufficient to show that G($2n$) $\geq$ 1, for all n, as this statement is equivalent to the original problem. One way of trying to prove that statement, it is sufficient to prove that, for all n, G($2(n + 1)$) $\geq$ G($2n$). If we now look at the graph of G for an initial range of values, this is the result (see Fig. 1). Clearly this is an increasing function but, in addition, we get some information about the size of the increase. We also learn something about the density that, for a given n, clearly does not appear to be uniformly distributed but rather comes in clusters. We are not talking here about confirmation but rather about insights and generation of ideas and concepts, a topic that will be revisited in this chapter. It also implies that we are not interested in the proofs of all the individual statements, such as G(10) = 6, as that would not be helpful. We are, in a real sense, performing an exploration of unknown territory and, in that sense, it definitely qualifies as an experiment. And it compares well with scientific experiments as often they too are explorations. The outcomes of the *Large Hadron Collider* almost literally produce maps that are the result of a huge amount of data. For sure, they are used to confirm theoretical ideas, such as the existence of the Higgs boson, but, at the same time, it helps researchers in their exploration, hoping that things will crop up that they did not expect.

Coming back to the scheme, it leads to the following completion:

- Scientific theory T → Mathematical theory T
- The world W → Mathematical universe U

- Procedures P → "Number crunching"
- Instruments M → Calculating power.
- Relations R → Getting insights in patterns or structures.

We can however do more. The completed scheme refers to "number crunching" and "calculating power," and it seems clear that this can only cover a small part of possible procedures and instruments. Is there a way to generalize these items? The answer is, I believe, a firm yes, especially if for the instruments computer power is used. Of course they are perfectly suited for number crunching procedures but they can do a lot more. As far as the procedures is concerned, what number crunching does is to deliver interesting graphs but the insights that may result from an inspection of and a reflection on those graphs, seem to be governed more by chance than by a more systematic approach. One happens to stumble onto something, as the expression goes. So, the question becomes whether there exist procedures to arrive at those insights in a more systematic way? The answer, once again, seems to be positive, as there are strategies and heuristics that can help and/or guide us. This leads us to the following scheme:

- Scientific theory T → Mathematical theory T.
- The world W → Mathematical universe U.
- Procedures P → Strategies and heuristics.
- Instruments M → Computer programs.
- Relations R → Getting insights in patterns or structures.

In fact, this description fits a new research domain in mathematics, namely experimental (or "experimental") mathematics. As the label suggests, it is considered to be experimental but the question remains of course whether that label is indeed justified. In the next section we will have a closer look and defend a positive answer.

4 A New Research Field: Experimental Mathematics

Let me start with a quote from two researchers in the field:

> The English word "prove" – as its Old French and Latin ancestors – has two basic meanings: to try or test, and to establish beyond doubt. The first meaning is largely archaic, though it survives in technical expressions (printer's proofs) and adages (the exception proves the rule,[16] the proof of the pudding). That these two meanings could have coexisted for so long

[16] This is not of real importance, but I cannot resist to point out that the adage "The exception proves the rule" means something different from what is usually assumed (as in this quote). In Latin the verb "probare' is indeed used so "to test' is certainly a correct translation but what was meant is that, if in court a party claims that something is an exception, then this presupposes that there must be a rule to which it is an exception. So the exception tests the idea that there must be a rule (and, hence, in legal practice it is justified for the other party to now ask what that rule is).

> may seem strange to us mathematicians today, accustomed as we are to thinking of "proof" as an unambiguous term. But it is in fact quite natural, because the most common way to establish something in everyday life is to examine it, test it, probe it, experiment with it. (Epstein and Levy 1995, 670).

By making a reference to an older use of the verb "to prove," the authors want to make clear that, because the older version is sufficiently different from the other (and recent) use, it merits to be called something else and, because of the idea of "trying" and "testing," the label "experimental" seems justified. What I have done here, is to follow another route that leads to the same conclusion: if "number crunching" can be considered to be an experimental procedure, then an extension of it should also count as such. However, let us look first at an example to get some clearer idea of what we are talking about.

The example concerns, perhaps not really unsurprisingly, the number π. There is a multitude of ways of expressing π in terms of sums of series and the like. A recent addition is this formula:

$$\pi = \sum_{i=0}^{\infty} \frac{1}{16^i}\left(\frac{4}{8i+1} - \frac{2}{8i+4} - \frac{1}{8i+5} - \frac{1}{8i+6}\right).$$

It is worthwhile to say a few words about how the formula was found. First, it is important to distinguish two phases in the "discovery" process,[17] namely (a) how was the formula found, and (b) is there a proof?

As to (a), the computer program, called PSLQ,[18] was used, based on the following strategy. Starting from the observation that numbers such as *log* 2 can be expressed as the sum of a series, namely

$$log\ 2 = \sum_{k=0}^{\infty} \frac{1}{k2^k}$$

It might be interesting to look at a generalized form of this expression, namely

$$\sum_{k=0}^{\infty} \frac{p(k)}{q(k)2^k}$$

where $p(k)$ and $q(k)$ are integer polynomials. The next step is to consider equations of the form $a_1.\alpha_1 + a_2.\alpha_2 + \ldots + a_n.\alpha_n = 0$, where the α_i are real numbers, the a_i are integer constants such that $\alpha_1 = \pi$ and the other α_i are constants as mentioned above. What one does is, given an initial choice, to apply a form of matrix reduction-

[17] Who says discovery often says justification, especially in philosophy of science, where the distinction between the context of discovery and the context of justification seems to be still very much alive. I will return to this issue near the end of this chapter.

[18] PSLQ stands for **P**olynomial-time algorithm, involving the **S**um-of-square and **LQ** decomposition schemes, where LQ refers to one of the methods to decompose matrices.

decomposition in consecutive steps, to see whether or not the equation can be brought to 0, preferably as close as possible. In this particular case, an interesting result come up, namely

$$\pi = 4F(1/4, 5/4; 1; -1/4) + 2\,arctan(1/2) - \log 5,$$

where F is a hypergeometric function. "Cleaning up"[19] this result leads precisely to the formula above. It is important to emphasize here that, at this stage of the process, no proof has been delivered (yet), as the following quote makes clear:

> The ratio between the smallest and the largest y entry when a relation is detected can be taken as a "confidence level" that the relation is *a true relation* and not an *artifact* of insufficient numeric precision. Very small ratios at detection, such as 10^{-100}, almost certainly denote a true relation (although, of course, such results are experimental only, and do not constitute rigorous proof). (Borwein and Bailey 2004, 231–232, my emphasis)

The distinction, made by the authors, between a "true relation" and an "artifact" is an interesting piece of support for considering such explorations as experiments. If we make, once more, the comparison with scientific experiments, then it is clear that the phenomenon of instruments producing artifacts is a well-known feature of scientific investigation. It is therefore an important characteristic that mathematical and scientific experiments are sharing, thus further supporting the case for genuine mathematical experiments.

As to (b), there is in fact a proof of the formula. Quite amazingly, it is no more than half a page and involves a clever use of connections between series and integrals. But, unless one has the formula as a guidance, it seems very implausible that one would think of such a connection. At the same time, it is not the case that the strategies and heuristics used to find the formula were a direct help for the proof itself. Thus, to use the terms of Epstein and Levy, the first part is indeed about probing and the second part is about proving. The two stages can be clearly distinguished from one another and the first stage has a sufficient number of features to merit the label "experimental."

Although the label "experimental" might seem more than justified, there is a counterargument that needs to be addressed. In its simplest formulation it states that, even if the search for the formula, using the program PSLQ, can be described as experimental, once the formula has been proven, it unavoidably ceases to be experimental, as it has now become a mathematical theorem. In contrast, so the argument continues, in the sciences, an experiment in a sense remains an experiment, as it can be repeated over and over again. But it can be argued that this is a misleading

[19] I will not explore this matter here but there are good arguments to claim that the development of notations and diagrams also involves experiments to see what notations do and do not "work." This is however a separate theme as this involves semiotics, specifically of notations and diagrams. See, e.g., Pietarinen et al. (2020) to have some idea of the richness of the domain. That being said, I cannot exclude that fitting this kind of experiment into the scheme of this chapter might lead to a revision (but hopefully an extension) of the scheme.

representation of how experiments function in the sciences. None of us is presently in the situation of, say, Johannes Kepler, who was trying to find out what the trajectory of a planet around the Sun looks like, based on observational data. In any decent present-day astronomy course, the movement of such a planet is now derived from basic equations, such as the law of gravitation and no observations are needed, which corresponds quite neatly to an experimentally obtained equation being proved. In addition, there seems to be little or no difference between, on the one hand, familiarizing a student with the PSLQ program and, on the other, repeating experiments in a physics class that have been done a billion of times all over the planet. This process has more to do with a form of "re-enactment": understanding the historical process by recreating parts of it. It also goes together with the acquisition of "tacit" knowledge, as Polyani in his (Polanyi 1966) already argued for years ago, a form of knowledge that requires practices rather than theories. Seen thus, it seems that mathematical and scientific experiments are perhaps more similar than we imagined. And that raises a very important question. If indeed the similarities are that strong, could it be that mathematical experiments are possible not only in the (abstract) mathematical universe U but also in the real world W itself? The exploration of that question will be the theme of the next section.

5 Can There Be "Real-World" Mathematical Experiments?

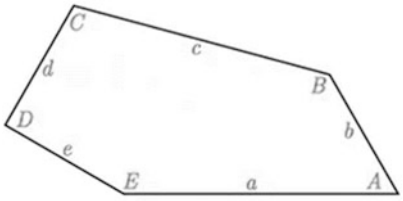
To get started, consider this simple example. Imagine that you have a pile of little squares at your disposal and "playing" around with them, you notice that you can decompose a 5×5 square into two smaller squares of sizes 4×4 and 3×3. You have in fact "discovered" an instance of the Pythagorean theorem, $5^2 = 4^2 + 3^2$. Could this count as a "real-world" *mathematical* experiment? On the one hand, the answer seems to be yes, if we take into account that a "negative" experiment is possible. So, imagine that you have 25 squares and, no matter what you do, you do not succeed in decomposing this square into two smaller squares. If that were to happen, this would constitute a serious problem for mathematics. This means that the outcomes of the experiment can make a difference. On the other hand, the answer seems to be no. To see why, imagine that we are in the close vicinity of a very dense black hole. The surrounding space-time will be strongly warped and distorted and surely very strange things will happen. Whatever comes out of Pythagorean experiments in those circumstances will not have any effect on the Pythagorean theorem itself. Actually, for one thing, the notion of a square will become problematic itself. An additional argument in favor of the negative answer is that in the description given above I made no reference whatsoever to specific properties of the little squares. Certainly not physical properties, apart from being a square and it is precisely that property that is crucial in the black hole scenario. The material, the color, the density, the solidity[20] . . ., it all makes no difference. Can we then not claim

[20] Perhaps solidity is a borderline property. One could imagine that the squares are made of ice, straight out of the freezer but that start to melt at room temperature. On the other hand, a square that is half melted is no longer a square and so the solidity is dependent on the property of being a square.

that we are actually dealing with a mathematical object rather than a physical object, even though we will be manipulating the physical object? There is another example that helps to understand what is said here. There is a famous puzzle that asks, given an amount of (real) oranges, whether it is possible to build both a square-based and a triangle-based pyramid with that given amount. It is straightforward to calculate the number of oranges needed in both cases and that leads to the equation $n(n+1)(n+2) = m(m+1)(2m+1)$. We now know that this Diophantine equation has no solutions,[21] except for the trivial one, $n = m = 1$. Imagine that there was a solution involving very large values for n and m. Then it does not make sense to claim that that solution is not acceptable as the bottom layer of a pyramid of that size will be squashed to orange juice. Quite similar to the squares, it means that the oranges have ceased to be oranges and hence we have another problem. In short, we need to look further.

A potential candidate could be tessellations. Similar to the previous discussion on computations, calculations, and the search for patterns and structures, the Pythagorean example is a "brute-force" case, simply trying out a finite number of cases, whereas tessellations involve a certain amount of not necessarily highly sophisticated mathematics. In that sense it is much closer to experimental mathematics, as discussed in the previous section.

The example illustrated in Fig. 2 is the result of such a search to find a pentagonal tile that tiles the plane.[22] However, looking more closely, the problem does boil



$$A = 60° \qquad a = 1$$
$$B = 135° \qquad b = 1/2$$
$$C = 105° \qquad c = \frac{1}{\sqrt{2}(\sqrt{3}-1)}$$
$$D = 90° \qquad d = 1/2$$
$$E = 150° \qquad e = 1/2$$

Fig. 2 Plane-filling pentagonal tile

[21] As a matter of fact, the history of this particular problem is quite interesting in itself. It started as a question asked in the advanced problems section, problem no. 3951, of the *American Mathematical Monthly* in 1940. One has to wait until 1966 for the answer (in the same journal) that the trivial solution is the only solution, see Finkelstein [1966]. The proof does involve some sophisticated mathematics (in itself not that surprising since we are dealing here with Diophantine equations). Later on connections are made with elliptic curves and measures of the irrationality of certain algebraic numbers. I am mentioning all of this because it shows that, in contrast with the Pythagorean example, it is excluded to consider a set of physical actions that one could undertake to transform one pyramid into another.

[22] Actually this problem is itself a quite curious and interesting case study. It starts a bit more than a century ago, with the construction by Karl Reinhardt of five types of pentagons that tile the plane. The classification was thought to be complete for about half a century. The example found by Casey Mann, Jennifer McLoud and David Von Derauad was solution number fifteen(!), apparently interesting enough to get mentioned in the newspapers. So far no proof has been found (after peer review) that this list of fifteen cases is a complete list.

down to finding solutions of a set of equations, relating angles and lengths of the sides of the pentagon, and thus to a mathematical problem, where the search can be done by computer:

> We discovered the tile using a computer to exhaustively search through a large but finite set of possibilities, said Casey. We were of course very excited and a bit surprised to find the new type of pentagon.[23]

There seems to be no need whatsoever to work with concrete tiles made from particular materials and trying out different patterns. Even if we are thinking of a counterexample. Imagine that a mathematician proposes a particular candidate for tiling the plane and it turns out if one actually tries it out, that a non-eliminable gap appears. Do we need really need the concrete tile to find this out? The answer is negative as a calculation of angles and sides can produce the same result. "Playing around" with concrete tiles can be inspirational but so is "messing around" with equations and trying out specific values. That is not enough to count as an experiment (though I will come back to this issue in Sect. 7).

The reasoning above does lead to an important observation: if indeed specific properties of the objects, involved in the experiment, should play a role, such as being a square, an orange, or a tile, we need arguments and justifications related to these properties to show that their physicality is somehow crucial, if not necessary. To provide arguments and justifications requires a theoretical framework, in short we need theories. What the examples above show, it cannot be a *mathematical* theory but rather it should be a scientific, say, a physical theory. If so, this leads us the following idea: given a mathematical theory MT and a scientific theory ST, can there exist experiments, related to ST, that have a relevance for MT? If so, such an experiment can be interpreted as a (perhaps partially) mathematical experiment. In fact, the answer to that question turns out to be quite deep. But, first, an example to see what we are talking about.

The example is a "great classic" and involves the existence of minimal surfaces. Figure 3 shows a wire framework and a soapy solution, attached to it, that forms a surface of minimal tension. The mathematical partial differential equations that describe this surface are well known. In fact, how otherwise could we know that they are indeed minimal? At first sight, we seem to be no better off than in the Pythagorean and tessellation examples. But let us have a closer look. What can happen when we perform experiments? I see at least three possible scenarios:

- *Case 1*: a minimal surface appears that is known. It is clear that the outcome can count as a confirmation for the physical theory PT (making abstractions of all the subtleties that surround the idea of confirmation). But for MT, this makes little or no difference. It is nothing but a known solution to a given equation. To claim that it

[23] See https://www.theguardian.com/science/alexs-adventures-in-numberland/2015/aug/10/attack-on-the-pentagon-results-in-discovery-of-new-mathematical-tile, consulted on 30 April 2021.

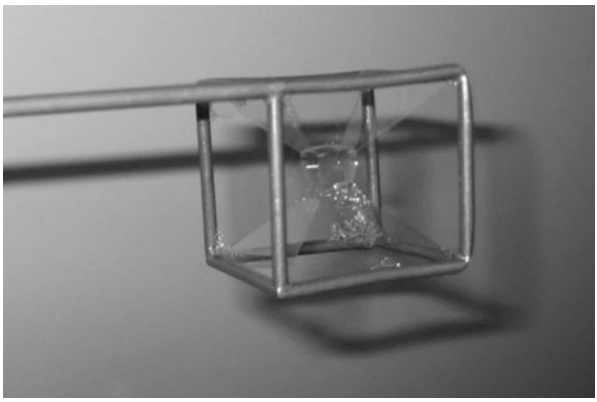


Fig. 3 A surface of minimal tension

also confirms the mathematical theory begs the question how the physical realization of a known mathematical object can add anything extra? Phrased differently, nothing comes from this case that would generate new mathematical ideas, concepts, insights, problems, proofs . . . This case therefore can be dismissed.

- *Case 2*: a minimal surface appears that is not known. Here something interesting may happen. Typical for the equations involved is that, taken together with the initial and boundary conditions, firstly, it is not certain at all that there is a solution, and, secondly, not certain at all that the solution is unique (or not). In both cases, the experiment is mathematically speaking relevant. In the former case, because it shows us a solution, this can strongly simplify the search for the mathematical solution since one might expect that mathematical characteristics can be derived from the physical form we are observing.[24] And, in the latter case, if we are in a situation where a solution is known but unicity has not been established, and where we witness a second solution[25] then the search for a unicity proof can be abandoned and that surely is a mathematically relevant result. This case at least holds a promise for mathematical experiments via the real world W into the mathematical universe U. But there is a third case to be considered.
- *Case 3*: a surface appears that is not minimal. And, let us assume, that we know that the surface is not minimal because we can mathematically prove that it is not minimal. What conclusions can be drawn from this situation? Probably the most

[24] Think, e.g., of continuous and discontinuous features of the surface. Is it smooth all over or does the surface shows the presence of sharp ridges, showing a form of discontinuity? Such considerations might lead to an enlargement of the set of solutions (and even to a better understanding of the equations themselves).

[25] What constitutes a second solution is itself a delicate matter. The surface has to be "sufficiently" different from the first one but that means some features have to be selected such that a difference can be established. A possibility could be whether or not the solution contains holes, a typical topological characteristic. This of course implies that the difference is itself co-determined by mathematical considerations. Such forms of circularity need not be harmful, only when they are vicious care should be taken.

straightforward conclusion to draw is that there is something wrong with the physical theory PT. Such an outcome of the experiment constitutes a simple refutation of PT (again, leaving aside all the intricacies surrounding the notion of falsification). Hence the mathematics remains "untouched" and it is PT that needs mending.[26] But that need not be the end of the story. As it happens, the standard mathematical treatment of such surfaces will introduce some idealizations, such as the soap film being infinitely thin, that is, as a two-dimensional structure. A strong motivation for such idealizations is of course mathematical tractability. If however (variable) thickness is taken into account as an additional parameter, the minimality of the surface can lead to new solutions and explain why the surface, that appeared to be non-minimal, turns out to be minimal after all. Such a result is both physically and mathematically relevant. From the physical point of view, it shows that the equations have to be changed to include additional parameters (that can be left out in special circumstances but not necessarily always) and that can be seen as a response to the falsification that occurred. From the mathematical point of view, it is relevant in the study of geometrical structures in relation to dimension (which in fact has happened in the study of this problem). This is perhaps less clear-cut than the second case but at least the weak conclusion seems justified that *both* PT and MT benefit from this real-world experiment.[27]

It is less evident how we should complete the scheme, considering the different cases. Trying to keep things as general as possible, I suggest the following as a possibility:

- Scientific theory T → Mathematical theory MT.
- The world W → The world W
- Procedures P → Performance of a scientific experiment
- Instruments M → Instruments as used in scientific experiments
- Relations R → Different forms of impact both on the underlying scientific theory and on the underlying mathematics used

[26] One might argue that this way of reasoning has a Quinean flavor. In a one-line summary: if revisions are to be made, start with the scientific theories, then the mathematics, and, if there is really no other option, the underlying logic (see, e.g., Quine and Ullian 1978). Seen from the perspective of this chapter, this order of revision seems to lead to a denial of mathematical experiments, if PTs are concerned. Whatever happens, will first of all be attributed to the PT. To deal with the full intricacies of this issue requires a separate paper.

[27] As one might expect, what is presented here is only an extremely rough outline of a case study worth pursuing. The interaction between mathematics and physics, when studied in more detail, becomes more and more intricate, up to the point where it becomes clear that there is a two-way traffic between the two domains. Especially the generalizations into surfaces of dimension k in a space of dimension n, greater than k, mainly done by mathematicians, has led to physically interesting consequences, e.g., concerning the occurrence of singularities. A nice survey is presented in Almgren (2001).

Note that the difference resides almost entirely in the relations R. In case 2, it is the mathematics that benefits most, whereas in case 3 it is a mutual relationship. That being said, case 3 in a more detailed study will most likely lead to special subcases. One such subcase could be the situation where there are very good and accepted arguments to not doubt the PT, that is, the equations are deemed to be a correct description of the processes occurring in the actual world, so the outcome of the experiment is not considered to be a falsification. In such a case, there would be a genuine problem for the mathematics itself. A possible answer could be that we have made mistakes in deriving solutions from the equations. Such an answer could lead to a reconsideration of the mathematics itself and count as some form of falsification as the experimental outcome forces us to change the mathematics.

Although I will not explore this idea any further – other chapters in this handbook deal with this issue in a more profound way – there seems to be a link with the discussion surrounding explanation of physical events, involving mathematics, and where the topic is the question whether *genuine* mathematical explanations are possible in such contexts.[28] By extension, this section raises the whole complex of problems and issues of the applicability of mathematics in the sciences (see Sect. 7 for some comments on this issue). The same goes for another phenomenon, involving the notion of experiment, and that occurs both in the sciences and in mathematics. And that is thought experiments, a deep and complex issue, the topic of the next section.

6 Thought Experiments

In the philosophy of science one finds a rather extensive and still growing literature on the topic.[29] A host of issues surrounds the topic, ranging from whether thought experiments (TEs) should be seen in first instance as experiments or as something else, e.g., rather as an argument (as I myself defended back in 2003, see Van Bendegem (2003)[30]). This of course seriously complicates the issue if within philosophy of science itself it is not clear whether a TE is an experiment or not. At the same time this generates a great deal of freedom vis-à-vis the question whether *mathematical* thought experiments (MTEs) exist or not. Let us note first of all that the factual question is easy to answer: indeed, MTEs exist in the sense that certain "items" that are being discussed carry that label. But that in itself is of course not sufficient, the question here is whether they can actually claim to be experiments (in some sense).

Although in this section I will be presenting evidence for the idea that there are very good reasons to consider the possibility of MTEs, it is important to realize that

[28] An excellent overview is to be found in Mancosu (2018).

[29] A standard work of reference is Stuart et al. (2018).

[30] To which must be added that in an earlier paper, Van Bendegem (1998), I defended the idea that there are no such things as experiments! The most positive reading of this multiple change of position is that it is indeed a hard and difficult topic to deal with.

they are distinct from the previous forms of mathematical experiment, in the sense that they are more closely connected to mathematical proofs. In that sense, it has many points in common with "experimental" mathematics, as discussed in the previous sections, but it does stand apart. (At the same time, it should be noted that MTEs will also fit within the scheme that is the backbone of this chapter.) As it turns out, here too we notice that the role of insight and understanding is one of the more important elements, as is also the case in classical TEs. Similar to the PSLQ algorithm, presented in Sect. 4, they do not lead necessarily in a straightforward way to a mathematical proof itself but it provides at least some elements to obtain such a proof. This somewhat vague description cries out for a specific example.

In Starikova and Giaquinto (2018), such an example is given:

> It is not news that we often make discoveries or find reasons for a mathematical proposition by thinking alone. But does any of this thinking count as conducting a thought experiment? The answer to that question is "yes," but without refinement the question is uninteresting. Suppose you want to know whether the eq. [$8x + 12y = 6$] has a solution in the integers. You might mentally substitute some integer values for the variables and calculate. In that case you would be mentally trying something out, experimenting with particular integer values, in order to test the hypothesis that the equation has no solution in the integers. Not getting a solution first time, you might repeat the thought experiment with different integer inputs. The fact that there are such mundane thought experiments is no surprise and does not answer the question we are really interested in. (257)

Note that they do consider this example to be a MTE, though perhaps not an interesting one but that is a different matter. Of course, in the quote they refer to simple calculation, i.e., the case we dealt with in Sect. 3 and then we could be skeptical about MTEs being experiments at all. But in line with the position taken in Sect. 4, other strategies can be constructed. An easy example would be to generalize and look at the eq. $8x + 12y = n$, for n an arbitrary integer. An elementary technique that is familiar to us all is that the eq. $8x + 12y$ can be equivalently rewritten as $4.(2x + 3y)$, hence that n has to be divisible by 4 for a solution to exist (or, if one is familiar with modulo arithmetic, that $n = 0 \pmod 4$). But 6 is not $-6 = 2 \pmod 4$ – hence there are no solutions. In this case, the "extended" thought experiment does produce the proof but that has to do with the basic techniques involved. Formulated in this way, it looks that MTEs of this type are close to the examples in Sect. 3 and certainly in that sense we can talk about the genuine possibility of MTEs. It is worthwhile to reiterate one more time that, once the proof has been found, the experiment as such can be "forgotten," although for a MTE a case could be made that the experiment remains as it contributes in the best of cases to the understanding[31] of the proof.

[31] I just mention here that there is a discussion going on in both the philosophy of science and of mathematics, what understanding a mathematical proof (or a mathematical concept for that matter) can mean and how it relates to scientific and mathematical explanation. They are definitely not the same but apparently it is not an easy matter to characterize mathematical understanding. A nice analysis is to be found in Folina (2018).

If we now look at the more interesting examples, one striking feature is that the MTEs tend to be visual, up to the manipulation of specific objects in the real world W (which brings us back to the previous section). Examples, discussed in the already mentioned Starikova-Giaquinto paper, are:

- *Knots*, as described in knot theory. If a set of moves are specified then one of the interesting questions is to decide whether a given knot can be transformed into the unknot. In their own words: "So one may really be experimenting, in the sense of performing a series of actions in order to test the hypothesis that the original diagram is a diagram of the unknot" (261).
- *Cayley graphs*: "Why bother with the visible diagrams of Cayley graphs? Because they can help us grasp the nature of the Cayley graphs they represent; they can help us reason about them; they can suggest to us hypotheses about them; they can help us to discover or explain facts about them" (268).
- *Cycle graphs*: "The results of the experiment are the forms we find; we use them as input to further thinking leading to our mathematical conclusion" (266).

When we referred to the actual manipulation of objects, the last example can provide a perfect illustration. A cycle graph is basically a closed chain so there is an "easy" visual representation. If we define the distance between two vertices as the length of the shortest path between them and the length as the number of edges, then we can define the diameter of a graph as the maximum of all distances. Mathematically one can prove that, if the number of vertices $= n$, then the diameter $= \lfloor n/2 \rfloor$. There is a straightforward MTE to "see" this. Imagine the graph is an actual necklace, that is, the beads have a weight and we are on the surface of the Earth so gravitation is present. If we now take the necklace by one of the beads and lift it up, the following figure (s) should result (Fig. 4). What this example suggests, is that we are now moving more in the direction of experiments as described in Sect. 5. We could in fact even perform the experiment in the real world. And, in addition, we are using here properties of the physical objects themselves (and not just their mathematical properties). This can be made clear simply by pointing out that the MTE would probably not work in the neighborhood of the already mentioned strongly warped black hole, hence the specific structure of real space enters into the MTE to be effective.

As said above, these examples emphasize the visual nature of MTEs,[32] but it would not be correct to say that these few examples are to be considered as prototypes or "exemplars" of MTEs. Two quick examples to justify this claim:

- *Negating the continuum hypothesis*: in this MTE, devised by Chris Freiling (1986), it is stated in the abstract that: "We will give a simple philosophical

[32] In that sense visual MTEs are related to so-called "proofs by looking" (or "proofs without words"), i.e., where, instead of a written-out text with standard mathematical symbols a picture is used and a mental exploration of that picture should produce the same result as the written version. See, e.g., Nelsen (1993, 2000, 2015) for an elaborate set of examples.

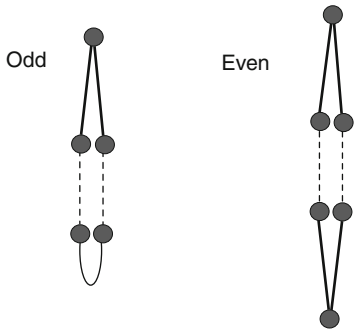

Fig. 4 A thought experiment about cycle graphs

"proof" of the negation of Cantor's continuum hypothesis (CH)." This in itself is quite interesting: the author himself prefers to speak of a "proof" (and, in addition, philosophical!) rather than a thought experiment. However its very description points in a straightforward way to a MTE: "Suppose we were to throw a random dart at the real number line (i.e., the interval [0, 1]) and ask whether the dart landed on a rational number. The outcome is, of course, predictable. We could say in advance that the dart will (with probability one) land on an irrational number." (191) Even if we can have a visual representation of the real number line, it is hard, if not impossible, to understand what it can mean "to hit a rational number." If this is a MTE then it is almost the counterpart of the necklace example above. Note also that it does not directly provide elements for a possible proof. It is not immediately clear what kind of insights are presented here. They do seem to illuminate something but what exactly? Apart from these questions, it is justified to conclude that, if we count this as a MTE, then the scope of MTEs will be wide.[33]

- *The sum of inverse squares*: this example occurs almost everywhere in the literature on mathematical practices. It concerns the famous "proof" – the quotation marks are justified because whatever it is that Euler has done, it is not to have written a proof – of the sum of the inverse squares being equal to $\pi^2/6$. The core of the matter is that Euler extends a procedure that is perfectly justified for the finite case to the infinite case where such justification is lacking.[34] Could this count as an experiment? It differs clearly from all preceding examples but one could argue that the object of what Euler did was to obtain the number $\pi^2/6$ without an acceptable proof and in that sense it can be seen as an experiment as it uncovers a particular number in the very same way that a scientific experiment delivers us data that need to be interpreted and made sense of in the framework of a theory.

[33] It must be noted that Freiling's "experiment" has received highly mixed responses but that should be a topic for a separate paper.

[34] An excellent historical presentation is to be found in Calinger (1996) and in other chapters of this handbook.

The final outcome can be counted as an insight as it guides the search for the proof as we now have a specific number to look for.

All of this shows that the field of MTEs is a complex and heterogeneous one, and that observation leaves us with one final challenge to be dealt with: how shall we complete the scheme? Here is a proposal:

- Scientific theory T → Mathematical theory T
- The world W → Mathematical universe U or the World W
- Procedures P → (Visual) arguments, (symbolic) experiments,
- Instruments M → Mental imagery
- Relations R → Getting insights in and understanding of proofs and, possibly, gathering elements to construct an actual proof

Do note that for the procedures P, I have deliberately used both the terms "arguments" and "experiments" as this particular handbook chapter is not the right place to settle the discussion whether one of the two terms is reducible to the other. We refer to the already mentioned chapter of Irina Starikova in this handbook. There is however something that the reader must have noticed: the completion of the scheme tends to become more and more general. It seems therefore legitimate to ask the question what the limits of this scheme are and to wonder whether a "grander" scheme should be envisaged. This will be the topic of the next section.

7 Opening up the Scheme

Let me start with a warning: I will not in fact present here such a "grander" scheme but rather sketch a number of roads that depart from the original scheme I have used in this chapter. I expect these roads to lead toward other chapters in this handbook for more detailed and in-depth analyses. It is worth remembering that all of the previous sections were meant to demonstrate the existence and importance of mathematical experiments. To the extent that that task has been successfully completed, we should ask ourselves what the next steps could be. What follows is nothing but a non-exhaustive list of possibilities that should include at least the following items:

- Up to now the starting point has been a mathematical theory MT. There is however no particular reason to limit oneself to MTs. I list here three examples. Firstly, mathematicians not only use theories but, as indicated in the scheme also methods: geometrical constructions, algebraic algorithms, particular proof methods such as induction, reduction, and proof by cases[35] …. Finding out what method is most suitable, effective, simple (to implement), justifiable … all of this can be done in an experimental way in the sense of an exploration. Secondly,

[35] A fuller treatment is to be found in Van Bendegem (2004).

what goes for methods, certainly goes for (symbolic) notations. The history of mathematics is also a history of the development of notations – a famous example[36] is of course the introduction of variables x, y, z . . . – involving experiments in the sense of trying out and see what works and what not. Thirdly, going back to MTs, we can look at pairs of MTs and translations between them. 2 in ordinary arithmetic becomes s(s(0)) in Peano Arithmetic, {{Ø}} or {Ø,{Ø}} in set theory, or (ιn)(Pr(n) & (∀m)(Pr(m) → m ≥ n))[37] in first-order predicate logic. And, of course, we are all familiar with the standard translation(s) between the geometry of the Euclidean plane and real and complex number theory. Note, in addition, that the three routes sketched here are not independent from one another. Translations between methods and/or notations are also possibilities to explore.

- In previous sections it has been mentioned that one of the purposes of mathematical experiments is to guide us toward proofs. In the case of the search for patterns and structures, computing power becomes important and hence the hardware, implementing the software, is an element that has to be taken into account. Two examples that come to mind are quantum computing and DNA computing.[38] It should be noted that in both cases the understanding of the computing processes requires an elaborate theoretical background, respectively, in physics and in biology. This implies that we are also dealing here with experiments in the sense of real-world experiments. What if, e.g., the quantum computer tells us that a mathematical pattern is present in the data that seems to conflict with mathematical results already known? Is mathematics in trouble, physics or technology or . . .? At the same time we should not forget that human search processes can challenge us as to how insights are generated. Let me simply mention Ramanujan. It still remains a deep problem to understand the mental processes that generated all the beautiful and deep results he produced.[39]
- Another road that certainly needs to be explored involves the proofs themselves. The well-known Euler example mentioned in the previous section is a fine example of an "almost" proof, so to speak, but it would be too narrow a view to assume that this can be the only form of "experiment." A fine example are the

[36] See, e.g., Heeffer (2009).

[37] The logical formula is perhaps somewhat unusual but it shows that we do not need a particular name for 2 in order to be able to define it. The only thing that we have to assume is that a primitive predicate Pr exists that states that a number n is a prime number. Once we have that predicate and the iota-operator "ι', the statement reads as follows: the number n, if it exists, that is a prime number and such that for any other number m, if that number is prime, then it must be at least as great as n. The second half is a logical translation of the property that 2 is the smallest prime number.

[38] For an overview of these and other forms of so-called "natural' computing, see Nunes de Castro (2006).

[39] See Kanigel (1991) for a biography of Ramanujan that shows the quite extraordinary mathematical mind he possessed. It is usually assumed that it is as good as impossible to understand his reasoning processes but recently in Raayoni et al. (2021) the so-called Ramanujan machine is introduced that seems to mimic to some extent some of his mathematical powers. The method outlined there relies on polynomial continued fractions and is related to the PSLQ algorithm mentioned in this chapter.

so-called probabilistic proofs. At play is an intriguing interaction between a rigorous proof on the one hand and a theorem that states that an object has a certain property with a probabilistic measure. A specific case concerns tests for primality that lead to conclusion that a given natural number n is prime or composite with a certain probability.[40] A related area that needs to be explored is proof verification: the computerized control of the correctness of given proofs. In ideal circumstances this control is itself of "proof quality," i.e., there is full guarantee of the proof being correct. In real circumstances it is often a probabilistic claim that is being made.[41] This leads in a rather straightforward way into the idea of tests in a statistical setting and statistical thinking in general as the relations between "pure" mathematics and statistics are complex and intricate. This opens up not so much a road as an avenue.

- This avenue is itself part of a larger network that looks at the relations between "pure" mathematics and "applied" mathematics. As the applications of mathematics are mostly in the sciences,[42] this necessitates looking at the philosophy of science. Via this route relations can be investigated between the cluster concept of experiment in the sciences versus the cluster concept of experiment in mathematics, as presented in the previous sections of this chapter. This investigation will imply a second look at mathematical experiments, now from the perspective of what scientific experiments are. This in its turn might lead to a re-evaluation of the classification presented here and eventually lead to a "reflective equilibrium,"[43] thereby firmly establishing the very notion of a mathematical experiment.

As said, this is an incomplete list for, among many other things, nothing has been said about mathematics education and the role of experiments (in any of the sense discussed above) within the educational process. And, of course, there is still that other domain to deal with, namely philosophy. Apart from the reference to "folk platonism," I have tried to keep the presentation philosophically "neutral," in the sense that, whether one is a Platonist, formalist, intuitionist, constructivist, nominalist …, a notion of mathematical experiment will need a place somewhere in the chosen philosophical framework. This thought leads straightforward to the conclusion of this chapter.

[40] The basic format is, given a number n that is to be tested, take any number $a < n$. Calculate some equation involving a. If the result is positive then a is a witness and the number is composite. If not, then chose another a and repeat. As more and more numbers do not lead to a positive result, the probability increases that the number n is prime (and the probability can be effectively calculated).

[41] The core problem is the complexity and length of some of the present-day proofs such as the four colour theorem (that has now been fully checked) and the classification of finite, simple groups. See Alama and Kahle (2013) for a nice philosophically motivated discussion of proof checking.

[42] It is a separate study to look at the interactions between mathematics and the arts.

[43] Reflective equilibrium is a method first proposed by John Rawls and refers to a back-and-forth movement to check and countercheck one's beliefs and arguments, make necessary changes and adaptations, go for another round until a form of equilibrium is reached. See Daniels (2020).

8 General Conclusion

Instead of a conclusion in the form of a summary, I think it is worthwhile to return to that philosopher who is considered as (at least one of the strong favorites to be) one of the founding figures of the philosophy of mathematical practices, namely Imre Lakatos. We are all familiar of course with *Proofs and Refutations* but one should not forget that he is also responsible for the introduction of the intriguing term "quasi-empiricism" in the philosophy of mathematics (see Lakatos 1978). It is, of course, all too easy to say that Lakatos was too strongly focused on Popperean falsification and on mathematical proofs and accompanying proof activities but the first introduction dates back to 1967, more than 50 years ago. What has happened since then is not merely an elaboration of Lakatos' approach to mathematics but also a "strengthening" of his views. If what has been presented in this chapter supports the idea of genuine experiments in mathematics then it is time that we can drop the "quasi" and instead speak about full-fledged "empiricism" in the philosophy of mathematics. In terms of the title of this chapter, experiments are indeed a fact and, on the assumption that understanding how to get to a proof is just as important and essential as actually having the proof, it is clear that mathematical experiments are an essential ingredient of what is what mathematicians do when they do mathematics and thus the final answer is that indeed they are the future.

Abstract

The philosophy of mathematical practice sometimes investigates the social constitution of mathematics but does not always make explicit the philosophical-normative framework that guides the discussion. This chapter investigates some recent proposals in the philosophy of mathematical practice that compare social facts and mathematical objects, discussing similarities and differences. An attempt will be made to identify, through a comparison with three different perspectives in social ontology, the kind of objectivity attributed to mathematical knowledge, the type of representational or non-representational semantics adopted, and the justificatory or coordinative role entrusted to axiomatics. After a brief introduction to key issues in social ontology, Sect. 3 of the chapter offers a survey of contributions by Feferman, Ferreirós, and Cole, highlighting a difference between approaches based on rules, practices, and intentional states,

respectively. Section 4.1 also discusses results by Carter, Collin, Giardino, and Pantsar, focusing on differences between the objectivity of knowledge and objectivity of objects and showing that many authors combine a realist, structuralist, and pragmatist perspective, as well as the idea that objectivity comes in degrees. Section 4.2 focuses on the kind of semantics that is adopted in socially oriented approaches. A representational semantics is preferred by authors grounding their views on mental states, whereas a non-representational semantics best fits with views based on practices. Section 5 considers how axiomatics can be understood in a social perspective. Axiomatics generally plays a justificatory role also in theories that aim to explain the social constitution of mathematical knowledge. Yet, if one shifts from approaches based on mental states to approaches anchored on rules or habits, axiomatics can be viewed as an institution based on obligations, functions, coordination problems, and agent's actions and roles, thus playing an organizational and coordination role.

1 Introduction

The philosophy of mathematical practice is a constellation of researches having various aims and interests. Many authors share some form of anti-foundationalism, attention to history, and interest for ontological and epistemological questions that arise from mathematical case studies, partly in opposition to classical trends in analytic philosophy. Recent surveys have detailed the origins and the history of the study of mathematical practice, recalling its interdisciplinary nature, its multiform approaches based on agency, epistemological concerns or historical studies.[1] Most authors agree that mathematical knowledge is not obtained through the analysis of abstract properties of entities that can be analyzed independently of the practices in which they emerge. They claim that it should be understood through the study of human activities. However, it is not always clear to what extent the study of such activities can still be the prerogative of philosophy and not precisely of other disciplines such as history, sociology, psychology, cognitive sciences, or educational theory. Indeed, one may wonder whether the pragmatic turn does not end up undermining the normative viewpoint in favor of a merely descriptive approach.[2] The question we will ask here is whether mathematical knowledge understood as a product of intersubjective social practices exhibits radically different characteristics (e.g., in terms of objectivity) or raises new logical problems (e.g., the development of

[1] For a survey of the different notions and traditions included in the philosophy of mathematical practice, see Mancosu (2008), van Bendegem (2016), Giardino (2017), Carter (2019), Hamami and Morris (2020b), and of course other chapters of this handbook.

[2] See, for example, Gandon's (2013) criticism.

non-representational semantics) or allows for a better understanding of the axiomatic practice.

The aim of this article is to shed light on some more recent philosophical trends that analyze how mathematical objects can be socially constituted and at the same time exhibit a kind of objectivity that is, if not identical to the objectivity granted by platonistic approaches, at least sufficient to explain the stability and interculturality of parts of mathematical knowledge. In a sense, now that the presence of a whole range of prelinguistic, pre-symbolic, and informal practices is deemed legitimate, it becomes possible but also urgent to question how these practices were constituted and whether they can give rise to the mathematical objects that are typically investigated by philosophy. For example, the development of the philosophy of mathematical practice goes hand in hand with the development of the idea that mathematics is also an informal discipline. But what then of formal demonstrations and axiomatics? Do the objects studied in the philosophy of mathematical practice really have the same degree of objectivity as formal demonstrations, axioms, and theorems understood as abstract propositions? If mathematical objects are no more considered as independent entities, but are viewed as a byproduct of interactions between agents, how can one account for their objectivity? This chapter will offer a survey of several recent theories that attempt to solve this problem, explaining how intersubjectivity gives rise to practices and practices give rise to objects, considered either as the outputs of certain processes or as a reification of roles or social habits. This has various consequences, including the discovery that mathematical objectivity is not a matter of all or nothing, as it is in ontology (an object exists or does not exist), but a matter of degrees (an object is more or less robustly constituted by certain practices).[3] That mathematical objectivity is a matter of degree leads to questions about the possibility of drawing a sharp line between formal and informal methods in mathematics. On the one hand, formal approaches cannot disregard the analysis of intentional contents (e.g., the intended model of an axiomatic theory). On the other hand, the notion of interpreted formal language is gaining more and more legitimacy, suggesting that formalized axiomatics need not be based on uninterpreted symbols.[4] In both cases, the study of intentionality and interpretation refers back to epistemic actions and interactions that suggest the importance of studying underlying human practices and activities.

The study of the social constitution of mathematical objects is thus of interest not only to philosophers who believe that mathematics is essentially a human practice and who investigate its informal aspects but also to philosophers who wish to account for the formal aspects of mathematics, because the latter cannot be fully understood except against the backdrop of a more pointed analysis of the practices associated with the

[3] On the effects that this change of viewpoint has on mathematical objectivity, see the TOPOI special issue "Mathematical practice and social ontology," where different degrees of objectivity are compared (Cantù and Testa 2023).

[4] See Sundholm (2002) on formal interpreted languages and expressions without meaning and Cantù (2021) on the distinction between uninterpreted and as-if uninterpreted symbols in the Peano School axiomatics.

construction of formal axiomatic systems. For this very reason, this chapter will not only present a survey of some promising lines of research on the social constitution of mathematical objects, discussing key features of mathematical knowledge such as objectivity and semantics, but also offer new insights on a mathematical practice that is generally regarded as a formal activity and rarely described using the tools of social ontology: axiomatics.[5] Comparisons between social ontology and mathematical practice serve on the one hand to show how investigations into the social constitution of mathematics are not beyond the scope of philosophical inquiry into mathematics; indeed they even bear similarities to metaphysical approaches to the study of social interactions such as those conducted by social ontology. On the other hand, they suggest the need to make explicit the philosophical-normative frameworks underlying much research in philosophy of mathematical practice.

The approach followed in this chapter opens a new perspective on the philosophical investigation of mathematical practice, because attention is paid to authors who question the relationship between social and mathematical facts. Even if tendencies in the direction of a disciplinary crossover between philosophy of mathematics and social ontology can be traced, bridges between the two disciplines still have to be developed and no general survey has been offered yet of existing preliminary explorations. Since it is not usual to analyze mathematical practice from the concepts of social ontology, we will provide in Sect. 2 a brief introduction to the latter, focusing on some of its characterizing aspects, such as social constructivism, collective intentionality, and regulative and constitutive rules, which we hope will be helpful in orienting readers experienced in mathematical practice studies but less familiar with the key concepts of social ontology. We will recall John Searle's ideas, which are necessary for understanding Julian Cole's contributions, and then the criticisms advanced from Guala and other naturalist philosophers.

We will then move in Sect. 3 to the presentation of recent studies that describe mathematics as socially constituted knowledge. It is certainly not possible to offer here an exhaustive and organic survey of all the literature analyzing mathematics as a social activity. Reuben Hersh was among the first authors who explicitly claimed that mathematics is a human activity and a social, cultural, and historical phenomenon. Hersh (1997) claimed that mathematical objects are created by humans, not arbitrarily, but as a byproduct of interactions with existing objects and from the needs of science and daily life. Hersh created a history of what he called (following Aspray and Kitcher 1988) the Maverick tradition including modern (Peirce, Poincaré, Wittgenstein, Lakatos, Pólya, Polányi, White, Wilder) and contemporary authors (Popper, Bunge, Kitcher, Piaget, Vygotsky, Ernest), and ethnomathematics. He opposed mathematical foundationalism and especially Platonism and formalism. We will start where Hersh stops, including twenty-first-century authors who were not already mentioned in Hersh or other existing surveys in the literature, and which

[5] A notable exception to the investigation of hypothetico-deductive axiomatics as a mainly formal activity is Schlimm, who, quoting Bourbaki, claims that formalization is just one aspect and the least interesting of axiomatics (Schlimm 2013, 41).

we consider particularly relevant to a comparison with the processes of social construction, language, intentionality, and rules discussed in social ontology.[6]

The starting point is Solomon Feferman, who explicitly brings to the table many of the issues we are interested in: he asserts the structuralist, intersubjective, and objective nature of mathematical knowledge and its similarity to other social constructions. And indeed, Ferreirós and Cole's research, which we will analyze afterward, can be seen as two relatively independent developments of Feferman's central ideas: the social constitution of mathematics from empirical activities and the study of mathematical concepts as social facts.[7] In their perspective two central issues are the explanation of the possibility for mathematics to be both socially constituted and objective and the development of a non-representational semantics capable of expressing the inferential component of mathematics without presupposing abstract entities existing independently of human activity.

After outlining some key points of the research of Feferman, Ferreirós, and Cole, we will move on to a comparative analysis of their work, considering further research by Carter, Collin, Giardino, Pantsar, Hartimo, and Rytilä. We will see how their views interact with three different approaches in social ontology, centered on intentional states, rules, and habits.

Points of contact and divergences between social ontology and approaches in philosophy of mathematics that defend the social constitution of mathematical objectivity might include (1) different ways of characterizing objectivity – as a property of mathematical knowledge or as a property of mathematical objects; (2) the function assigned to intentionality, language, and rules in the constitution of the intersubjectivity necessary to justify a certain degree of objectivity; and (3) different ways of analyzing mathematical agents: through a naturalization of mathematical practice that requires the analysis of the cognitive and epistemic abilities of agents, through a historical and comparative study of the development of mathematical abilities in different cultures or through a normative approach, which considers agents as dialectical roles. In the second section of this chapter, we will mainly focus on objectivity and semantics, leaving aside the discussion of the other directions of research.[8]

[6] We will not discuss the work of Paul Ernest either, who, like Hersh, analyzed the contributions of Maverick authors, but was more interested in discursive practices and in characterizing mathematical knowledge. Adopting Bloor's theory of objectivity, he distinguishes between explicit and implicit mathematical knowledge, claiming that both produce an objective knowledge, i.e., a knowledge that is shared and intersubjective, deployed and used in public, for persons to witness (Ernest 1998: 144ff). For recent developments of Ernest's views, see chapter ▶ "The Ethics of Mathematical Practice," this volume.

[7] See Ferreirós (2022) for an explicit discussion of Feferman's conceptual structuralism, in which, however, the author explicitly distances himself from the idea that the kind of objectivity proper to mathematics, called robust, is akin to the objectivity of social facts.

[8] On collective agency we refer to Yacin Hamami's article ▶ "Agency in Mathematical Practice," this volume. On language, symbolization, and artifacts, see Valeria Giardino 2018b and 2023. For further directions of research see also M. Kremakova's article "The Sociology of Mathematical Practice," this volume and the paper by M. Inglis and K. Weber "Education and Mathematical Practice," this volume.

To illustrate how this comparative approach between disciplines that rarely interact can suggest new perspectives in the study of mathematical practice, we will provide in the last section some new results suggesting how axiomatics, a practice combining formal and informal elements, can appear in a different light when analyzed as the fruit of a social constitution. Should axiomatics be understood only as a mathematical method based on relations (inference rules) between given sets of sentences (axioms, theorems, definitions) expressed in a formal language or also as an institution based on rules, obligations, functions, and agent's actions and roles? Is its goal merely foundational or includes coordination and organization of knowledge?

2 A Brief Introduction to Key Issues in Social Ontology

This section briefly introduces the notions of collective intentionality, regulative and constitutive rules, and status functions, as introduced by Searle. This choice is based on the fact that many of the later theories in social ontology were developed in response to Searle's views. However, Searle was not specifically interested in mathematical phenomena as social facts, but in social phenomena such as "money, property, marriage, governments, elections, football games, cocktail parties and law courts" (Searle 1995: xii and ff.).

Using linguistic theories and tools developed in earlier work – the theory of speech acts and performatives – he grounded social ontology on intentionality and in particular collective intentionality and rule-governed behavior. He opposes social facts, depending on human activities and language, to brute facts, which are taken to be what makes human utterances true.[9] To ground the opposition between brute and social facts, Searle assumes a distinction between properties that an object inherently has (being made of wood) from properties that depend on an observer (being a screwdriver). Among the latter he identifies properties that are assigned or imposed on a natural object or artifact by a given function, acquiring a normative value (e.g., "That river is good to swim in" or "That computer is user-friendly").[10] Searle rejects any reduction of functions to causal chains and believes that whenever we talk about the function of an object, we do so because we insert the causal chain into a normative system defined by purposes, goals, and values. This holds both for non-agentive functions (causal processes to which the observer attributes a function)

[9] According to Searle's correspondentist theory of truth, an utterance is true if and only if it corresponds to the fact that makes it true. However, with Strawson, Searle agrees that facts cannot be considered as groups or agglomerations of things and that a picture theory of meaning, according to which sentences have the meanings they do because they are conventionalized pictures of facts, does not work. Facts are conditions in the world that satisfy the truth conditions of the statements.

[10] For example, to discover the function of the heart is to discover causal processes but also to place them in a teleological framework, which distinguishes hearts that function well from hearts that function poorly, depending on how they contribute to the maintenance of what we assume to be the highest value: life (Searle 1995: 14–15).

and for agentive functions, which "are matters of the use to which agents put entities," and to which belong semantic functions, that symbolize, represent, stand for, or signify something (Searle 1995: 23). The terms denoting social facts are nodes in a network of practices (owning, buying, selling, earning, paying for services, paying off debts, etc.), and in a sense the word "money" is a placeholder for the linguistic articulation of these practices (Searle 1995: 33–51).

Language is used to distinguish cooperative animal behavior from collective intentionality: it is only when a collectively recognized status is continuously attributed to a function (only when there is the imposition of a *status function*) that an institutional fact is created, and this requires language, because the linguistic label *Y* in the formula "*X* counts as *Y*" is a constitutive part of social facts (Searle 1995: 37). The role of language is crucial, and indeed it is considered as the primary institution that conditions the existence of all others. The key point is that when asserting and believing that a physical object *X* counts as *Y*, agents attribute a symbolic role to *Y*, because *Y* stands for a pattern of activities. What is required is thus at least a primitive form of symbolization. We will see in Sect. 3 how the notion of status function is further developed by Cole into that of surrogacy function.

Even if Searle does not specifically discuss the status of mathematical facts, he mentions a mathematical example suggesting, according to my reading, that mathematics' dependence on symbolism does not appear to have the same necessity as language dependence proper to social facts. Mathematical facts, e.g., the addition $371 + 248 = 619$, seem to be a thought that cannot be realized without the aid of symbols, but for Searle this is an empirical and not a logical impossibility: it depends on how we are made and is something that could change in the course of evolution. On the contrary, social facts are language dependent because symbolic mental representations are constitutive of them. Can symbols be entirely eliminated in mathematics? One could think the result of the addition operation even without expressing it linguistically (at least, if one were constituted otherwise), but there certainly are other mathematical operations where there is no prelinguistic way to represent the Y element and a symbol is needed. Many of the studies in cognitive science evoked by philosophers of mathematical practice can be taken as confirming Searle's claim. Since a part of arithmetic can be achieved by prelinguistic operations of subitizing, etc., at least a part of human arithmetic abilities are shared with animals, while for larger numbers and more complex number systems, the introduction of a symbolization becomes necessary. In both cases the role of language in the differentiation between animals and humans plays a key role.

Searle argues that neither an internalist phenomenological approach nor an external behaviorist approach can explain the functioning of institutional facts, but only an intentional approach, whether expressed in the first person or through the vocabulary of capacities, abilities, tendencies, and dispositions (Searle 1995: 2–5). Intentionality is the capacity of the mind to represent objects and states of affairs in the world other than itself. Intentionality is a capacity of complex systems of physical particles that are organized to constitute living organisms endowed with consciousness: intentional acts are either conscious or accessible at least in principle to consciousness and are guided by intentional states (beliefs, desires, etc.).

Collective intentionality is animal capacity to engage in cooperative behavior sharing intentional states. It is a primitive phenomenon, i.e., one that is not traceable to a form of individual intentionality to which shared beliefs are added.

Another relevant feature of Searle's theory is the distinction between regulative rules, which serve precisely to regulate or coordinate a phenomenon that exists prior to the creation of the rule (driving on the right) and constitutive rules, which create the possibility of a certain activity (the rules of chess) and are, unlike the former, unconventional and therefore non-arbitrary (Searle 1995: 22–28).[11]

In social ontology there are alternative theories to Searle's that do not attribute a similar role to language, to collective intentionality, to the distinction between regulative and constitutive rules, nor to the opposition between brute and social facts in the characterization of social facts and institutions. Francesco Guala, e.g., develops a perspective starting from the presumption of the importance of social institutions as instruments of economic growth and human flourishing and analyzing the mechanisms by which they arise and are maintained. Structures originate for Guala as rules that constitute a tool for coordinating human activities and are maintained in place through a system of incentives that serve to ensure that social agents follow the rules. In the book *Understanding institutions*, a key role is played by game theory and by coordination games with multiple equilibria and dilemmas of cooperation. The coordination promoted by institutions is based on the understanding of deontic powers as costs that transform individual incentives in a strategic game. Institutions are "behavioral patterns that tend to persist because individuals have no incentive to deviate from the pattern unilaterally (unless everyone else does the same)" (Guala 2016a: xxiii). Two general claims interest us here.

There is an essential difference between tokens of institutions, which are solutions to coordination problems, and types of institutions, which are characterized by the general function of facilitating coordination and cooperation (see chapter Reform). The emphasis is not on the cognitive abilities of agents, or their intentional mental states or the representational role of language, but rather on the organization of knowledge and the reasons that might have made one institution prevail over another. Institutions depend on the mind, but in a causal way, and language is one of many possible devices that can be used to send signals that people use to converge on new equilibria, creating expectations about what each agent will do in the interaction. The focus thus naturally shifts from the investigation of theories of mind to the

[11] To compare social facts and mathematical facts, it is useful to have an idea of several phenomena peculiar to social facts that Searle intends to explain with his theory (although they do not apply indiscriminately to all social facts): (1) self-referentiality (for something to fall under the concept of money, it must be believed to be used or be regarded as money, which is also expressed by saying that being a type of money is a constitutive property of money); (2) the creation by explicit performative utterances as in the example "I appoint you chairman"; (3) the existence of social facts on top of brute facts, which are logically prior; (4) the existence only in a set of systematic relations to other facts (e.g., money cannot be conceived independently of some exchange system and property ownership); (5) social objects are just the continuous possibility of a social activity, because the process is prior to the product; and (6) language is a constitutive property of social facts (Searle 1995: 33–37).

sociohistorical study of institutions, to understand the motivations and incentives proper to token institutions, which are characterized by a precise geographical and historical location. The macroscopic investigation of institutions proposed by Searle (2005) is complemented by the possibility of a microscopic investigation of institutions, which can include traffic regulation as well as marriage.[12]

Another key criticism concerns rules: Guala and Hindricks claim that all constitutive rules can be obtained from regulative rules via the introduction of theoretical terms (Guala 2016a, Chap. 5). Constitutive rules are naming devices for regulatory rules and are not constitutive of institutions: they have the function of "term-introducing principles that state the conditions of application of the theoretical terms that we use to label institutions. They are, first and foremost, naming devices for regulative rules" (Guala 2016a: xxvii). Symbolization becomes crucial when regulative rules are considered as constitutive rules, but the key elements to explain social mechanisms are only regulative rules and therefore intentionality is not presupposed.[13]

One of the ideas that Guala recognizes as primary motives for the development of his game-theoretic approach is a kind of naturalization of social ontology, aimed at showing that the dependence of social phenomena on representation can be explained in purely causal terms, without the need to introduce collective intentionality (Guala 2016b). Other theories of social ontology criticize Searle's anti-naturalism, not only to reduce the role of language as presupposition of all social interactions but also to criticize the relationship of logical primacy between individual and group. If Guala explains intentionality through the motives and interests of individuals in a strategic game, Italo Testa, reconstructing Dewey's social ontology, explains collective intentionality as a second nature generated by habits and thus as a point of arrival and not a presupposition of social interaction (Testa 2017). Indeed, the habits of individuals are explained through the habits of a group, the interactions with the interests and habits of other groups, and with the environment. Applying this perspective to the study of mathematical practices could help to better understand both the interactions between mathematical groups (schools, research traditions, scientific journals, etc.) in the constitution of mathematical facts and the role of the applicability of mathematics, whose centrality would be explained by the interactions with the environment. In this framework, a pragmatist approach prevails, but also a tendency to bridge social ontology and cognitive sciences (Testa 2020), as is also increasingly common in the philosophy of mathematics after Lakoff and Núñez (2000).

[12] The token-type distinction could be applied to mathematics, asking whether and how the number type differs from tokens related to specific number systems. Applying this theory to mathematical knowledge, it would then be a matter of explaining that some extension of the number system is non-arbitrary, not so much because it is the result of constraints imposed by status functions but because it results from a strategic interaction between agents guided by motivations, incentives, and expectations.

[13] An interesting research direction would be to compare abstraction procedures in mathematics with the way in which constitutive rules are obtained from regulatory rules through the introduction of theoretical terms.

3 The Social Constitution of Mathematical Objectivity: A Survey

3.1 Solomon Feferman's Conceptual Structuralism

In a paper on the continuum hypothesis, Feferman characterizes mathematical objectivity as a special case of intersubjective social objectivity. According to Feferman, research in mathematical practice has been dominated by structuralist views at least from Dedekind onward,[14] since all questions about zero, negative quantities, irrational magnitudes, imaginary numbers, and infinitesimal quantities are questions about the coherence of these ideas with other meaningful ideas of mathematics (Feferman 2011: 8). This view together with the idea that "the source of all mathematical thought [is] in human conceptions," forms the core of the version of structuralism proposed by Feferman and that differs from those proposed by Hellman, Resnik, Shapiro, Chihara, and Isaacson in the insistence that mathematical entities are human conceptual constructions (Feferman 2011: 10). Without summarizing all ten theses that Feferman introduces to characterize conceptual structuralism, let us bring attention to a few key points for understanding the social constitution of mathematical concepts.

All mathematical knowledge proceeds from mental concepts, but these concepts have their origin in the empirical activities of counting, ordering, matching, combining, separating, and locating in space and time, which give rise to pre-mathematical ideas of order, succession, collection, relation, rule, and operation (Feferman 2011: 10–11). From this pre-mathematical knowledge, theoretical or pure mathematics emerges through an awareness of the repeatability over time and on different objects of these activities, their interconnection into structures, and the subsequent conceptual expansion of these structures. What guarantees the objectivity of mathematics is its relative stability over time and the independent activity of different agents but also the fact that what does not withstand intersubjective critical scrutiny is abandoned (Feferman 2011: 10–11).

With social ontology Feferman shares the basic question, "How can there be an objective reality that exists in part by human agreement?" For Feferman, in fact, the objectivity of mathematics does not fail once its social constitution is explained. On the contrary, quoting Searle 1995, Feferman believes that mathematical objectivity (intended as some kind of non-arbitrariness of human conventions) is explained by the constraints that social facts and institutions impose on our choices (Feferman

[14] On the relationship between structuralism and mathematical practice, see Reck and Schiemer (2020), presenting in the first part mathematical practices related to structuralism from Grassmann to McLane. See also Cantù and Patras (2023) and Carter (2008). Carter distinguishes different ways in which structures operate in mathematics: structures are not only objects of study but also ways of studying sets initially conceived as devoid of structure, of which one investigates whether they have or can be given one or more structures. Cantù and Patras claim that structures often play a dual role in axiomatic practice: e.g., in Bourbaki (1948) the notion of structure plays the role of an epistemic object (formalized in the theory through an axiomatic definition) as well as the role of an epistemic concept (used in the architectural construction of the axiomatic framework).

2011: 12–13). While we cannot go into detail here about the construction of the structure of natural numbers and its subsequent expansions, it seems necessary to point out that in Feferman there appears, albeit in an implicit form, the idea of a scaffolding of mathematical knowledge and of different degrees of objectivity characterizing it. In the case of the sequence of integers, there is no doubt about the definite meaning of the statements describing it, while in the case of the continuum, there are distinct concepts with different degrees of structuring and axiomatization, which make the question of the definiteness of the problem much more complex. In other words, there are more degrees of arbitrariness than in the case of natural numbers, whose structure is modeled on the activity of counting (Feferman: 13–22).

Feferman explicitly acknowledges, citing Cole 2013, a similarity between mathematical concepts and other social institutions: both allow substantial intersubjective agreement and have concepts that are understood without assuming reification. But he adds that there are also differences: "What makes mathematics unique compared to institutions and games is its endless fecundity and remarkable elaboration of some basic numerical and geometrical structural concepts" (Feferman 2014). We will see how Ferreirós develops this idea of the uniqueness of mathematical concepts compared to other social institutions.

Feferman distinguishes not only between pre-mathematical and mathematical activities but also between basic mathematical activities and axiomatized mathematical activities or subject to systematic logical development (Feferman: 11).[15] The analysis of a prelogical and a basic level of mathematical knowledge was one of the central themes of Paul Lorenzen's research, although its primary goal was not to explain the objectivity of socially constituted mathematical knowledge. His two main aims were to highlight a mathematical core common to formalists and intuitionists in the dispute over foundations and to characterize a part of mathematics as operational, picking up on Dingler's views (Lorenzen 1955: 4). As we have pre-mathematical activities in Feferman, and basic skills that cannot be further analyzed in Dingler (1931),[16] we have in Lorenzen "protological" activities underlying logic and arithmetic, that is, practical faculties of operating with figures, recognizing them as equal or different, without thereby already possessing the assertion (*Behauptung*) of their equality (Lorenzen 1955: 7). A part of mathematics is in fact regarded as a theory of calculus (an idea Lorenzen derives from Curry (1951) but which he restricts to a part of mathematics only), where a calculation is not necessarily formulated in a language. The axiomatic method intervenes only at a later stage not so much to justify but to organize operational mathematics and enable a better understanding of the relationships between the various parts of "concrete" mathematics (Lorenzen 1955: 8).[17]

[15] We will return to this point in the next section, but it is important to note that axiomatization is conceived by Feferman as a formal activity that presupposes the choice of one language and one logic and whose goal is basically to transform undefined into defined statements.

[16] On Dingler see also Gödel (1932).

[17] See also Heinzmann and Wolters (2021).

A further aspect of Lorenzen's research is of interest to us here, namely, the development of propaedeutic logic as a dialogical theory of rational argumentation, in which logic emerges from *Lebenspraxis*. In particular, the truth-verification principle of simple and compound statements is intersubjective and dialogical, and the meaning of logical constants is their use in a dialogue. A proposition *Q(b)* is true when a speaker "rightly" attributes the predicate *Q* to the object denoted by *b*. Attributing "rightly" means that any other speaker who is knowledgeable (open to the ideas of the partner in the dialogue) and rational (capable of formulating discourse that is not determined only by emotions, traditions, habits) would, after appropriate verification, attribute that predicate to that object. To determine whether a compound statement is true, it is necessary to imagine a dialogue between two ideal speakers playing different and asymmetrical roles (a proposer and an opponent), set the logical rules (establishing the meaning of the logical constants) and the general dialogue rules (e.g., who starts speaking first, that the interlocutors have the floor in turn, that the proposer has to defend only the assertion made in the immediately preceding turn by the opponent, while the opponent has to defend each of his own assertions, etc.), and finally see who wins: if the proposer wins, the compound statement is true; if the opponent wins, it is false.[18]

The main reason why we discussed Lorenzen's view in the analysis of Feferman's perspective is because we think that it might well make explicit what remains implicit in Feferman's brief survey. According to Lorenzen, (1) mathematics is constructed in stages from some practical activity (and this is true not only for geometry, of which a material, empirical, semi-empirical, and abstract component had long been distinguished in relation to educational needs,[19] but also for arithmetic); (2) the main reason for isolating an operational part of mathematics is to show that although conventional, mathematical knowledge is not arbitrary; (3) the formal axiomatic method, which requires the choice of a language and a logical system, is not part of operational mathematics but serves to structure its parts; (4) formal logic itself, presented in dialogical form, reflects the intersubjective constitution of truth and shows how agreement on the truth of an utterance is the result of a dialogical and dialectical practice centered on ideal agents, who embody roles and follow rules.

3.2 José Ferreirós Interplay of Practices

José Ferreirós (2016) defines mathematical practice as an activity supported by individual and social agents and characterized by stability, reliability, and intersubjectivity. The two essential elements of the definition of practice are agents and a framework. There are two kinds of frameworks: theoretical and symbolic (Ferreirós

[18] See Kamlah and Lorenzen (1967) and Cantù and Testa (2006).

[19] See, for example, Veronese (1909) and Veronese and Gazzaniga (1895–97), discussed in Cantù (2000). Another example suggested to me by Dirk Schlimm, whom I thank for several precious comments to a preliminary version of this chapter, would be Moritz Pasch, who claimed that both arithmetic and geometry can be constructed in stages from some practical activity. See in particular Pasch 1923.

2016: 26–28).[20] Agents are individuals, but their practices are communal, so it is necessary to consider groups, schools, or entire research traditions. This notion of communities of agents shows that Ferreirós's approach is far from the idea of reducing the study of agents to the investigation of individual mental states, values and goals, but considers the historical development of schools and research traditions as a key element in defining what a practice is. Ferreirós's notion of practice differs from Kitcher's (1984) in at least two respects: it explicitly introduces the notion of agent and renounces defining practices as frameworks. Practices also include ways in which agents use frameworks and thus also exemplars (in Kuhn's sense), questions of style, and other cultural differences in the configuration of knowledge.[21] Practices can be recognized by the fact that they can be taught and learned and that there are success conditions that should be met for one to know them, which allows Ferreirós to include the notion of norms (implicit more often than explicit) and norm transmission among the characteristics that identify a practice (Ferreirós 2016: 28).[22] The approach is agent-based and cognitive, pragmatist or practice-oriented, historical, and hypothetical (Ferreirós 2016: 3). Agents are investigated through their biological and cognitive abilities, but the latter are mediated by culture, so that no established model from cognitive science is applied as such to mathematics.[23] The practices are of various kinds: practices of everyday life, technical practices, specifically mathematical practices and scientific practices. The approach is historical because it is based on the idea that historical changes in practices and their interconnections affect mathematical concepts themselves.

Mathematics progresses through conceptual diversification, and the latter is due to the transformation of networks of practices and knowledge. Whenever a practice is modified or new practices are developed, new connections are made between these practices. Since concepts are socially constituted by practices, then, whenever practices change, concepts also change. It follows that "agents who command

[20] The distinction between the two is taken to be fuzzy, but symbolic frameworks generally contain ideograms, technical expressions, and symbolic methods (symbolic frameworks need not be only formal nor only linguistic), while theoretical frameworks include statements or propositions, proofs, theoretic or proof methods, and open questions (Ferreirós 2016: 55).

[21] One of Ferreirós's goals is precisely to avoid the identification between frameworks and paradigms or disciplinary matrices à la Kuhn: that is why he claims that different frameworks can coexist in the same historical period and even in the same agent (Ferreirós 2016: 37).

[22] Among the examples cited by Ferreirós, one finds traffic regulation (Ferreirós 2016: 29) – a paradigmatic example in social ontology studies on institutions as instruments of social coordination (see Guala 2016).

[23] Indeed, the biological and cognitive component of human abilities is included – it was recalled as one way to explain the cultural invariance of mathematics in Ferreirós 2005 (p. 64) – but the historical dimension clearly prevails. For example, Ferreirós claims that the number concept is a cultural product, even if it is based on some specific cognitive abilities of the human species (Ferreirós 2016: 68). Besides, the second part of the volume on the interplay of practices is entirely dedicated to historical case studies ranging from ancient China to contemporary mathematics. Furthermore, the term cognitive is used in such a broad sense (basic abilities such as perception, memory, and language) that cultural components also enter into such abilities (Ferreirós 2016: 77).

different webs of practice and knowledge may differ in their conceptions" (Ferreirós 2022b: 101). This could lead, from a discontinuous historical perspective, to question the commensurability of concepts constituted in different networks of practices, but Ferreirós rather focuses on the possible cooperation between mathematicians with different expertise.

The hypothetical component of the approach relies on the fact that mathematics is built up from different layers, i.e., from the interplay of different kinds of practices, going from basic skills involving perception to more abstract practices of hypothetical reasoning. Some of these layers (advanced mathematics) are grounded in hypothetical elements, i.e., on a non-representational use of language.[24] This allows for different degrees of objectivity of different parts of mathematics (Ferreirós 2016: xiv). If only elementary parts of mathematics such as the theory of natural numbers can be known with certainty, advanced and hypothetical mathematics also undergo constraints, because new hypotheses are linked with previous strata of mathematical knowledge and force certain results upon agents: "objectivity can still be found in a form of knowledge that falls short of perfect certainty" (Ferreirós 2016: 161).

Despite his insistence on the origin of mathematics from the interplay of practices that are not only specifically mathematical, Ferreirós aims to ensure some kind of specificity to mathematical knowledge, rejecting a holistic approach à la Quine. Mathematical knowledge is distinguished both from scientific knowledge in general and from other forms of knowledge peculiar to the human sciences. Science is based in a different way on experiential practices (or at least on different experiments, dealing not only with symbols and diagrams but also with activities on physical objects) and makes essential use of mathematical results (particularly in the processes of conjecture formation, model formulation, and theory).[25] On this same basis, Ferreirós contrasts the objectivity of mathematics, which is robust, with the objectivity of other socially constituted forms of knowledge. Against those who identify mathematical objects with institutions, Ferreirós claims that the stability of mathematics is much stronger than that of marriage or private property: the latter are highly variable among different cultures.[26]

[24] As in the pragmatist tradition, meaning is elucidated in terms of use, and mathematical understanding in terms of elementary practices and cognitive roots, but Ferreirós tries at all costs to avoid reductionism, suggesting that it is a form of substantiation (Ferreirós 2016: 5).

[25] See Ferreirós (2016, p. 14). In other words, Ferreirós assumes that there is a difference between mathematical and physical experiments and retains a version of the indispensability thesis, even if the emphasis on the interplay between mathematical and non-mathematical practices apparently dissolves the problem of applicability.

[26] Ferreirós, unlike the enculturation tradition (see Pantsar 2023 for a review of enculturation studies), does not provide an explanation of this difference based on cognitive science. He does not attempt to explain but merely notes this difference, suggesting that historical evidence supports a cross-cultural universality of mathematics (Ferreirós 2023).

3.3 Julian Cole's Institutionalization of Mathematics

If Ferreirós develops Feferman's idea of an interplay between mathematical and pre-mathematical practices, Julian C. Cole develops another suggestion by Feferman, i.e., the effort to explain the non-arbitrariness of mathematics by analogy with the case of social facts, which impose constraints on us even though they are social constructions. Cole explicitly introduces mathematical objects as institutional facts, referring to Searle's theory of collective intentionality.

The initial impetus for investigating the social constitution of mathematical objects comes to Cole from structuralism (see Cole 2010). His goal is not so much to show that mathematics is a social activity, a result he believes has already been sufficiently proved by Hersh (1997) and Ernest (1998), but to discuss whether and how it is possible to show that mathematical domains (a general term under which structures fall) are socially constructed. Cole reprises Haslanger's (1995: 98) distinction between causal social construction (when causal factors bring into existence a social fact) and constitutive social construction (when social factors enter into the definition of a social fact) and further distinguishes the class of pure constitutive social constructs, i.e., constructs that exist wholly in virtue of the undertaking of certain acts, decisions, or practices of social significance, but do not require any kind of associated physical object. His central thesis then is that "mathematical domains (and the items of which they are composed) are pure constitutive social constructs constituted by mathematical practices" (Cole 2008: 115). The way these practices constitute mathematical domains is through a consistent characterization, culminating, as Cole notes in the case of Euclid's two-dimensional geometry, with axiomatization (Cole 2008: 117). Indeed, Cole does not deny that the characterization of a domain is the product of an individual, but he believes that it is detached from its originator by becoming an object of study for a larger community and that it is objective precisely because of the logical nature of its axiomatic characterization. Cole, however, also discusses the objectivity of mathematical entities and proposes a version of realism, called practice-dependent, which assumes that "many mathematical domains genuinely exist and have objective features, but their existence is dependent on the existence of mathematical practices that constitute them" (Cole 2008: 121). Cole even goes so far as to say that mathematical objects share many properties with abstract objects, such as acausality, non-spatiotemporality, eternality, and changelessness. Why then do we prefer practice-dependent realism to Platonism? Cole claims that the latter is explanatorily and justificationally superfluous since it is neither necessary to account for the truth value of mathematical utterances nor to construct an adequate semantics (Cole 2008: 126–127).

Cole's adherence to a form of structuralism becomes even stronger in later papers, in which he introduces a distinction between "pure" mathematical facts "that wholly concern mathematical domains" (Cole 2013: 10) and obtain in virtue of collective agreement, and other mathematical facts Cole focuses on the imposition of a particular kind of functions – representational functions – that facilitate our abilities to represent, analyze, reason about, and discover truths. To explain how they constitute social objects, Cole draws on Searle's theory of language acts (via

declarations). To explain how it is possible to account for the fact that there are, apparently, two kinds of objects, physical and symbolic, Cole takes up Amie Thomasson's solution, introducing a hybrid theory of reference and a related meta-ontological perspective. Mathematical domains are thus "freestanding institutional entities that, at least typically, are introduced to serve representation functions" (Cole 2013: 27).

The difference from nominalism or fictionalism is that an individual's commitment to a mathematical domain is sufficient to guarantee its existence and that it is maintained in existence by the collective recognition of the deontic powers attributed to that mathematical domain. Mathematics results from a successive series of layers: in the first layer mathematical entities serve to represent non-mathematical aspects of reality, in the second layer to represent elements of the first, and so on. In particular, the representation function must apply to all (external) possibilities of some kind and thus be free of modal and spatiotemporal restrictions, which would allow for the derivation of the characteristics usually attributed to mathematical entities: being abstract and atemporal. Not only that, but mathematics would also be robustly objective because representational functions are subject to greater constraints than status functions and in the case of the first layer are constrained through abstraction principles from non-mathematical aspects of reality (Cole 2013: 32).

Having thus claimed that mathematics can be objective, abstract, timeless, and even appear to be necessary, Cole believes he has refuted the main arguments against the thesis that mathematics is a social construction (Cole 2015). He also tries to account for the plurality of different theories that can perform representational functions (e.g., classical mathematics or constructive mathematics) by insisting on various possible operations of generalization and extension of a system of objects compatible with their application. Cole introduces the idea of surrogate object: "we find it significantly easier to engage in various representational activities when their subject matter is treated as an object in our representations" (Cole 2015: 1109). For example, the natural numbers are surrogates that are useful when we engage in representations of the cardinalities of finite pluralities: the representational function is thus considered as a property of an object, but this depends on collective intentionality.

Cole's problem then becomes that of answering Benacerraf's (1965) dilemma. If different collections of ordered sets serve the representational function performed by the natural numbers, how can the choice of the latter be not arbitrary? Cole answers that non-arbitrariness concerns only the core surrogacy function, which is to form an omega-sequence (Cole 2015: 1118). In other words, mathematical structures are surrogates, characterized only by positions and relations, and thus metaphysically incomplete (Cole 2017: 11). Structuralism thus becomes, I would say, a necessary correlate of social constructivism, and non-arbitrariness can be characterized only up to structural isomorphism.

In a more recent paper, the scaffolding of mathematics is considered not only through different core surrogate functions but also through different degrees of non-arbitrariness: a social construction is constrained by collective agreements, but the strength of the constraint exerted by those collective agreements depends on their

degrees of codification and explicitness and on different levels of convergence on what follows from a given semantic content. The strongly constrained semantic objectivity of mathematics is explained by a greater symbolic codification of the collective agreements on which institutional mathematical entities are founded, on a greater convergence on the interpretation of the consequences of a semantic content, and on the applications considered as relevant in a particular context (Cole 2023: 10–11).

4 The Social Constitution of Mathematical Knowledge: Key Issues

Social ontology is a branch of metaphysics that investigates various objects of study – including social groups, institutions, language, artifacts, and artworks – the components of social things, and the way they are socially constituted. It investigates not only the grounding of social facts, i.e., their constituents – psychological states of individuals, actions, and practices – but also the anchoring of social facts, i.e., the sources of social constitution: attitudes, language, and causal patterns (Epstein 2018). When analyzing a social fact or institution, one can ask what it is made of, as in mathematics we ask what the features of the concept of number are, or one can ask what makes something a social fact, as in mathematics when we ask how humans came to determine or create numbers. This distinction can be fruitfully applied to mathematical knowledge in two ways. On the one hand, one might claim that social constitution of mathematics is aimed at anchoring and thus is a complementary approach to Platonism, which, being primarily concerned with ontological issues, is instead aimed at grounding. On the other hand, one could suggest a classification of the various theories of the social constitution of mathematical knowledge as based on different groundings: cognitive states, practices, or coordination rules.[27] Indeed, Cole's and Ferreirós's proposals are respectively based on intentionality and practice, as we will claim by analyzing the role of objectivity and semantics in Sects. 4.1 and 4.2, respectively. We will then suggest how axiomatics can be seen as a social institution anchored in coordination rules in Sect. 5.

4.1 Objectivity With or Without Objects?

Ferreirós analyses the objectivity of mathematical knowledge without reference to mathematical objects or rather as an explicit inquiry on objectivity without objects, a tradition he refers to Kreisel and Putnam (Ferreirós 2016: 9). Mathematical

[27] Epstein distinguishes three main kinds of grounding: (a) cognitive states, as in the theories of Searle and Levi-Strauss; (b) practices, considered as embodied routines in the social world combined with physical actions and symbolic systems (Bourdieu) or in the interaction with social environment (Giddens and Sewell); and (c) functions, as in Millikan and Boyd's theory (Epstein 2016: 245–246).

objectivity is granted by the cognitive intersubjectivity and the applicability of mathematical knowledge. This is achieved by abandoning the referential semantics and the correspondentist theory of truth that is usually assumed for natural language. Consequently, the semantics of mathematics differs from the semantics of natural language. It is not representational, in the sense that mathematical terms do not refer to objects existing outside our minds. Mathematical hypotheses have the peculiar characteristic of performing a constitutive and non-representational function, in the sense that they constitute or lay out a mathematical domain (Ferreirós 2016: 156). And yet for Ferreirós, Platonism remains an obligatory reference, insofar as he ends up explaining (especially in the article on Feferman) how a moderate Platonic theory, e.g., the theory of thin objects (Linnebo 2018), would turn out to be compatible with his own approach.

What constrains mathematical knowledge? First, how we are made, that is, certain biological and cognitive traits proper to the human species; second, certain fundamental technical activities, such as counting, measuring, etc.; and third, inferential relations between mathematical statements and between mathematical statements and those of other sciences. It clearly appears that there are different cores that contribute to objectivity, which therefore is not an all-or-nothing affair but something emerging by degrees and for that very reason modifiable and reformable.[28]

Objectivity does not mean certainty (even if elementary mathematics, as the theory of numbers, is certain): it is compatible with the hypothetical nature of mathematics (this holds at least for advanced mathematics). Certainty is conditional (due to proofs that transmit the certainty of the premises to conclusions) but is constrained from a strong form of intersubjectivity that limits the choice of new hypotheses (depending on related practices) (Ferreirós 2016: 159–160). Historical contingency, hypotheticity, and objectivity go along together, and there is no full autonomy of mathematical practices from other scientific practices: yet holism is sweetened by a pragmatist and cognitive flavor. The focus on agents is often obscured by the primacy accorded to the analysis of texts and thus of byproducts of an activity, rather than to the activity itself and the specific characteristics of agents. Objectivity is akin to what was formerly called progress, a necessary or rational development with respect to the historical change of practices and the involvement of historical agents in them. In this sense, Ferreiros' project could also be seen as a historical epistemology, as his reference to Cavaillès also confirms.

If Ferreirós characterizes his own approach as pragmatist in the practice-oriented sense, other authors take a pragmatist approach in a proper sense, inspired by Peirce's philosophy. Such is the case with Jessica Carter, who combines a structuralist approach with a form of pragmatist realism to explain the non-arbitrariness of mathematical knowledge. Although she assumes mathematical knowledge as an interrelationship of mathematical domains Jessica Carter seems specifically interested in explaining why many mathematicians are realists and take mathematical

[28] "Mathematics is not given a priori, but is the 'science that is sought' (to abuse words of Aristotle), constantly being reshaped and reconstructed." (Ferreirós 2016: 314).

utterances at their face value, when they speak of the existence of certain mathematical objects (Carter 2005). Combining the hypothetical nature of mathematics with a form of realism, Carter argues that mathematical hypotheses do not assert the existence of abstract entities, as in ontological realism, and yet are pragmatically real because the truth of mathematical propositions is pragmatically dependent on the validity of other utterances (and especially utterances about primary substances at some prior level). If fictionalism rightly suggests ways to talk about truth without stating that the discourse is about independently existing abstract objects (we can tell stories about such objects), yet the way mathematical objects are postulated is different, because the choice of new hypotheses is severely limited by previous methods, local and global concerns (the object of one story might interact with the objects of other stories), as well as the activity of reasoning itself (Carter 2023: 211–212). The pragmatist component is strong, and in fact Carter feels no need to justify the timelessness, or abstract nature of mathematical entities nor to guarantee a degree of objectivity to mathematical entities comparable to that offered by Platonism.[29]

Cole is mainly interested in the objectivity of mathematical objects, rather than in the objectivity of our knowledge about them. The starting point is opposed to that of Ferreirós. Cole's interest in objects has a twofold origin. On the one hand, it is driven by the analogy between mathematical objects and institutions. On the other hand, it is driven by the effort to answer a typical criticism against the lack of objectivity of mathematical objects considered as social constructions. Finally, it arises from the social ontology perspective, which aims, as the term "ontology" clearly indicates, to investigate the kind of objects that are socially construed.

Let's recall Searle's insistence on the priority of brute facts over social facts and compare it with the philosophy of mathematical practice. For Searle, every imposition of a status function requires something on which this function can be imposed, and even if it is itself a status function, one must necessarily arrive at a level where the imposition occurs on a brute fact. The question is whether in the philosophy of mathematical practice there is an analogous level of natural facts (objects that are counted, extended surfaces that are measured), which are regarded as logically prior to the concepts of number or measurement or not, and whether this leads, as in Searle's case, to a form of realism.[30] This is a point developed by Carter, who offers two reasons why mathematical objects differ from social constructions in Cole's sense: they are introduced to reason with them (and this holds not only for advanced

[29] On the analysis of the relationship between the practical turn in philosophy of mathematics and developments in pragmatism as a philosophical method, a topic we cannot develop here, see Heinzmann (2015).

[30] Of particular interest for a comparison with mathematics is Searle's claim that is possible to reiterate the imposition of status functions, affirming formulas in which *X* occurs as *Y* in some preceding formula: for example, when I affirm that "only a citizen of the United States can become President." Another point he makes – and that might be relevant in a perspective, like that of Ferreirós or Carter, based on an interplay of practices – is that the persistence of a social fact depends on the possibility of continuously reactivating not only a single social activity but also its interactions with other social activities (Searle 1995: 80–81).

mathematics but also for elementary mathematics) and "can be used to tell us something about the real world of physical phenomena." Carter offers a reformulation of Peirce's principle, claiming that "the reality of mathematical entities thus depends on the truth or validity of statements concerning a more primary substance" (Carter 2023: 212–213). Comparing Cole, Carter, and Searle's approaches, it becomes clearer why realism is considered a plausible option. All three theories seem to assume the existence of physical or brute facts as the starting point for the construction of mathematical facts. Besides, in all three authors, realism is not associated with Platonism but with structuralism, even if different versions of structuralism are in play.

Another element of interest is the link that Searle establishes between the relational nature of social facts and their being placeholders for patterns of activities and thus their being primarily processes and not products (in fact, a paper ticket is money only insofar as there is continual renewal of the activity that assigns to object *X* the role *Y*). I would like to make the point that in philosophy of mathematics, in general, it is not common to identify an explicit relationship between the reasons for a structuralist view and the reasons for holding that mathematical objects are social processes. But this survey may prove otherwise. Comparing Ferreirós's explanation of the mathematical concept of number as structurally connected to a network of interrelated practices, it becomes clear why several theories of mathematical practice focusing on the social constitution of mathematical facts tend toward a form of structuralism: they consider mathematical objects as the result of social processes, and social processes are structurally related through agents' interactions.

Despite this common proximity to structuralism, three different guiding ideas should be distinguished: naturalization, historicization, and normatization of mathematical practices and mathematical agents. Many attempts to explain the objectivity of mathematics without going through the objectivity of mathematical entities are anchored in human practices, which are themselves constrained by biological and cognitive features of agents (Ferreirós, Pantsar, Giardino), by semantic relations between utterances (Carter, Collin), by layered collective agreements in which each level produces constraints on subsequent levels (Cole), by the function of representing certain aspects of reality (Cole, Carter) or certain intersubjective practices (Ferreirós, Giardino), and by cultural and historical factors (Ferreirós, Hartimo, and Rytilä).

Markus Pantsar (2023) opts for an approach aimed at the naturalization of mathematical practice and appeals to empirical evidence. He claims that neither Cole's nor Ferreirós's account explains objectivity, but only biologically determined proto-arithmetical abilities can account for the intercultural stability of mathematics.

Valeria Giardino offers a good example of two different but complementary strategies for providing a normative framework for the philosophy of mathematical practice. The goal is to combine a primarily descriptive theory – Hutchins' distributed cognition – with a normative semantic theory: Brandom's inferentialism. Mathematics can thus be described not only as a symbolic human activity, distributed across a community of agents who interact with each other and with the environment, but also as a specifically symbolic activity based on an interplay of actions that give rise to a dialectic of entitlements and commitments in the game of

giving and asking for reasons (Giardino 2023: 261–264). Giardino takes naturalism as an inescapable starting point, at least insofar as it allows us to explain how human practices are anchored in cognitive attitudes common to other nonhuman animals and not necessarily linguistic. Mathematical reasoning is know-how, but it is not limited to giving and asking for reasons linguistically: it also includes the ability to manipulate material objects that serve as anchors for conceptual models (Giardino 2018a). While Ferreirós proposes a historicization of agents, Giardino simultaneously offers a naturalization and normatization of them.

The idea that Brandom's semantic inferentialism can be developed to account for mathematical facts as social facts is also developed by James Henry Collin (2023), who uses it primarily to explain the objectivity of mathematical knowledge. Collin proceeds very differently, however, because his goal is to show that semantic inferentialism, although it is based on norms and not on mental states, can account not only for the semantic content of utterances through inferential actions, for their subsentential components through substitution and anaphoric actions – as proposed by Brandom – but also for the way semantic content is socially instituted. There is normatization but no naturalization in Collin's view. Social facts and mathematical facts differ, because in the latter case, there is no physical object to which a normative status can be attributed. In mathematics this function is performed by the principles of abstraction, which play the role of rules of introduction and elimination. Collin thus succeeds in accounting for the abstract and objective nature of mathematics, without, however, presupposing the existence of abstract entities but rather accounting for the object-directedness of human discourse through human actions of deontic scorekeeping.

Mirja Hartimo and Jenni Rytilä make a different proposal, which combines a realistic conception of mathematical objects – viewed as independent of individual mathematical practices – with the idea that they are "internal to the sociohistorically generated mathematical practice." They combine a Husserlian phenomenological approach to the investigation of mathematical practice with theories on the social constitution of mathematical objects (Hartimo and Rytilä 2023). The phenomenological approach is aimed at capturing "the mathematicians' view of the purpose of their practices," but the latter, being exclusively internal to mathematical practice itself, is not sufficient to provide a complete picture of the ontology of mathematics, a picture that is then sought in the social construction of mathematical objects. They claim that the social constitution of mathematical practice not only explains the phenomenological appearance of the object as transcendent and separate but also accounts for the pluralistic view of phenomenology by considering historical and social factors that can explain the variety of methods used in mathematics.

4.2 A Representational or Non-representational Semantics?

Another point we would like to make is that three different trends emerge in the discussion of what is the semantics of mathematics. All three have to do not so much with grounding, to use an expression dear to Epstein, but with anchoring. What

explains how a certain term came to take on a certain meaning? For Cole it is clearly a form of collective intentionality; for inferentialism (Collin, Giardino) it is through mechanisms of anaphora, etc., that the meaning of terms is fixed in relation to the meaning of other terms; and for Ferreirós and Carter, intersubjective practices and mathematical domains interact with each other, giving rise to rules that constitute the meaning of mathematical terms themselves. One wonders, then, in which approaches mathematical utterances are really taken at face value and which approaches require a radical modification of semantics. To explain social facts as the result of collective intentional processes of imposing functions, Searle takes three elements as relevant: the imposition of functions, collective intentionality, and constitutive rules. As we will see in the brief survey that follows, these three elements are based on the key role of language and on a correspondentist semantics.

While Searle maintains a representationalist semantics for both linguistic terms denoting natural facts and linguistic terms denoting social facts, many philosophers of mathematics who explain the social constitution of mathematical knowledge rely on a non-correspondentist semantics and do not necessarily speak of social facts (see, e.g., inferentialist semantics above). Cole expands Thomasson's semantics, ensuring that objects falling under a given concept are determined by the coapplication and application criteria related to representational functions. The semantic content is determined by the functions imposed on social entities (or rather collective agreements – e.g., on what is a number and on what land mass is the territory of the United States – are partially responsible for the truth value of the statement). However, thanks to the notion of surrogate introduced in later writings, Cole also accounts for the origin of a representational semantics (based on objects and properties), which can be justified and retained for mathematical language.

Ferreirós aims at granting objectivity to mathematical knowledge without grounding it on mathematical objects and explicitly assumes that mathematical language, unlike natural language, has a non-referential semantics, where terms constitute rather than represent objects: mathematical hypotheses are "constitutive and not representational, in the sense that they constitute or lay out a mathematical domain" (Ferreiros 2016: 156). Yet, it is not strictly necessary to oppose natural language and mathematical language: adopting the Brandomian theory of semantic inferentialism, Collin (2023) adopts the same semantics for natural language and mathematical language, focusing on an activity rather than an object domain. If, however, in Ferreirós the focus is on activities that may also be prelinguistic, such as counting, measuring, etc., in Collin all activities are linguistic. One question that remains open is to what extent naturalization and historicization are necessary to account for all prelinguistic aspects – including not only different varieties of iconicity (Giardino and Greenberg 2015; Schlimm 2021) but also different types of manipulation with artifacts, who seem to be excluded from exclusively normative approaches.

Although the positions of the different authors mentioned above differ in their choice of the most appropriate semantics for mathematics, authors such as Searle or Cole, who base the social constitution of mathematical facts on mental states, tend to maintain a representationalist semantics. In contrast, authors who seek to take into

account cultural and historical factors and interrelated mathematical practices seem more sensitive to the need to formulate a non-representationalist semantics for mathematics.

5 Axiomatics as a Social Mathematical Practice

The goal of Feferman's paper was to explain why and in what formulation the continuum problem can be considered as a definite statement (i.e., liable to be true or false). In answering this question, it seems to us that Feferman also implicitly brought to the table a new challenge to understanding mathematical practice in social perspective: what can be the role of axiomatics in socially constituted mathematical knowledge? If language or at least symbolic activity seems to be essential in all the authors discussed, it would be interesting to see if it is possible to develop a different analysis of axiomatics – often considered the quintessential mathematical formal activity – an analysis in which neither language nor symbolization occupies the stage, but the notions of rule and function come to the forefront.

Axiomatics as the adoption of a method based on the distinction between propositions assumed without proof and propositions in need of a proof has been regarded as one of the leading activities of mathematicians at least from Euclid's *Elements* onward, even if the role and meaning of axiomatics changed with time. Axiomatics is nowadays often considered to be the main aim of formal logic, a way to demarcate formal from social sciences, and especially a means to justify or ground the truth of the former. What we want to understand in this section is whether axiomatic objects (axioms, theorems, rules of inference) are described differently when studied as the result of intersubjective practices.[31] Analyzing axiomatics as a social institution, does it suggest new roles for axiomatics alongside the justificatory one?

Recent literature has shown that axiomatics need not only have a justificatory role but might have a variety of objectives. Sieg distinguished between formal and structural axiomatics in Hilbert's works (Sieg 2014). Schlimm (2013: 39) distinguished a descriptive from a normative function and claimed that the same set of axioms can be employed in different roles (semantic or syntactic). Cantù (2022: 6–12) suggested a variety of objectives of axiomatics: heuristics, conceptual analysis, quest for rigor, modular analysis, coordination tool, and descriptive, genetic-historical, architectural, and pedagogical aim. Ferreirós distinguished between a

[31] First, one might ask why one should use the tools of social ontology to investigate axiomatics in logic and mathematics. The chosen ontology might have consequences on the kind of problems and puzzles one must solve in the development of a given science. Taking axiomatics to be a method or a system is not the same as taking it to be a mode of discourse or symbolic order; an informal institution based on norms, conventions, customs, laws, organizations, groups, and roles; or an entity sustained in existence by collective recognition and serving status functions. The explanation of axiomatics' persistence in time has been partly investigated by an analysis of the function of the axiomatic method, and eventually of its changes in time, but has not been related to an analysis of its specific constituents.

formal-logical side to axiomatics, attentive to the inferential structure of a theory, and a conceptual-mathematical side, aiming to make new connections in mathematics (Ferreirós 2022b). In the survey of the philosophies of mathematical practices centered on the social constitution of mathematical knowledge and objects, formal and informal axiomatics played the role of adding constraints on the arbitrariness of social constructions. For example, axiomatic symbolization added further degrees of codification in Cole, making the objectivity of mathematics more robust. So, in a sense, axiomatics was regarded primarily as a symbolic activity, and its role appeared to be mainly related to increasing mathematical objectivity, and thus, at least in a broad sense, as a justificatory activity. The question is whether considering axiomatics in light of a different theory of social ontology, one that does not presuppose language and intentionality as key elements, might lead to different results.

The question is whether the philosophy of mathematical practice, framed in a normative framework such as that of Guala's rather than Searle's social ontology, (a) explains the intersubjective and social origin of axiomatics and (b) accounts for it as the result of human interactions producing rules, obligations, and coordination functions.

There are some very simple problems of coordination that axiomatics facilitates: (a) it avoids proving the same theorem again; (b) it offers a common framework to compare different proofs of the same theorem; (c) it facilitates the interaction and the coordination between different researchers, research teams, and research projects in the proof of new results; and (d) it helps organizing scattered results in a whole. Axiomatics – as the social institutions studied by Hindriks and Guala (2015) – induces several obligations, which are independent from selfish desires, but probably not from any desire whatsoever. Examples of general obligations are consistency (it is undesirable that a statement and its negation are axioms or theorems of a system) and completeness in Hilbert's geometrical sense (it is desirable that the axiom system has an adequate level of generality). Examples of specific norms are logical rules (the quantifiers introduction and elimination rules, the modus ponens, the argument by transitivity) and some specific rules such as the law of induction in arithmetic. Yet, axiomatics should have other constituents than functions, obligations, and rules in order to be a social institution: social agents and social roles.

Let's briefly consider two examples. One is Lorenzen's dialogical logic and the other is Peano's *Formulario*.

In Lorenzen's logic, and more generally in dialogical logic (Hintikka's game-theoretic approach is another good example)[32], the truth of an elementary sentence is nothing else but the willingness of an expert and rational interlocutor to accept that the predicate holds for a given object. Similarly, the truth of a complex sentence is determined by a dialogue in which each participant has a specific role, that of proponent or that of opponent, and each role is in turn determined and specified

[32] Even if Lorenzen's operative approach is non-axiomatic, it is "compatible with the axiomatic approach in its non-fundamentalist interpretation" (Heinzmann 2021: 15).

by a set of rules, some of them being logical (determining the meaning of logical constants as their possible use in a dialogue) and some of them being rather dialogical (the proponent starts talking, then participants have the word in turn; the proponent must defend only the last assertion made by the opponent, whereas the opponent has to defend all her assertions, because she can assert elementary sentences, whereas the proponent cannot). Logical and dialogical rules are thus abstraction of roles played by people (nowadays also by computer agents). What is said here about logic can be extended to argumentation theory, where the roles of the participants in a dialogue are regulated by less rigid norms, some of which might be conventions, habits, and actions for which people have incentives, because they often obtain general acceptance (argument by analogy, appeal to the expert opinion).[33]

Teaching and education offer other interesting examples of how axiomatics, and the logics on which it is based, are taught and developed in school, thanks to targeted incentives that reward students who better apply the logical and argumentation rules (see the rating grid items, which usually include logical structuring, logical formulation, or logical order as key competences). Further examples can be driven from mathematics education, e.g., the independency of a system of axioms, which is sometimes considered as a rule in formal axiomatic systems (an axiom should not be a theorem that can be inferred from the other axioms), but is certainly not a rule in teaching, where theorems that are too long or difficult to prove with respect to the level of the students are simply assumed as postulates. Further rules and roles emerge from recent investigations of proofs as planning activities (see, e.g., Bratman 2013, Hamami and Morris 2020a) and from inferentialist analyses of language (see, e.g., Brandom 1998 and Collin 2023).

I come now to a second example: Peano's *Formulario*, i.e., an interactive enterprise aiming at constructing a logico-mathematical dictionary that should contain all sentences used in logic and mathematics. The enterprise was at the same time descriptive and prescriptive. Peano published a call for contributions in his journal *Revue des Mathématiques*, asking readers and researchers to contribute to the project (see Peano 1892: 76). Peano held the idea that one should not enumerate a list of derivation rules, but rather first collect all sentences written in mathematical language, order them in axiomatic form, and then investigate the derivation rules thereby used (Cantù 2022).[34] This anatomic investigation underlines how rules come out of mathematical practices and techniques, because they bring some advantage to the coordination, organization, and division of labor. Vailati, for example, considered the normativity of mathematical logic as based in its increased efficiency in the achievement of mathematical results, even if the costs required by the substitution of

[33] A good example is Walton's *New Dialectic* (1998).

[34] Similarly, Otto Hölder (1924) considers that mathematical logic should be a normative logical theory that is derived from the investigation of mathematics itself, as in Lambert's unachieved anatomy of mathematics.

old equipment with new might for some time counterbalance it, just as the change of machinery is a costly way to rationalize production (Arrighi et al. 2010: xlvii).

To summarize, axiomatics can be viewed as based on several abstract roles: proponent and opponent in a dialogue logic, axiom and theorem in an axiomatic system. Instead of considering axioms and theorems, or claims and counterclaims as sentences, they are considered as dialectic roles codified by sets of rules and strategic moves obtained by generalization of behavioral rules of human participants in an argumentative game.[35] Axiomatics can be conceived as an institution along the lines of Guala's social theory: institutions are not the result of some act of collective acceptance that assign them status functions, but rather the result of a coordination device, whose rules need not be constitutive in Searle's sense. Axiomatics need not play a justificatory role but can be viewed as a coordination tool. Indeed, there are several behavioral rules in mathematics that can hardly be defined or explained according to justificatory criteria. For example, simplicity, be it syntactic, semantic, or epistemic parsimony, has been analyzed both as a virtue of axiomatic theories and as a virtue of mathematicians (Inglis and Aberdein 2015; Aberdein et al. 2021) but might profit from an analysis as social strategy.

6 Conclusion

The philosophy of mathematical practice investigates the social constitution of mathematics but does not always make explicit the philosophical-normative framework that guides the discussion. This chapter investigated some recent proposals in the philosophy of mathematical practice that compare social facts and mathematical objects, discussing similarities and differences. An attempt has been made to enucleate, through a comparison with different perspectives in social ontology, the kind of objectivity attributed to mathematical knowledge, the type of representational or non-representational semantics adopted, and the justificatory or coordinative role entrusted to axiomatics. After a brief introduction to key issues in social ontology, Sect. 3 of the chapter offered a survey of contributions by Feferman, Lorenzen, Ferreirós, and Cole, highlighting a difference between approaches based on rules, practices, and intentional states. Section 4.1 also discussed results by Carter, Giardino, Pantsar, and Collin, focusing on differences between the objectivity of knowledge and objectivity of objects and showing that many authors combine a realist, structuralist, and pragmatist perspective, as well as the idea that objectivity comes in degrees. Section 4.2 focused on the kind of semantics that is adopted in socially oriented approaches. A representational semantics is preferred by authors grounding their views on mental states, whereas a non-representational semantics best fits with views based on practices. Section 5 considered how axiomatics can be understood in a social perspective. Axiomatics generally plays

[35] For a historical and philosophical survey of dialogical logic and argumentation theory, see Cantù and Testa (2006). On dialogical deduction see Dutilh Novaes (2020).

a justificatory role also in theories that aim to explain the social constitution of mathematical knowledge. Yet, if one shifts from approaches based on mental states and practices to one anchored on rules, axiomatics can be viewed as an institution based on rules, obligations, functions, coordination problems, and agent's actions and roles, thus playing an organizational and coordination role.

This chapter can in no way be regarded as an exhaustive survey of the new results that bridges between social ontology and mathematical practice could lead to. Interesting research directions that we could not discuss here include (1) the role of intentionality, language, and rules but also of epistemology in the constitution of mathematical social objectivity;[36] (2) an inquiry of collective agency and planification;[37] (3) different ways of analyzing mathematical agents: through a naturalization of mathematical practice that requires the study of cognitive and epistemic abilities of agents, through a historical and comparative study of the development of mathematical abilities in different cultures, or through a normative approach, which considers agents as dialectical roles; (4) a comparison between the symbolic and diagrammatic dimensions of mathematics and social theories studying the origin of human artifacts;[38] (5) a comparison between experimental approaches to mathematics and experimental methodologies in use in social disciplines;[39] (6) whether there is a distinct place assigned to mathematical kinds within the distinction between natural and social kinds when building a bridge between social ontology and mathematical practice;[40] (7) whether intersubjective mathematical objectivity is necessarily connected to a structuralist position or can be compatible with Platonism, logicism, intuitionism, and naturalism; (8) whether axiomatic knowledge can be explained without reference to mathematical structures as abstract objects, given that the objectivity of mathematical knowledge can be explained without reference to mathematical objects; and (9) whether there would be any difference in grounding intersubjective mathematical objectivity on intentions (phenomenological, planned, or shared intentions), on rules, or on habits.

Acknowledgments I would like to thank Italo Testa, because without our discussions the project of comparing social ontology and mathematical practice would never have come into being, and also the institutions that made it possible to organize two workshops on the topic (the Faculty of Arts at the University of Aix-Marseille and the Department of Humanities at the University of Parma), the participants in these workshops, two referees very generous with valuable advice, and numerous colleagues (especially Dirk Schlimm and Jessica Carter) who carefully read a preliminary version of this chapter.

Abstract

Paying attention to the inner workings of mathematicians has led to a proliferation of new themes in the philosophy of mathematics. Several of these have to do with epistemology. Philosophers of mathematical practice, however, have not (yet) systematically engaged with general (analytic) epistemology. To be sure, there are some exceptions, but they are few and far between. In this chapter, I offer an explanation of why this might be the case and show how the situation could be remedied. I contend that it is only by conceiving the knowing subject(s) as embodied, fallible, and embedded in a specific context (along the lines of what has been done within social and feminist epistemology) that we can pursue an epistemology of mathematics sensitive to actual mathematical practice. I further suggest that this reconception of the knowing subject(s) does not force us to abandon the traditional framework of epistemology in which knowledge requires

justified true belief. It does, however, lead to a fallible conception of mathematical justification that, among other things, makes Gettier cases possible. This shows that topics considered to be far removed from the interests of philosophers of mathematical practice might reveal to be relevant to them.

Mathematical justification · Mathematical practice · Social epistemology · Feminist epistemology

1 Introduction

In a first analysis, it might seem that contemporary analytic epistemology[1] cannot be fruitfully applied to the philosophy of mathemtical practice. In this chapter, I suggest that this first impression is wrong-headed and that a systematic exchange between the two disciplines would be fruitful.[2]

Applying epistemology to mathematical practice might be thought as problematic for two reasons. First, the standard apparatus of general epistemology, in which (propositional) knowledge involves justification, truth, and belief, has been deemed to be overly narrow for capturing interesting features of mathematical practice.[3] Second, the application of epistemology to mathematics has been traditionally guided by the desire to eliminate the knowing subject as much as possible in order to get an objective, logical analysis of mathematical knowledge. Ideally, the resulting analysis would then be independent of actual mathematical practice.[4]

Although they might appear to be unrelated, these two reasons are connected. As I shall explain, it is only by reconceiving the knowing subject(s) of mathematics as embodied, fallible subjects embedded in specific mathematical contexts that the traditional analysis of knowledge (appropriately developed along the lines traced by social and feminist epistemologists) can be fruitfully applied to mathematical practice.

Let me start with some platitudes about general epistemology to bring out why its application to mathematical practice might seem uncalled for. The almost exclusive focus of epistemologists is directed toward *propositional attitudes,* that is, attitudes like *believing* and *knowing* that are related to propositions. Beliefs attach to propositions,

[1] Throughout the chapter, I will use *epistemology* to mean *analytic epistemology*. This clarification is needed in a context like the one of the present volume, which assembles heterogenous contributions belonging to different traditions. As I use the term, analytic epistemology is the theory of knowledge (and justification) in the analytic philosophical tradition of the Anglo-American world – a very different topic compared, for example, with *épistémologie* in the French tradition, which has to do with the critical and historical study of science and scientific knowledge.

[2] To be sure, there are significant exchanges already, albeit not systematic ones – I will turn to some of those in the conclusion. See, for example, Azzouni (2006), Easwaran (2015), and Tanswell and Kidd (2020).

[3] Lakatos (1976), Kitcher (1984), and Ferreirós (2016).

[4] See, for example, the discussion in Kitcher (1992).

and propositional knowledge is *knowledge that* such-and-such is the case, where this such-and-such is a proposition. Typical questions are: When is a belief that p (where p is a proposition) justified? When does it constitute knowledge? This seemingly innocuous starting point already clashes with a widespread commitment of philosophers interested in scientific and mathematical practice. This commitment is voiced explicitly by Reviel Netz in the context of his analysis of ancient Greek geometry:

> [W]hat unites a scientific community need not be a set of beliefs. Shared beliefs are much less common than shared practices. This will tend to be the case in general, because shared beliefs require shared practices, but not vice versa. [. . .] Whatever is an object of belief, whatever is verbalisable, will become visible to the practitioners. What you believe, you will sooner or later discuss; and what you discuss, especially in a cultural setting similar to the Greek, you will sooner or later debate. But the real undebated, and in a sense undebatable, aspect of any scientific enterprise is its non-verbal practices. (Netz 1999, 2)

Being verbalizable, the objects of belief can be thought of as corresponding to sentences, which can be associated with propositions. But non-verbal practices, says Netz, must also be taken into account if we want to paint an accurate picture of scientific inquiries. It is safe to say that Netz's commitment can be associated with a widespread view among philosophers interested in mathematical practice, namely, that mathematical knowledge cannot be reduced to the knowledge of propositions alone.[5] Accordingly, all forms of knowledge should be considered, including *knowing how* to do something. The epistemologists' analysis is then seen as overly narrow and in need of broadening up beyond propositional attitudes.[6]

This point is well taken. Still, accepting that beliefs (and other mental states that take propositions as their content) are insufficient to accurately describe scientific or mathematical practices does not force us to marginalize them. We can still think of them as *central* to scientific practices. Indeed, this aligns with a practice-oriented tradition in the philosophy of science and mathematics – it will be enough to refer to Thomas Kuhn's (1962) description of scientific paradigms and Philip Kitcher's (1984) analysis of mathematical practices. More recently, José Ferreirós (2016) emphasized the importance of going beyond propositional attitudes to understand mathematical practices but admitted that "[m]athematics, as we understand it, is not just practical knowledge but has at its core theoretical knowledge" (Ferreirós 2016, 30). This theoretical knowledge, I submit, can be cashed out in propositional form. And in fact, according to Ferreirós, it is always possible, albeit in some cases just in retrospect, to associate a mathematical practice with a particular mathematical *theory* (*ibid.* 29).

The above considerations show that the fact that epistemology is almost exclusively focused on propositional attitudes does not thereby preclude its application to mathematical practice. What is more, recent efforts in epistemology are bringing into

[5] This view is explicitly endorsed in Ferreirós (2016) and implicitly assumed in a plethora of works, such as the ones discussing (like Netz's) the roles of diagrams and notations in mathematics; see, for example (Chemla 2018; Manders 2008).

[6] Thanks to Gisele Secco whose criticism helped me realize the importance of this issue.

focus the analysis of *knowing how* and assessing the hypothesis that it is not always reducible to propositional knowledge, or *knowing that*.[7] These efforts could contribute to a better understanding of what unites scientific practices besides shared beliefs, to use Netz's expression in the quotation above. That is, philosophers of mathematical practice could take advantage of the tools developed to talk about knowledge how in general and apply them to their preferred domain.

The first obstruction to the application of epistemology to the study of mathematical practice is thus cleared. This much will suffice to convince the reader, I hope, that the traditional focus on propositional attitudes should not be a reason for philosophers of mathematical practice to brush aside epistemology. But this is by no means the sole obstruction.

Philosophers of mathematical practice might also be dissatisfied with how epistemology developed. Here is a cartoon version of the story. Going way back to Plato's *Theaetetus*, (propositional) knowledge has been thought of as something like justified true belief. And then, in the 1960s, Gettier (1963) came around and showed that justification, truth, and belief are not jointly sufficient for knowledge. This is because there are cases in which a subject is justified in believing a true proposition, but the proper connection between justification and truth is severed by some sort of epistemic luck that is incompatible with knowledge.

Suppose that I am justified in believing the proposition <Valeria is in Paris>. I am therefore justified in believing <Valeria is in Paris or p> for any proposition p since this is a simple logical consequence of <Valeria is in Paris>.[8] Therefore, even if I have no justification for believing that Valeria has a car, I am justified to believe proposition q = <Valeria is in Paris or she has a car>. As it turns out, unbeknown to me, Valeria just bought a new car and drove to Barcelona with it. In this case, q turns out to be true, but not for the reason I thought. I believe q, I am justified in believing in q, and q is true. But something has gone awry. I do not know q. Gettier cases like this one are cases in which a subject holds a justified true belief that does not constitute knowledge because some type of luck is at play.

For a while, after Gettier's publication in 1964, epistemologists set out to find an elusive fourth condition for knowledge. This new enterprise, however, did eventually stall. Many epistemologists decided to let go of knowledge to focus exclusively on justification. Others took knowledge as a primitive notion.[9]

The problem is that Gettier cases seem to be utterly irrelevant to mathematics. Even setting aside the vexed issue of how we should conceive the truth of mathematical propositions, Gettier cases seem to be impossible in mathematics because justification in mathematics has been traditionally associated with proofs, and these entail their conclusion, leaving no gap between justification and truth – at least if we

[7] See, for example J.A. Carter and Pritchard (2015), Bengson and Moffett (2011), and Habgood-Coote (2019).

[8] Note that this "or" is inclusive. It is the standard disjunctive connective of classical logic: "A or B" is true unless both A and B are false.

[9] This lead to *knowledge first* approaches in epistemology; see Williamson (2000).

take mathematical propositions to be conditional on their premises (i.e., the axioms). Moreover, mathematical propositions are necessary, and thus it is unclear how epistemic luck could enter the picture.

Furthermore, several of the analyses of knowledge developed by epistemologists after Gettier did explicitly exclude mathematical knowledge. For one, Alvin Goldman's causal theory of knowledge is designed to apply to empirical beliefs exclusively.[10] And this is not considered to be a problem at all:

> My concern will be with knowledge of empirical propositions only, since I think that the traditional analysis is adequate for knowledge of nonempirical truths. (Goldman 1967, 357)

The causal theory was then replaced by *reliabilism* (Goldman 1979). Very roughly, this view says that a belief is justified if and only if it is produced by a reliable belief-producing process. Reliabilism applies to mathematics, but it is not immediately clear how it can help us with the specificities of *mathematical* justification, especially if this is connected with the notion of proof. This is because it delivers an overly idealized account of mathematical beliefs based on proofs. Since the premises of genuine proofs entail their conclusions, it is plausible to think that beliefs justified by genuine proofs will be produced by an ideally reliable process. But this is certainly not what happens in practice. A broadly reliabilist framework could, however, be used to paint a faithful picture of mathematical practice. However, to do that, we would have to move away from an infallible conception of mathematical justification and begin to explain how our belief-forming processes at play in mathematical practice are in fact reliable, even if not ideally reliable – for an effort in that direction, see Avigad (2021).

Other attempts to characterize knowledge invoke modal notions (e.g., sensitivity and safety) to get at some sort of robustness that is intuitively peculiar to knowledge. Modal notions do not, however, apply to necessary truths in non-trivial ways.[11]

This cartoon story makes it clear that the concerns of general epistemologists do not meet the ones of philosophers of mathematics, let alone the ones of philosophers of mathematical practice. What is more, in the background of many epistemological discussions about knowledge lurked the problem of skepticism. How can we revindicate the fact that we know most things we think we know? Like that we have hands, that water is H_2O, or that Trenton is the capital of New Jersey. And here, too, the focus is on ordinary beliefs rather than mathematical beliefs.[12]

One strategy to show that epistemology still has something to offer to philosophers of mathematical practice is to observe that there are other topics besides the mainstream ones. I mentioned already recent efforts toward the analysis of

[10] It is therefore somewhat bizarre that the famous *problem of access to abstract objects* originally formulated in Benacerraf (1973) involved Goldman's causal theory of knowledge (more on this later).

[11] There are ways to apply them to mathematics, however. See, for example, Clarke-Doane (2020).

[12] This has not always been the case. For instance, Descartes's most radical form of skepticism involved mathematical beliefs, but these do not feature in most contemporary discussions.

knowledge how. I will later indicate a few other such themes. My main goal, however, is to suggest something stronger. Namely, that even these traditional topics that seem so far from the concerns of a practice-oriented philosophy of mathematics could be applied to it. Among other things, I will draw on previous work (De Toffoli 2021a, 2022) to show that Gettier cases are indeed possible in mathematics, and that thinking about them can be instructive to philosophers of mathematical practice. Gettier cases, I will indicate, arise when we substitute the traditional infallible notion of mathematical justification associated with proofs with a fallible counterpart. This substitution is natural when we put at the center of our epistemological inquiry fallible human subjects rather than highly idealized ones.

Summing up, it is not hard to explain why it seems that mathematics is not relevant to general epistemology. Moreover, when epistemology has been applied to mathematics, it is not the mathematics that philosophers of mathematical practice seek to investigate – but rather a mathematics conceived as a realm of necessary truths, the knowledge of which can be gained a priori. To my mind, this gives a plausible (if only partial) answer to why the philosophy of mathematical practice and epistemology have been overlooking each other, with just a few (but notable) exceptions. I want to suggest that it is time for a change. My goal here is to prepare the terrain for further work at the intersection of the philosophy of mathematical practice and epistemology by showing that we can fruitfully think about mathematical practice by adopting long-established epistemological frameworks.

Here is the plan for the chapter. Section 2, which is the bulk of the chapter, is devoted to exploring how to characterize the knowing subject(s) if we want to pursue a successful epistemology of mathematical practice. I will indicate some points of contact with the characterization of the subjects by social and feminist epistemologists. In Sect. 3, I turn to the traditional analysis of knowledge and discuss how it can be applied to mathematics. I build on previous work (De Toffoli 2021a) to sketch a fallibilist account of mathematical justification that makes it plausible to think that Gettier cases could arise in this context. I then sum up the discussion and point to further epistemological themes relevant to mathematical practice.

2 With or Without Subjects?

I start my analysis of the knowing subject(s) by discussing how the epistemology of mathematics (and of science more generally) has been conceived by Karl Popper and others as an enterprise aimed at the study of "knowledge in the objective sense" in which subjects do not figure at all. Afterward, I consider how highly idealized subjects entered the picture. I then sketch a different type of subject: a fallible subject whose rationality is bounded. It is only with this type of subject in mind that we can pursue a *human* epistemology of mathematics. But in order for this epistemology to be tethered to actual practice, subjects should not be considered in isolation but connected with other subjects and embedded in a specific mathematical context. I then explore the possibility of indexing knowledge to groups rather than to individuals – as has been done by some social epistemologists. I also consider how this

reconception of the knowing subject(s) could bring philosophers of mathematical practice close to feminist epistemologists. I wind up the section by canvassing the importance of conceiving epistemic subjects as not entirely passive, but as active members of specific mathematical practices.

2.1 The Epistemology Without a Subject

Descartes, Locke, and Hume are illustrious among the so-called *belief-philosophers*. This is a label introduced by Popper to describe those philosophers that are "interested in our subjective beliefs, and their basis or origin" (1968, 334). According to Popper, epistemology is a theory of scientific knowledge in which the knowing subject plays no role:

> Knowledge in the objective sense is knowledge without a knower: it is knowledge without a knowing subject. (Popper 1968, 335)

In Popper's view, there are three worlds. The world of material objects, the world of subjective ideas, and a third world, which is the world of *objective contents of thought*. Driven by a similar motivation of separating subjective ideas from objective non-material items, Frege had already introduced a *third realm*.[13]

General epistemology – to be clear, the one pursued by belief-philosophers such as Descartes and later by analytic epistemologists – focuses on the second world and, according to Popper, should be reclassified as psychology or sociology, being utterly irrelevant to his conception of epistemology, which refers exclusively to the third world. According to him, epistemology relates to items such as scientific problems, conjectures, and theories. These items are created by human animals but, most importantly, are *autonomous*. Crucially, Popper's objective knowledge is not constrained by the cognitive abilities of any subject. Indeed, it even includes pieces of knowledge that no human subject will ever acquire.

Why was Popper so adamant in rejecting the knowing subject? It is because he wanted, like Frege before him, to shun *subjectivism* at all costs.[14] In Frege's case, the threat was *psychologism*,[15] and what had to be saved was mathematics. Frege assumed that *ideas* (i.e., things belonging to the second realm) would inevitably vary between subjects. If mathematical entities were ideas, then we would be forced

[13] Frege's third realm, however, differently from Popper's third world, only accommodates necessary immutable truths, leaving out the laws of science.

[14] As Susan Haack (1979) explains, it is not trivial to pin down the exact locus of the negative feature of the type of subjectivism Popper had in mind. First, the objective/subjective dichotomy can be conceived in several different ways. Second, the notion of *intersubjectivity* can be placed in between, thus leaving the dichotomy to give space to something more nuanced.

[15] For an analysis of the reasons (some of which are institutional in nature) why psychologism started to be conceived as a major sin in the German philosophy departments of the beginning of the twentieth century, see Kusch (1995).

to distinguish, for example, between *my* Pythagorean theorem and *your* Pythagorean theorem. But that is absurd.[16] Popper's worries have a similar flavor.

Popper's attitude toward epistemology is not unique to him. It is endorsed by other players in the twentieth-century philosophical landscape. The "epistemology without a subject," as Ferreirós (2016, 11) labels it, found fertile ground in the realm of mathematics, which, after all, was where Frege's inquiries took place. In France, Jean Cavaillès (1937, 1938) developed a philosophy of mathematics focused on concepts, rather than on subjects.[17]

Focusing on mathematics is congenial to an epistemology without a subject because mathematics is prima facie a realm of necessary truths that admit indefeasible justification.[18] After all, it is reasonable to think that we could not be wrong that $1 + 1 = 2$. This infallibility indicates that there are no relevant individual differences in mathematics. The main assumption of philosophers of mathematics was that mathematical justification (and knowledge) is underwritten by proofs, which were conceived as deductions from axioms. The focus thus was to justify mathematical theories rather than mathematical beliefs. The epistemology without a subject ignored individual beliefs and the inner working of mathematics and focused on very general issues.[19]

If the application of epistemology to mathematics led to an *epistemology without a subject*, it is not surprising that philosophers of mathematical practice felt the need to look elsewhere for philosophical inspiration. But this is not the end of the story. Besides efforts toward the justification of mathematical theories, in the second half of the twentieth century, philosophers of mathematics started tackling different epistemological issues. And this time, subjects were needed. The problem, however, is that these subjects, as we are about to see, were too idealized to be taken as the subjects of inquiry for a philosophy of mathematical practice.

2.2 Ideal Rationality

In 1973, Benacerraf published what would become one of the most influential papers in the philosophy of mathematics of the twentieth century, "Mathematical Truth" (1973). The paper poses a dilemma. If mathematics is, as it seems to be, about mathematical objects, and if mathematical objects are abstract, then how is knowledge of such objects possible at all? A quandary arises from combining a view of mathematical objects as not spatiotemporally located (and thus causally inert) with

[16] To be sure, this is a simplification. Frege critique of psychologism is sophisticated and developed across multiple works.

[17] See Sinaceur (2019).

[18] And in fact, the most virulent form of psychologism, against which Frege's criticism were levelled, arises from the application of psychology to logic and mathematics.

[19] Think, for example, about conventionalism and Quine's holistic empiricism. For an elaboration on these ideas, see De Toffoli (2021a).

the causal theory of knowledge. *Benacerraf's dilemma*, as it is now commonly referred to, has generated a massive amount of scholarship. The causal theory of knowledge is surpassed by subtler alternatives, but Benacerraf's dilemma has proven to be robust with respect to different epistemological theories of knowledge.

Benacerraf's dilemma has to do with individual knowledge, and thus it introduces individual subjects into the epistemology of mathematics. But the problem it raises is very general and has to do with metaphysical considerations that practicing mathematicians are generally oblivious to. From such a general vantage point, the knowledge that 2 is a prime number poses no more and no fewer problems than the knowledge of Fermat's Last Theorem. This is because Benacerraf's dilemma focuses exclusively on our knowledge of mathematical objects *in general*. In other words, the type of discussion of mathematical knowledge it generates does not require considering any sophisticated mathematics at all.

What is more, mathematical reasoning is not relevant at all to Benacerraf's type of questions. The only propositions that matter for such an epistemological inquiry are the starting points. Given the axioms, the rest follows unproblematically by means of deductions, or so the story goes. That is, given the axioms, we can infallibly know all the rest of mathematics by proofs. If there is a fallibilist component at all in our justification of mathematical facts, it is relegated to our beliefs about the axioms. Any other type of fallibility would have to do with human (in)competence. It should be borne in mind that nobody denies that we are fallible and at times make mistakes – what is rejected is that such fallibility is of any interest in the epistemology of mathematics.

These considerations do not square with a philosophy of mathematics interested in mathematical practice. Mathematicians seldom concern themselves with the axioms and are generally indifferent to the choice of a particular formal system.[20] More crucially still, the subjects for which only the starting points matter are logical omniscient subjects.

Note that although it is ill-advised to study mathematical practice by conceiving subjects as logically omniscient, this is not the case for other domains. In the context of formal epistemology, it is perfectly suitable:

> [I]n many standard applications of the Bayesian machinery, the assumption [of logical omniscence] is natural. Suppose, for instance, we're trying to use it to decide between two hypotheses about the chance with which a coin will land heads when it is tossed. [. . .] In this case, logical omniscience tells us that we must be certain that, if the coin didn't land heads on the first toss, it landed tails; it tells us to be at least as confident that it landed heads on the first toss as we are that it landed heads on the first two tosses; and so on. In these cases, logical omniscience seems a reasonable requirement. And it was such cases where Bayesianism first found application. (Pettigrew 2021, 9992)

In cases such as the one described in the quote above, it is plausible to think that we are forced to assign the same probability to all logically equivalent propositions, on pain of irrationality. And then, Richard Pettigrew explains, it is natural to extend

[20] See Burgess (2015, 145) illuminating discussion of different types of *indifference* in mathematical practice.

further such a requirement. Logical omniscience is a requirement that arises from the Dutch Book Arguments, which govern the norms that regulate rational credences and were developed by Frank P. Ramsey and Bruno de Finetti.

But even in the context of Bayesian epistemology, logical omniscience can become a *problem* since it clashes with our ordinary judgments of rationality. And in fact, there are several attempts to *solve* the problem of logical omniscience and to apply formal epistemology to logical learning and other cases of bounded rationality.[21] But these efforts have not considered in detail sophisticated mathematics, which arguably is the main target of study for philosophers of mathematical practice.

2.3 Non-Ideal Rationality

If logical omniscience is a requirement of rationality, it is not a very useful one to evaluate the epistemic achievements and falls of *human* subjects. Nobody would be able to pass the bar. As David Christensen (2004) explains:

> When we call someone "irrational," we are saying that he is deficient *relative to a contextually appropriate standard*, which need not be—and typically is not—the standard of absolute rational perfection. (152, *emphasis added*)

Developing *contextually appropriate standards* allows us to distinguish between different types of failures. One thing is a careful mathematician who makes a subtle mistake. An entirely different case is the one of an absent-minded mathematician who comes up with a bogus proof for some result or another. As Daniel Greco and Brian Hedden (2016) explain:

> [I]t is important to distinguish being irrational in the sense of falling short of the rational ideal from being irrational in the sense of being less rational than (most of) the rest of us. (3677)

The type of rationality we are concerned with when analyzing mathematical practice is *non-ideal,* and it is going to be indexed to a particular mathematical context. The challenge is then to focus on specific mathematical practices and spell out the context-dependent norms that regulate such practices. And this is perfectly in line with a philosophy of mathematics interested in mathematical practice.

As a matter of fact, several works produced by philosophers of mathematical practice can be understood as a reply to such an epistemological challenge. As a way of example, consider the multiple studies on diagrams in mathematics. Albeit focusing on different practices and endorsing different methodologies, most of these studies aim at unveiling the (often implicit) norms governing the use of diagrams in different contexts. For example, there is ample literature discussing the epistemic role of diagrams in Euclidean geometry and the way in which their use was regulated (Netz 1999; Manders 2008; Macbeth 2010; Panza 2012). Diagrams from other historical practices have been considered as well – in this regard, the work

[21] For a recent endeavor in that direction, see Pettigrew (2021).

of Karine Chemla (2018) on diagrams in ancient Chinese mathematics is a prime example. Examples of studies considering diagrams in contemporary mathematics are Carter (2019), De Toffoli and Giardino (2014), and De Toffoli (2023).

These studies put at the center of their inquiry fallible, limited subjects with a specific cognitive makeup and inhabiting particular contexts. It is precisely because of their cognitive shortcomings that representational choices (such as the ones to use diagrams) are relevant in practice.

2.4 Social Epistemology

Putting at the center of epistemological inquiries non-ideal subjects embedded in a specific mathematical practice obliges us to look at the social dimension of mathematics. In point of fact, contrary to the romantic image of the mathematician working in isolation, most members of a mathematical practice interact systematically with each other and with the broader mathematical community. It is for this reason that the epistemic norms at play in mathematics present a social dimension.

For instance, what counts as a proof is not fixed once and for all: what is acceptable in one context might not be acceptable in another. This does not mean that we must renounce to a context-independent notion of logical validity, but that arguments put forward as proofs cannot be evaluated independently from the audience to which they are addressed. By way of example, in topology but not in other branches of mathematics, arguments involving sequences of visualizations might be acceptable as proofs.[22]

Moreover, it has been pointed out that some of the norms governing justification in mathematics guarantee the possibility of the mathematical community to perform a self-monitoring activity on the results it produces, thus aiding single mathematicians to overcome their individual limitations.[23] These considerations point to the fact that to paint a faithful picture of mathematical practice, the social dimension of mathematics should be considered. To do so, it is possible to import into the philosophy of mathematics some of the tools that have been developed by social epistemologists.

There are already some efforts in this direction. For example, Kenny Easwaran (2009) has argued that proofs should be *transferable* – that is, roughly, that they should convince the relevant experts of their correctness without any appeal to testimony.[24] He then explains:

> Philosophers of mathematics have long focused on individual epistemic norms for mathematics, and deductive logic has been very useful in helping to understand these norms.

[22] See De Toffoli (2021b).

[23] See Easwaran (2009) and De Toffoli (2021a).

[24] In my view, transferability can also be understood in terms of the a priori – given a minimal, fallible conception of a priori justification. In this volume, Danielle Macbeth (2021, 13) also connects transferability to the a priori: "The proof is, as it is sometimes put, "transferable" (Easwaran 2009). Indeed, it is in just this sense that mathematical knowledge is a priori: It is a priori not because it is infallible but because and insofar as it does not rely on empirical evidence, whether that of one's own senses or that given on the testimony of another."

> However, transferability is a social norm—it can help the community develop a better grasp on the knowledge of its members, even though it may not have any advantages for the individual considered in isolation. (Easwaran 2009, 356–357)

Although general epistemology has traditionally focused on individual subjects in isolation, social epistemology is growing very rapidly. This is a branch of epistemology that puts particular emphasis on the fact that the subjects under inquiry are embedded in specific social contexts.

Sanford Goldberg (2018) ventured so far as to trace the very source of epistemic normativity to our social nature. In his view, interacting with others has many benefits, but it also puts us in a vulnerable position. That is why we are entitled to require specific standards of the doxastic lives of others – and these entitlements give rise to the normativity of epistemological notions such as justification and knowledge. His proposal applies to beliefs in general, but it would be worth considering how it could be modulated in specific for the mathematical case.

One respect in which social epistemology could be applied to the study of mathematical practice is the following. Social epistemologists are not only interested in how social norms and social contexts do influence epistemic notions such as individual justification and knowledge, but also in how such notions *themselves* can be indexed to a plurality of subjects. This suggestion could be evaluated and tested by considering specific cases from the practice of mathematics. For example, several proposals have been put forward on how to characterize group beliefs (Gilbert 2004; Lackey 2016, 2020). The literature can be broadly divided into two camps: the one formed by those who endorse an *inflationary* approach and the one formed by those defending a *deflationary* approach. Briefly, according to the latter but not to the former, group beliefs are reduced to the beliefs of the members of the group.

Looking at the social structure of mathematics could offer important data in support of one or the other position. More specifically, contemporary mathematics offers us examples in which it is helpful to think of groups of practitioners themselves, rather than individual mathematicians, as epistemic subjects. *Big proofs*, that is, proofs that are not within reach of a single mathematician, are an ever more common phenomenon in contemporary mathematics – besides computer-assisted proofs, prime examples of big proofs are proofs that involve large collaborations. A famous example of the latter is the proof (or the multiple proofs) of the theorem of the classification of finite simple groups.[25] Focusing on such a case or similar ones could, for instance, be used to evaluate and support the inflationary approach to justified group belief.

2.5 Feminist Epistemology

I started this section by surveying the *epistemology without a subject* and, passing through an epistemology considering logical omniscient subjects, I ended with the consideration of fallible, limited subjects inhabiting specific contexts. I then suggested that subjects are better conceived as entertaining systematic relations with each other

[25] See Habgood-Coote and Tanswell (2021).

rather than as operating in isolation. Finally, I indicated that, in some cases, it might even be useful to think of multiple subjects rather than individuals as the relevant subject to which to index belief, justification, and knowledge.

Moving from a very abstract and disembodied way of thinking about the epistemology of mathematics to a more concrete and embedded way is in line with the methodological guidelines of feminist epistemology. And, in fact, I want to suggest that the philosophy of mathematical practice and the epistemology approaches that are most suitable for it share some joint tenets with feminist epistemology.

To be sure, feminist epistemology is a cluster of heterogenous views rather than a unified position.[26] Notwithstanding the great variety among the particular theories, they all share some core commitments. As Helen Longino (1998) has emphasized, one of such core commitments is to put at the center of investigation non-ideal subjects situated in a specific context:

> The shift from a transcendent and disembodied subject to empirical, embodied, and differentiated subjects is often represented as a loss, encouraging a representation of the aspects of situatedness as interfering with knowledge or cognitive access. [. . .] however, we might better think of them as focusing devices, or cognitive resources, directing our attention to features of that which we seek to know that we would otherwise overlook. (335)

Indeed, as I have suggested, without this de-idealization of the knowing subject(s), it would be impossible to appreciate the epistemic norms governing actual mathematical practice.

Longino also individuates another aspect that unites feminist approaches to epistemology: the consideration of social factors. Subjects are often considered to be interdependent. In her words,

> One further consequence of acknowledging the embodied character of knowers that feminists have explored is the dependence or interdependence of knowers. (*ibid.,* 335)

The methodology of feminist epistemologists is thus seen to converge with the one of social epistemologists.

It is therefore clear that an epistemology suitable to the study of mathematical practice conceives of the knowing subject(s) in a way that is in line with how these subject(s) are conceived within feminist epistemology. This is not surprising. After all, some of the feminist approaches, like Longino's own approach,[27] emerge precisely from what can be called the *practice turn in the philosophy of science*[28] – a trend that started well before[29] the *practice turn in the philosophy of mathematics*.[30]

[26] See Garavaso (2018).

[27] See Longino (2002).

[28] See, for example, Soler et al. (2014).

[29] Its beginning could be pinned to Kuhn's (1962) influential work on scientific revolutions; later on, emphasis on practice was prominent among historians and sociologists of science.

[30] Although there are important precursor, like (Lakatos 1976), the philosophy of mathematical practice took off much later. See, for example, Mancosu (2008).

2.6 Subjects or Agents?

Before moving on to the analysis of knowledge, I want to address a last issue on the nature of epistemic subjects. Ferreirós favors talking of *agents* rather than *subjects*. Although I share some of Ferreirós's motivations, I will take sides against his proposal.

Ferreirós strives to emphasize the active nature of mathematicians producing and sharing knowledge in a specific mathematical practice. The problem is that etymologically, "subject" has a passive connotation ("sub-jacere": to throw under). In his words:

> I dare say that the *oblivion of action* was the worst defect of traditional epistemology, its main shortcoming that, in my view, has made impossible a well-grounded account of human knowledge. Even perception, which modern philosophers from Descartes and Locke onward understood as a passive reception of impressions, is in the light of neurobiology and cognitive science a complex system that results from the interplay of sensory input and motor output (not anything like a primitive faculty of the mind, as philosophers tended to think). Input and output, sensation and action–without this feedback, one cannot even make sense of perception, let alone the further complexities of knowledge production. (11)

I agree with Ferreirós that traditionally epistemic subjects have been conceived of as entirely passive – and that this is ill-suited to study mathematical practice. However, naturalized epistemologists do nowadays consider the lessons of cognitive science and are aware of the important feedback between sensory input and motor action. Moreover, epistemologists that are sympathetic to the embodied cognition movements and its cognates are certainly happy to consider the subjects of epistemology as embodied. As we saw, this is also one of the main tenets of feminist epistemology:

> One of the consistent themes running through the feminist rethinking of the subject of knowledge is the insistence on its embodiment. (Longino 1998)

Still, there is an important sense in which the *agents of ethics* and the *subjects of epistemology* are better kept separate. What we believe is not *up to us* in the same way as what we do. This is clear for perception: most of my perceptual beliefs are formed without conscious deliberations. Trivially, I might influence what my perceptual beliefs are by controlling what sensory stimuli I expose myself to. For instance, if I turn my head right and keep my eyes open, which I can control, I will inevitably see out of the window and form the belief that the sun is shining. There might also be other forms of indirect control. However, even for reflective beliefs such as mathematical beliefs, it is plausible to think that they often result automatically from exposure to the relevant evidence.[31] There are various positions in the doxastic voluntarism debate that indicate several ways in which we might be

[31] For instance, this would be in line with Kornblith (2012).

able to have some kind of control over our beliefs,[32] but they generally take for granted the difference between belief and action.

When I go through a proof, and I understand it, or when I read a compelling argument, I cannot help but form a belief.[33] There is no direct choice there. But action is different. If I see a child drowning in a pond, I can choose between saving him and ruining my beautiful Italian boots or watching him drowning and preserving the boots.[34]

Crucially, saying that belief and action are different in this respect does not entail that we cannot talk about normative notions and responsibility in epistemology. To be sure, we can still talk about justified and unjustified beliefs. Moreover, there is a substantive body of literature on how we can be considered responsible for our beliefs – and the *ethics of beliefs* is a sub-field in epistemology that has grown exponentially in the last few years.[35]

There is yet another sense in which the subjects of epistemology can be conceived as active. Namely, the status of *being justified* may be connected to the *activity of justifying*. As Ferreirós notes, this can be traced to the tradition of the American pragmatists and goes against what Adam Leite (2004) calls the "Spectatorial Conception," which he characterizes as follows:[36]

> The fundamental idea shared by these views is that being justified is something which happens to you. According to these theories, the justificatory status of a person's belief is determined by certain facts which obtain prior to and independently of the activity of justifying. The activity itself plays no role in determining justificatory status; it is simply a secondary and optional matter of attempting to determine and report, as far as is conversationally necessary, the prior and independent facts which determine the justificatory status of one's belief. Consequently, even if things go badly wrong in the course of the activity, that will not determine one's actual justificatory status. On this conception, one stands in a primarily theoretical or epistemic relation to the justificatory status of one's beliefs: positive justificatory status is something which one finds out about, not something which one brings about. I therefore call this view the Spectatorial Conception. (222)

Leite proposes an alternative account in which the *basing relation*, that is, the relationship that exists between a belief based on a reason and the reason on which it is based, is something that can be described in terms of the activity of justifying. This is another example of how a traditional epistemological debate, the one about the nature of the basing relation, can be applied to a philosophy of mathematical practice – and how in turn considering mathematical practice could bring the debate forward. For instance, in De Toffoli (2021a), I proposed an account of the basing relation for

[32] See, for example, Hieronymi (2006).

[33] Note that such a belief might not be an unqualified belief in the conclusion of the proof but can be the conditional belief that the conclusion is implied by the (explicit or implicit) premises.

[34] The example is adapted from the classic Singer (1972).

[35] See Chignell (2018).

[36] This is also related to John Dewey's critique to traditional epistemology according to which the subject of knowledge, like the classical subject of perception, is passive.

mathematics that is in line with Leite's and that puts the emphasis on our ability to provide reasons for our beliefs rather than on their causal origin.

Let's take stock. I agree with Ferreirós that appropriate subjects of an epistemology of mathematics taking the practice seriously should be considered as embodied and situated in a particular context. I further agree that they should be conceived as active members of their communities. Still, I prefer to keep in line with the tradition and call them epistemic *subjects* merely to emphasize that the focus of our inquiry is belief rather than action – which, to be sure, are interrelated.

Having discussed how epistemic subjects can be characterized, we can turn to the traditional analysis of knowledge and evaluate whether it can be fruitfully applied to mathematical practice.

3 The Analysis of Knowledge

In general epistemology, it is common to deploy formulas beginning with "S knows that p. . ." We now have a sense of how to conceive of the subject S. Rather than a disembodied, highly idealized subject in a vacuum, our subject will either be a fallible and embodied subject embedded in a social context or be a group of such subjects.

And then? After "S knows that p. . ." we can satisfy ourselves with an "only if" rather than an "if and only if." Gettier's lesson was precisely that justified true belief is necessary but not sufficient for knowledge. We have: "S knows that p only if p is true, S believes p, and S's belief that p is justified." More schematically:

$$\text{Knowledge} => \text{Justification} + \text{Truth} + \text{Belief}$$

If a subject knows that p, then she believes p. The *belief condition* is the least controversial. Moreover, it is plausible to think that if it presents problems at all, these are not peculiar to mathematics. For this reason, I will set it aside.

The other components require some discussion. The fact that propositional knowledge is knowledge of a true proposition is taken for granted by epistemologists. However, there are reasons to think that this is a non-starter for a philosophy of mathematical practice. I will address this point before turning to an account of justification that allows for Gettier cases in mathematics.

For reasons of space, it is not possible for me to go beyond these necessary conditions and discuss a full analysis of knowledge. I leave the topic for further work. However, let me just briefly list three promising strategies that can be deployed to develop an account of knowledge that fits mathematical practice. One is to tweak modal notions (such as safety or sensitivity) so that they can be applied to necessary truths.[37] A second option is to deploy the virtue epistemology machinery developed by Ernest Sosa (2007).[38] A third approach (which is compatible with the

[37] Some steps in this directions have been taken in (Clarke-Doane 2020).

[38] See Tanswell (2016).

second) is to go knowledge-first. Following Timothy Williamson (2000), the idea here is to take knowledge as a primitive notion and explain justification in terms of it rather than the other way around – note that although Williamson and other proponents of the knowledge-fist approach are infallibilist about justification (and thus in my view their theories can hardly be applied to analyze mathematical practice), fallibilist knowledge-first theories of justification have been developed as well.[39]

Let us then turn to the truth and justification conditions for knowledge.

3.1 True Propositions

If knowledge requires justified true belief, it must be knowledge of true propositions. I have already discussed in the introduction that to analyze a scientific practice, it might not be enough to consider beliefs exclusively. Beliefs play, however, a central role in any practice that has a theoretical orientation.

In the tradition of Robert Stalnaker (1976), propositions have been coarsely identified using the semantics of possible worlds. A proposition can be conceived as the set of possible worlds where it is true. But this implies that there is just one necessary proposition. David Lewis (1996) is explicit about this point:

> What I choose to call 'propositions' are individuated coarsely, by necessary equivalence. For instance, there is only one necessary proposition. (551)

But plausibly mathematical propositions are necessary propositions. And if there is just one mathematical true proposition, then propositional knowledge in mathematics will be quite uninteresting since it won't even be possible to differentiate our knowledge of different mathematical propositions. Lewis continues:

> So the necessary proposition is known always and everywhere. Yet this known proposition may go unrecognised when presented in impenetrable linguistic disguise, say as the proposition that every even number is the sum of two primes.[40] Likewise, the known proposition that I have two hands may go unrecognised when presented as the proposition that the number of my hands is the least number n such that every even number is the sum of n primes. [. . .] These problems of disguise shall not concern us here. Our topic is modal, not hyperintensional, epistemology. (*ibid.*, 552)

It is clear, however, that the problem of disguise must concern us *here*. And in fact, we need to individuate propositional content in a finer way to talk about mathematics at all! This problem should not be, however, a roadblock but a challenge to overcome. Several methods are available. One option is to index beliefs

[39] See, for example, Silva (2022).

[40] Actually, the Goldbach conjecture says that every even number *larger than 2* is the sum of two primes.

to sentences rather than to propositions.[41] Another is to adopt one of the strategies that have been developed under the label of *hyperintensionality*.[42]

Besides problems arising from the very conception of propositions, another issue concerns talking about *truth* in mathematics. Here is Ferreirós (2016) on the matter:

> From the time of the ancient Greeks, with their definition of knowledge as "justified true belief," to the twentieth century under the influence of denotational semantics, it has been common to consider mathematics as a body of truths (otherwise, it is felt, there couldn't be knowledge of them). Math has been regarded as the discipline that provides justifications of the strongest kind, namely deductive proofs. But what are mathematical truths true of? (6–7)

Let us bracket the claim about justification (to which I will return shortly) and focus on truth. To dodge the question "what are mathematical truths true of?" and avoid talking about truth altogether, Ferreirós completely abandons the classical analysis of knowledge. He prefers to focus on objectivity instead of truth.[43] I agree with him that concentrating on objectivity rather than truth is better suited to studying mathematical practice. "The problem," as Kreisel famously put it, "is not the existence of mathematical objects, but the objectivity of mathematical statements."[44]

However, I want to indicate here that we are not forced to abandon the traditional analysis of knowledge (that has at its center the notion of true propositions) altogether. The issue is massive; in this context, I just want to suggest that talking about true mathematical propositions could be applied even to Ferreirós's own account of mathematics, or something in line with it, anyway.

Ferreirós asks, "what are mathematical truths true of?" It is plausible to think that mathematical truths are truths about mathematical objects. This reflects Benacerraf's (1973) desideratum (shared by many philosophers of mathematics) of having a homogeneous semantics between mathematical and non-mathematical discourse. How we conceive of these objects is another matter, however. Moreover, there are alternatives to this simple answer. As a way of example, consider Geoffrey Hellman's (1989) modal structuralism. In his view, mathematical truths are about possible systems of objects that exemplify structures. In his words:

> [O]rdinary mathematical statements are construed as elliptical for hypothetical statements as to what would hold in any structure of the appropriate type [. . .] Absolute reference to mathematical objects is eliminated entirely. (53)

Hellman's position is inspired by Hilary Putnam's (1967) seminal (and controversial) paper "Mathematics Without Foundations," in which the author claims that

[41] This is done in Pettigrew (2021).

[42] See, for example, Berto and Nolan (2021).

[43] A similar approach can be (and has been) adopted with respect to science. See for example the discussion in Bird (2010).

[44] Reported in Dummett (1978, xxviii).

it is possible to give two different interpretations of the same mathematical fact: platonistic or modal.

We can endorse our favorite position in the ontology of mathematics – we can be platonists or nominalists, or neither of them.[45] We can adopt a structuralist strategy and think of mathematical objects as positions in abstract structures. This should not, however, force upon us a specific epistemology of mathematics. However, it is true that some metaphysical views may rule out certain epistemologies. For example, some versions of fictionalism take mathematical statements like "2 is a prime number" at face value to be false because they are about objects that do not exist.

Another relevant consideration is that, looking at the practice, it is often natural to focus on *conditional* mathematical propositions. Although traditional inquiries in the epistemology of mathematics have been focused on our knowledge of axioms, from the perspective of the working mathematician, the truth of axioms is seldom addressed.[46] What matters the most from a practice-based perspective is whether certain premises entail certain conclusions.[47]

When we consider mathematical knowledge in practice, we think about mathematicians producing correct proofs for some mathematical proposition. We have a pretty good logical story to understand what *correct* means[48] – although this story might not be readily applied to the practice.[49] It is then plausible to think that mathematical knowledge does not require a commitment to the absolute truth of the axioms we use to prove our theorems, but only a commitment to the correctness of our proofs.

In contemporary mathematics, it is often accepted that mathematical proofs are supposed to establish that their conclusions are true *if* their premises are true. Moreover, when investigating certain domains, it is common practice to discharge certain premises. In Euclidean geometry, when we talk about a theorem T, such as the Angle Sum Theorem, our real conclusion is not the stated conclusion of T, but rather: *in any Euclidean plane*, T.[50] Obviously, the same stated conclusion would not be a truth of hyperbolic geometry. Nowadays, everybody accepts that both Euclidean and non-Euclidean geometry are legitimate mathematical domains, and that we can know geometrical truths.

Thinking of mathematical propositions (or at least some of them) as conditional on the axioms is indeed Ferreirós' preferred approach. He offers a *hypothetical*

[45] See, for example, Burgess (1983).

[46] There are exceptions, however. Sometimes the truth of certain axioms (such as the axiom of choice) is debated by practicing mathematicians.

[47] This is in line with Peirce's view of mathematics. According to him, in deductive reasoning we start from an "hypothetical state of things and are led to conclude that, however it may be with the universe in other respects, wherever and whenever the hypothesis may be realized, something else not explicitly supposed in that hypothesis will be true invariably" (1998, 212).

[48] Even though this story is not universally accepted. For example, it is criticized by constructivist mathematicians. This unveils other instances (in this case linked to intuitionism) in which metaphysical positions can indeed lead one to endorse particular epistemological views.

[49] See Avigad (2021).

[50] To be sure, this holds nowadays, not of the historical practice.

conception of advanced mathematics[51] in which the axioms are only conditionally accepted. In so doing, he indexes truth to specific theories:

> My use of the word 'truth' at this point must be relativized by implicit or explicit reference to a mathematical theory. (Ferreirós 2016, 8)

It is because of this relativization that Ferreirós claims that it is advisable to talk of objectivity rather than truth – but this is no roadblock to understanding even mathematical knowledge in terms of true propositions.[52,53] And indeed Ferreirós himself does not renounce to such talk:

> I shall try to provide a strong account of how we arrive at–and share–mathematical truths, without invoking mathematical objects in any strong ontological sense. (*ibid.*)

Crucially, endorsing Ferreirós's hypothetical view, we do not have to postulate the existence of any mathematical object in a strong ontological sense. This is because rather than *describing* a given mathematical domain, axioms would *constitute* it. A final note on the hypothetical view proposed by Ferreirós is in order. It should not be conflated with a simple form of *if-thenism* in mathematics because, in his view, not all hypotheses are on a par – in short, this is explained by Ferreirós appealing to the internal relationships of different mathematical practices as well as to the relationships of mathematical practices with scientific and technical ones. It is by observing the close connection of mathematics with science and even technical practices (from the elementary ones of counting and measuring) that we can explain the non-arbitrariness of mathematics.

Let me also note *en passant* that talking about truth in mathematics does not need to parallel talking about truth in other contexts. Alethic pluralists contend that there are different ways of being true, which are appropriate to different domains of discourse.[54] For our concerns, it suffices to note that what truth amounts to in mathematics might not be the same compared to what truth amounts to when we talk about ordinary objects such as chairs and tables. For instance, while a correspondence theory of truth might be attractive for the latter, for the former, a coherence theory of truth might be more appropriate.[55] Moreover, there could be ways of modulating the same theory in different domains. For example, in her

[51] It is worth noting that he proposes a different account for elementary mathematics.

[52] Interesting similarities could perhaps be drawn from Putnam's *internal realism*, but Ferreirós does not discuss them.

[53] Ironically, Justin Clarke-Done (2020) uses examples similar to the ones by Ferreirós to argue for mathematical realism and *against* mathematical objectivity. In his view, an objective question admits a single answer. He uses the case of non-Euclidean geometry precisely to highlight the non-objective character of mathematics. Although there is much more to be said about this, for reasons of space I have to postpone the discussion to another time.

[54] To be sure, this claim can be interpreted in many ways – see Pedersen and Wright (2018).

[55] A coherence notion of truth for mathematics is developed by Crispin Wright (1992, 1999). For a detailed discussion on how to apply Wright's ideas to mathematics, see (S. Shapiro 2007).

investigations on logic, Gila Sher (2016) has argued in favor of the correspondence theory of truth. In her view, however, what this view amounts to changes in different contexts – she explicitly considers the case of mathematics.

How we should understand truth in mathematics raises monumental questions that I cannot even start to discuss. But I do not need to do so in this context. My aim was just to indicate that Ferrerirós's own proposal contains the resources needed to apply the traditional analysis of knowledge to mathematics. More generally, the suggestion here is that the epistemology of mathematics – especially an epistemology that aims at understanding mathematics as it is actually practiced – can be (mostly) separated from the metaphysics of mathematics.

Let us then turn to the notion of justification.

3.2 Justification

"Math has been regarded as the discipline that provides justifications of the strongest kind, namely deductive proofs," says Ferreirós. It is for this reason that Gettier cases are generally thought to be impossible in mathematics:

> [I]n general epistemology Gettier cases typically involve instances in which S's justification for p is understood to either *proceed through false assumptions* (as in Gettier's original examples) or be such that it is only "by luck" that it delivers a true belief (as in Goldman's Barn County example[56]). *The former issue is ruled out in the mathematical setting in virtue of the fact that a correct mathematical proof cannot proceed through false lemmas* (and that the presence of such fallacious steps can be decided by examining the structure of PROOF itself – a feature which is not true in the case, e.g., of perceptual evidence). And the latter is ruled out in the mathematical setting because the counterfactual dimension of the relevant notion of "luck" (e.g. that S happened to be looking at the one genuine barn in the field as opposed to a fake one in a nearby world) has no clear mathematical analog.[57] (Dean and Kurokawa 2014, 207, *emphasis added*)

In previous work (2021a), focusing on mathematical propositions conditional on axioms, I argued that there is a plausible account of mathematical justification according to which correct mathematical proofs are not the only arguments that provide mathematical justification – even excluding non-deductive methods. In my view, flawed arguments that look like proofs to the relevant practitioners may confer justification as well. Endorsing a fallibilist account of mathematical justification opens the possibility of Gettier cases arising in mathematics, at least those cases involving false assumptions.

To be sure, in the literature, different forms of mathematical fallibilism have been proposed – many authors have focused on how we justify axioms and urged us to leave behind the idea that they are self-evident. For one, Kurt Gödel (1964) himself

[56] This example is actually due to Carl Ginet.

[57] I changed the notation for the subject and the proposition to make it coherent with the one adopted in the rest of the chapter.

was explicit in claiming that some axioms could be justified only *extrinsically* in terms of their consequences. But as I mentioned in the previous section, it is natural for the philosophers of mathematical practice to focus on mathematical propositions other than axioms.

Imre Lakatos (1976) has linked his fallibilism to the quasi-empirical nature of mathematics and to the fluidity of mathematical concepts. However, the type of fallibilism proposed here is different than Lakatos' because it applies straightforwardly to contemporary mathematics as well, not only to the history of mathematics. Rather than deriving from the open-ended nature of mathematical concepts, it originates from our human inability to get things right 100% of the time.

If the subjects at the center of our inquiry are fallible and have limited resources, then it is reasonable to think that justification in general is not factive, that is, that a subject can be justified in holding a false belief or in holding a true belief for wrong reasons. Mathematical justification should be no exception.

Roughly, in my account, whether a subject is justified is not just a matter of logic but hangs on social considerations as well: arguments that are in line with a community's good inferential practices but that contain subtle mistakes may confer justification. In my terminology, these are *simil-proofs*:

> (SIMIL-PROOF) An argument is a Simil-Proof (SP) when it is shareable, and some agents who have judged all its parts to be correct as a result of checking accept it as a proof. Moreover, the argument broadly satisfies the standards of acceptability of the mathematical community to which it is addressed. (De Toffoli 2021a, 835)

Of course, this is a general proposal that needs to be specified in a case-by-case manner. For instance, we should be able to determine what the standards of acceptability of a mathematical community are. However, it is a start toward a fallibilist account of mathematical justification.

It is worth stressing that claiming that mathematical justification is not merely a matter of logic but depends on social and cognitive factors does not force us into some sort of relativism. There is a fact of the matter whether a simil-proof is a genuine proof or not, but we might not be able to establish this fact at a given time – and a notion of mathematical justification that is faithful to actual mathematical practice should be sensitive to it.

That justification is fallible means that there is a gap between justification and truth. Linda Zagzebiski (1994) showed that when this is the case, we can always construct Gettier cases. Analyzing such cases can give us special insight into mathematical practice because it leads us to the consideration of putative proofs that were accepted by the mathematical community for a time and were later deemed to be inadequate. One such example is Kempe's original proof of the 4-color conjecture – it was first published in 1879 and only found wanting 11 years later.[58] Another is Dehn's Lemma:

[58] See the discussion in De Toffoli (2022).

> (DEHN) In 1910 Max Dehn published an argument for what is now called Dehn's Lemma. In 1929 Hellmuth Kneser discovered that Dehn's argument contained a significant gap and thus that the lemma has not been proved (although it had been used as a premise to prove many other results). It was only in 1957 that Christos Papakyriakopoulos published a proof of it. (De Toffoli 2021a, 837)

It is my contention that Dehn was initially justified in believing his result. He had a justified true belief that did not amount to knowledge. Moreover, in the years in which Dehn's simil-proof was accepted by the mathematical community, it would have been perfectly fine in some contexts to use his lemma to establish other results. And this could lead to additional Gettier cases in which a subject is justified in believing a result, the result is true, but the justification is somewhat disconnected from its truth. In these cases, the subject's justification would proceed through false assumptions.

Building on these ideas, Neil Barton (manuscript) has argued that there are different kinds of Gettier cases in mathematics. Besides cases analogous to the one mentioned, Barton also discusses how Gettier cases arise with respect to our beliefs in axioms. In so doing, he builds on a more general conception of mathematical justification, one that does not apply only to conditional mathematical propositions but to axioms as well.

In light of these considerations, it is fair to say that the possibility of Gettier cases in mathematics was dismissed too quickly. And this in turn shows that even traditional concerns of epistemology, which seem so remote from mathematical practice, can be relevant to it.

4 Conclusion

Although the interests of epistemologists and of philosophers of mathematical practice might seem to be disjoint, they are not. I discussed the issue at a very general level.

To sum up, in order to fruitfully apply epistemology to the philosophy of mathematical practice, we have to reconceive the epistemic subjects along lines that have already been traced by social and feminist epistemologists.[59] The subjects at the center of our epistemological theorizing should be embodied, fallible, and embedded in a specific mathematical context. Bringing down the level of idealization at play for the knowing subjects leads us naturally to a fallibilist view of mathematical justification. This, in turn, opens the door to Gettier cases, which, contrary to what one might expect, can be of interest to philosophers of mathematical practice. This is a signal that other unexpected points of contact between the two disciplines could be found.

Moreover, I also stressed that epistemological concerns are better kept separate from metaphysical ones. It is my contention that we can pursue an analysis of

[59] Other relevant approaches in epistemology are ones inspired by the embodied cognition research program, broadly understood to include embedded, enactive, and extended cognition (Shapiro and Spaulding 2021).

mathematical knowledge, even within the traditional epistemological framework, without having to endorse any specific position in the metaphysics of mathematics.

Let me end by listing some specific themes in epistemology that are directly relevant to the philosophy of mathematical practice – themes that I could not discuss for reasons of space. I mentioned that the traditional focus on individual propositional knowledge could be broadened to include different forms of social knowledge as well as an analysis of knowledge how. Moreover, I alluded to the fact that the case of mathematics could be used to inquire about the nature of the basing relation – the relationship that holds between a belief and the reasons on which it is based. There are many other themes in epistemology that have already been applied, or that could be applied to the study of mathematical practice. Here are a few examples: epistemic defeaters (Easwaran 2015), themes in virtue epistemology (Aberdein et al. 2021), epistemic injustice (Rittberg et al. 2020), and disagreement (Aberdein 2023; De Toffoli and Fontanari 2023).

My goal was to lay the ground for more such specific applications and therefore to indirectly encourage them. More generally, I hope that clarifying how we should reconceive the epistemological subject(s) if we want to pursue an inquiry about justification and knowledge in mathematics that is faithful to the practice will dispel some skepticism with respect to the application of epistemology to the philosophy of mathematical practice.

Abstract

A characteristic feature of the philosophy of mathematical practice is to attend to what people do when they do mathematics. But what does it mean to *do* mathematics? This question raises several issues regarding the nature of action, activity, and agency in mathematical practice. The present chapter reviews contributions in the field that have attempted to theorize about these notions. It begins with some motivations for taking agents seriously in the philosophical study of mathematical practice. The core of the chapter discusses, in turn, what it means to carry out mathematical activities, do things with mathematical artifacts, engage with mathematical proofs, and perform mathematical actions prescribed by mathematical texts. Taken together, the various lines of work reported here provide an initial, but already sophisticated, picture of what it means to do mathematics. The chapter ends with some suggestions for future research on agency in mathematical practice.

1 Introduction

Mathematics is something that people do, from the research mathematician trying to prove Goldbach's conjecture to the student in elementary school working on her mathematics homework. But what does it mean to *do* mathematics? One may expect philosophical accounts of the nature of mathematics to provide some clues on this question. And yet, as Kenneth Manders remarked: "[c]urrent philosophical conceptions of mathematics are predominantly agentless" (Manders 2008, p. 118). Paradigmatic examples are the main developments in the foundations of mathematics where the objects of study are the notions of mathematical theories, proofs, and computations. The branches of mathematical logic investigating these notions – model theory, proof theory, and recursion theory – do not usually require appealing to agents doing things.[1] The same observation can be made for most philosophical theorizing on the nature of mathematical objects and mathematical truths.[2] The situation seems different for epistemological considerations aiming to explain how we can possess mathematical knowledge, since knowledge needs to be attributed to an epistemic subject.[3] But here again, it is easy to set aside considerations on actions, activities, and agency and to only focus on the conditions that need to be met to attribute knowledge to an epistemic subject, without describing what a subject needs to do to acquire such knowledge in the first place.

One way the philosophy of mathematical practice[4] departs from traditional approaches in the philosophy of mathematics is precisely by taking into consideration the *active* dimension of mathematics, i.e., by attending to what people *do* when they do mathematics. This has become a leitmotif in describing the field, for instance:

> The focus has turned thus to a consideration of what mathematicians are actually doing when they produce mathematics. [. . .] These historians and philosophers agree that there is more to understanding mathematics than a study of its logical structure and put much emphasis on mathematical activity as a human activity. (Mancosu et al. 2005, p. 1)

[1] Notable exceptions are logicians that take into account the active dimension of deductive inference, e.g., Frege (1879), Gentzen (1934), Prawitz (1965), and Martin-Löf (1984).

[2] Here again, there are exceptions, for instance, works from the precursors of the philosophy of mathematical practice – e.g., Wilder (1950), Lakatos (1976), and Kitcher (1984). Also, philosophical views that take mathematical objects and facts as being the result of social constructions – e.g., Hersh (1997), Feferman (2009), and Cole (2013) – may implicitly or explicitly appeal to mathematical agents. On social construction and constitution in mathematics, see the chapter by Cantù in this handbook (Cantù 2023).

[3] On the conceptualization of epistemic subjects in the context of mathematics, see the chapter by De Toffoli in this handbook (De Toffoli 2023).

[4] For recent overviews of the field, see Carter (2019) and Hamami and Morris (2020).

> The philosophy of mathematics has experienced a renewal in recent years due to a more open and interdisciplinary way of asking and answering questions. Traditional philosophical concerns about the nature of mathematical objects and the epistemology of mathematics are combined and fructified with the study of a wide variety of issues about the way mathematics is done, evaluated, and applied [. . .]. (Ferreirós 2016, p. xi)

Once it has been acknowledged that the active dimension of mathematics is a proper object of philosophical inquiry, the next step is to figure out how to study it. This raises methodological issues on how to investigate the whole range of actions and activities present in mathematical practices as well as the different forms of agency involved.[5] It also raises theoretical questions regarding the nature of actions, activities, and agency in the specific context of mathematical practice.

The aim of this chapter is to review various ways in which the notions of action, activity, and agent have played a role in philosophical studies of mathematical practice. The focus will be on contributions that have attempted to theorize about these notions. We begin, in Sect. 2, with some motivations for taking agents seriously when investigating mathematical practice. Section 3 is concerned with the notion of mathematical activity, both as an object of study in itself and as a way of building an epistemology of mathematics where mathematical knowledge is rooted into elementary mathematical activities. In Sects. 4 and 5, we will see how the notions of action and agent have played an important role in the philosophical study of mathematical artifacts and mathematical proofs. Section 6 will be concerned with mathematical agency and mathematical texts, and more specifically with how mathematical actions can be prescribed by mathematical texts. Taken together, these contributions already provide important clues on what it means to do mathematics. Section 7 concludes the chapter with some suggestions on how to pursue further the study of agency in mathematical practice.

2 Why Take Agents Seriously

An obvious reason to take agents seriously is that virtually all the mathematical practices one may be interested to investigate would not exist without agents engaging in it at a given point in human history. As Ferreirós emphasized: "[m]athematical practice always involves communities of agents in interaction" and "there is no practice without practitioners" (Ferreirós 2016, p. 45).[6] One may then expect that the notion of agent will, one way or another, figure in any philosophical analysis of mathematical practice.

[5] The nature of actions, activities, and agency are investigated in the branch of philosophy known as the *philosophy of action* (for overviews, see Schlosser 2019; Piñeros Glasscock and Tenenbaum 2023). The theme of this chapter naturally invites connections between the philosophy of mathematical practice and the philosophy of action. So far, interactions between the two fields have been rare, but see Chemla and Virbel (2015) and Hamami and Morris (2021, 2022a) for some attempts to connect the two.

[6] On Ferreirós' view of what a mathematical practice is, see also Ferreirós' chapter in this handbook (Ferreirós 2022).

Still, one may object that the essence of a mathematical practice lies in the norms or rules that are constitutive of it, and not in its particular, contingent implementation(s). From this perspective, one could investigate a given mathematical practice independently of its implementation(s), in the same way as one could study a judiciary system or an algorithm which may never have been implemented concretely. In opposition to this view, Manders (2008) has argued that, in the context of his analysis of diagram-based geometric reasoning in ancient Greece, taking into account different *roles* for the agents engaged in this practice was important in explaining its *success*. Manders distinguishes two roles that he considers of theoretical importance (Manders 2008, p. 122): that of *asserting* the different geometrical claims made in the text and taking responsibility for them, and that of providing critical scrutiny or *probing*. One way of probing a geometrical claim is to propose a *case*, that is, a diagram which satisfies the stipulations of the claim but which is topologically different from the diagram(s) considered by the protagonist. According to Manders, proposing cases is theoretically significant because it is an essential strategy to cope with the open-ended nature of case-branching in diagram-based geometric practice, i.e., with the fact that such a practice does not possess a procedure to make sure that all topologically different diagrams that are relevant in a geometric proof have been considered. As evidence for the importance of the role of probing, Manders argues that several propositions in Euclid's *Elements* can be conceived as responses to probing claims that could potentially be raised with respect to other geometrical proofs.

Another reason to take agents seriously is highlighted by cases where the mathematics themselves are primarily about actions. Typical examples are mathematical practices geared towards geometric constructions or concrete arithmetical/algorithmic procedures. For instance, ancient Greek geometry has been described by Reviel Netz as "the study of spatial action, not of visual representation" (Netz 1999, p. 60). Some mathematical traditions, such as those from Mesopotamia or ancient China, are primarily concerned with procedures for computations which are, by definition, set of actions to be performed (see, e.g., Chemla 2012). When analyzing mathematical practices of this kind, one may naturally be led to reflect on the nature of the actions involved and on the structure of the agents performing them.[7]

But one of the main reasons to take agents seriously is that the notions of action, activity, and agent have revealed themselves theoretically useful and fruitful when addressing a number of issues that appear prominently in the research agenda of the philosophy of mathematical practice. As we shall see in the following sections, this bundle of notions occupies an important place in philosophical work on mathematical activities, mathematical artifacts, mathematical proofs, and mathematical texts.

[7] We can also mention here practices that could be qualified as mathematical such as string figure-making (see, e.g., Vandendriessche 2015) or paper folding (see, e.g., Friedman 2018), though of course whether such practices can be qualified as mathematical is a debated question.

3 Agency and Mathematical Activities

Focusing on what it means to do mathematics amounts to seeing mathematics as an activity. In this section, we will be concerned with two lines of research that naturally emerge from this perspective. The first one consists in developing an epistemology of mathematical activities. The second one explores the possibility that mathematical knowledge is rooted or grounded into elementary human activities.

In a contribution entitled "Mathematical activity," Giaquinto (2005) started from the observation that, although philosophers of mathematical practice have set for themselves the task of investigating the activities that mathematicians engage in, they have so far focused on a narrow set of activities. Giaquinto proposed then a "preliminary map" of mathematical activities worthy of philosophical investigations, recognizing that this list is not meant to be exhaustive. His list consists of the following mathematical activities: discovery, explanation, formulation, application, justification, and representation. Once such a list is established, numerous questions arise: What is the nature of these activities? Are they really different kinds of activities? What are the relations between them? Can they be decomposed into smaller activities? Giaquinto tackled some of these questions. In particular, he argues that discovering, explaining, and justifying are distinct kinds of activities which do not reduce to proving. He also proposes that, for each of the activities in the list, one can distinguish between making it, presenting it, and taking it in. For instance, in the case of discovering, one can distinguish between making the discovery, presenting the discovery to other people, and being the one who is trying to "get" the discovery, that is, who is receiving or taking in the discovery. Giaquinto conceives of his contribution as a "springboard" to pursue further philosophical investigations into the nature of mathematical activities.

Some authors have argued that the origins, grounds, or roots of mathematical knowledge are to be found in certain elementary human activities. The mathematician Saunders Mac Lane put the general idea as follows[8]:

> [M]athematics started from various human activities which suggest objects and operations (addition, multiplication, comparison of size) and thus lead to concepts (prime number, transformation) which are then embedded in formal axiomatic systems (Peano arithmetic, Euclidean geometry, the real number system, field theory, etc.). These systems turn out to codify deeper and nonobvious properties of the various originating human activities. (Mac Lane 1981, p. 463)

Mac Lane offered the following list of correspondence between elementary human activities and domains of mathematics:

Counting	: to arithmetic and number theory
Measuring	: to real numbers, calculus, and analysis
Shaping	: to geometry and topology
Forming (as in architecture)	: to symmetry and group theory

[8] See also Mac Lane (1986, chapter XII).

Estimating	: to probability, measure theory, and statistics
Moving	: to mechanics, calculus, and dynamics
Calculating	: to algebra and numerical analysis
Proving	: to logic
Puzzling	: to combinatorics and number theory
Grouping	: to set theory and combinatorics

There are different ways in which this general idea can be exploited to articulate a view of mathematics and mathematical knowledge as rooted or grounded into elementary human activities. I will now describe two of the most developed proposals in this direction, namely those of Kitcher (1984) and Ferreirós (2016).

In chapter 6 of *The Nature of Mathematical Knowledge*, Kitcher (1984) endeavors to develop an account of mathematical truth according to which mathematical statements are true in virtue of certain operations or manipulations humans can perform in the world. In the case of arithmetic, two such operations are collecting and correlating: collecting is the activity of segregating or putting objects together; correlating is the activity of matching, relating, or connecting objects. According to Kitcher, the first type of operation leads to notions like set, number, and arithmetical operations, while the second type leads to notions like that of a function. Thinking in terms of mathematical activities such as collecting and correlating is key to Kitcher's mathematical ontology: "One central idea of my proposal is to replace the notions of abstract mathematical objects, notions like that of a collec*tion*, with the notion of a kind of mathematical activity, collec*ting*" (Kitcher 1984, p. 110). Kitcher emphasizes that the operations or manipulations he has mind are not those of any given human agent but that of an ideal agent. This ideal agent should be thought as an idealized version of human agents. Kitcher conceives then of arithmetic as an "idealizing theory": "the relation between arithmetic and the actual operations of human agents parallels that between the laws of ideal gases and the actual gases which exist in our world" (Kitcher 1984, p. 109). This approach allows Kitcher to argue that arithmetic constitutes a description of the structure of reality, that is, of some operations that can be done in the physical world. In a slogan, Kitcher says that arithmetic is true: "in virtue not of what *we can do* to the world but rather of what *the world* will let us do *to it*" (Kitcher 1984, p. 108). A main goal of *The Nature of Mathematical Knowledge* is then to show how advanced mathematics can emerge from such proto-mathematical knowledge through various stages of rational transitions.

Like Kitcher, Ferreirós holds that an account of mathematical knowledge should attribute a key role to certain elementary activities or practices: "I shall argue that our knowledge of mathematics cannot be understood without emphasizing the practical roots of math, including its roots in scientific practices and technical practices" (Ferreirós 2016, p. 5). But contra Kitcher, Ferreirós' approach is not reductionist – central to Ferreirós' account is the "interplay" or "interactions" between practices, not the transitions between different mathematical practices. Another important difference with Kitcher is that Ferreirós emphasizes the cognitive dimension of elementary mathematical practices and the fact that the cognitive abilities involved must be reenacted for an individual to gain mathematical knowledge, while Kitcher situates elementary mathematical practices at the historical roots of his genealogical account.

Ferreirós also offers a precise definition of what he calls a "technical practice," namely: "a recognizable type of activity that is done—and can be taught and learned—by human agents, involving direct manipulation of objects in the world, through the use of human-made instruments" (Ferreirós 2016, pp. 40–41). The three technical practices discussed by Ferreirós (2016) are that of counting, measuring, and drawing geometrical forms. An important thesis in Ferreirós' view is that knowledge of mathematics requires the mastering of these elementary techniques.

The notion of mathematical activity, intimately connected with that of a mathematical practice, is bound to play an important role in the philosophy and history of mathematical practice. As a matter of fact, many studies in the field precisely consist in the analysis of mathematical activities. The focus in this section has been on philosophical developments that have attempted to theorize about the notion of mathematical activity itself and/or to use it in the pursuit of larger goals. Here, much is to be gained by pursuing further the inquiry initiated by Giaquinto (2005). In particular, it would be theoretically and practically useful to identify and characterize the main components of what constitute mathematical activities as well as the mathematical agents able to perform them.[9] This could not only yield methodological tools to investigate specific mathematical activities, it could also provide a perspective to compare and relate different mathematical activities – a theme central to approaches like the one of Ferreirós which emphasize the interplay between mathematical practices, and thus between mathematical activities. Possessing a rich and precise account of the nature of mathematical activities will, in turn, be directly useful for building philosophical conceptions of mathematics rooted in mathematical activities.

4 Agency and Mathematical Artifacts

Doing mathematics involves doing things with mathematical artifacts such as diagrams, symbols, and graphs. A significant part of the literature in the philosophy and history of mathematical practice is dedicated to understanding and reconstructing what agents did or do with mathematical artifacts in various mathematical practices, from the use of geometric diagrams in Ancient Greece mathematics (e.g., Netz 1999; Manders 2008) to that of commutative diagrams in contemporary homological algebra (e.g., De Toffoli 2017). The aim of this section is not to review this literature. Rather, the focus will be on contributions that have attempted to conceptualize and theorize about what it means to do things with mathematical artifacts. This line has been pursued mainly in the cases of mathematical diagrams and mathematical symbols,[10] and I will review here some representative studies in this trend. Before

[9] As an example, Carter (2008) argues that investigating the activities that mathematicians perform with mathematical structures provides a new perspective on mathematical structuralism.

[10] These two kinds of mathematical artifacts are some of the most common ones in mathematical practices past and present, which is probably why they have received most of the attention in the literature. But there are also other kinds of mathematical artifacts that invite epistemic actions, for instance abacuses, geometric instruments such as ruler and compass, and computer simulations.

that, I will present the notion of *epistemic action* from Kirsh and Maglio (1994) which has played a central role in these discussions.

The distinction between pragmatic and epistemic actions was introduced by Kirsh and Maglio (1994) in their psychological study of the video game Tetris. Pragmatic actions are physical actions performed in the world whose aim is to bring a physical system closer to a specific goal. In Tetris, the pragmatic actions are those aiming to orient the falling shapes in order to create full rows, the goal of the game being to fill up rows. Epistemic actions are also physical actions performed in the world, but their goal is different: their aim is to gain information by performing computations externally. In Tetris, the epistemic actions consist in rotating the shape in order to decide where and in which orientation to position a falling shape. The main advantages of relying on epistemic actions in Tetris is that rotating the shape in the game is less cognitively costly and more reliable than trying to mentally rotate the shape in the mind. Kirsh and Maglio argue that epistemic actions play an important role in many human activities, and that acting in the environment to gain information, knowledge, and understanding is an essential part of human cognition.

One area of contemporary mathematics where diagrams are omnipresent is knot theory.[11] De Toffoli and Giardino (2014) have conducted a detailed analysis of the use of knot diagrams in the practice of knot theory. They have argued that knot diagrams are entities that support epistemic actions such as computations and inferences. These epistemic actions require a certain cognitive faculty on the part of the agent that they called "manipulative imagination" which, they suggest, is akin to the sort of concrete manipulations one can perform on deformable objects. The moves that can be performed on knot diagrams are codified in the mathematical theory. Accordingly, agents need to be appropriately trained not only to recognize the possible or legitimate moves one can perform on a knot diagram but also to be able to perform these moves. De Toffoli and Giardino have further argued that this manipulative imagination also plays a role in the practice of low-dimensional topology (see De Toffoli and Giardino 2015). Here again, the agent must be able to recognize the permissible actions that can be performed on a given representation and so need to be appropriately trained to do so. To show this, they have conducted a detailed analysis of Rolfsen's proof of the equivalence of two presentations of the Poincaré homology sphere. In this particular case, some of the permissible actions consist of continuous transformations. According to De Toffoli and Giardino, this faculty of manipulative imagination builds on preexisting spatial and motor cognitive capacities but needs to be appropriately trained to play its epistemic function in the practice of knot theory and low-dimensional topology.

Mathematical symbols are artifacts present in virtually every branch of mathematics. De Cruz and De Smedt (2013) have made the case that a primary function of mathematical symbols is to support epistemic actions. These epistemic actions consist in typical symbol manipulations such as those related to negative and

[11] Knot theory is a branch of topology that studies knots – a mathematical knot is defined as an embedding of a circle in $\mathbb{R}^3$.

imaginary numbers. These symbol manipulations are governed by specific rules associated to the relevant symbolic systems, rules that will need to be learned by the agents. Once acquired, they will provide the agents with an efficient way to perform various forms of mathematical thinking. De Cruz and De Smedt go even further and argue that mathematical symbols support forms of mathematical cognition that would not be possible without resorting to external representations, a view that they articulate by building on the so-called extended mind thesis (Clark and Chalmers 1998; Clark 2008). Their main source of evidence for this claim comes from the history of mathematics. One of their key examples is the case of negative numbers which have received strong oppositions in the past by distinguished mathematicians such as Vieta, Pascal, and De Morgan. De Cruz and De Smedt argue that the invention of the negative numbers, which appears as counterintuitive, was made possible because of the symbolization associated to the minus sign and the operation of subtraction, a symbolic system with which one can calculate.

This perspective naturally raises the question of what form of cognition underlies thinking and acting with mathematical symbols. Landy et al. (2014) have proposed a cognitive theory of symbolic reasoning – called the *perceptual manipulations theory* – that attributes central roles to perception and action. According to this theory, external symbols and notations are treated like physical objects by the cognitive system, that is, objects that can be perceived and manipulated. Symbolic reasoning would then rely on a wide range of sensorimotor abilities such as affordance learning, pattern-matching, object tracking, symmetry detection, etc. This theory could explain the importance of careful and effective design of mathematical notations. More specifically, a well-designed notational system is, from this perspective, one that can take advantage of the sensorimotor system capacities in order, for instance, to encourage valid manipulations and refrain invalid one, or to facilitate the application of structurally similar rules from one domain to another.

Giardino (2018) has advanced an encompassing framework aiming to account for different types of mathematical artifacts, including both mathematical diagrams and mathematical symbols. Her proposal is to conceive mathematical artifacts as representational cognitive tools whose main characteristic is to play the double function of representation and instrument. As instrument, the main function of representational cognitive tools is to carry out inferences, i.e., epistemic actions. Giardino offers an account of how epistemic actions operate on representational cognitive tools by building on the notions of *material anchor* from Hutchins (2005) and *affordances* from Gibson (1979). Thinking of representational cognitive tools as material anchors amounts to considering them as material entities which have been designed so that constraints associated to their epistemic functions, as well as to what they represent conceptually, are built in the artifacts themselves. The idea of affordances is that the epistemic actions than can be performed on a given representational cognitive tool are those that are afforded by the tool. These affordances depend on the context or practice in which the cognitive tool is used, which means that agents need to be trained to recognize these affordances, a necessary prerequisite to be able to perform legitimate epistemic actions with the tool.

What these different contributions show is that accounting for what we do with mathematical artifacts in mathematical practice naturally leads to considerations of mental and epistemic actions, and thus of mental and epistemic agency, and requires paying attention to the cognitive underpinnings of the mental activities under consideration. There is thus room on these issues for fruitful interactions between the philosophy of mathematical practice and related developments in the philosophy of mind, philosophy of action, and cognitive science.

5 Agency and Mathematical Proofs

Interacting with mathematical proofs[12] is an essential part of what mathematical agents do. This includes evaluating, verifying, communicating, explaining, understanding, and reframing mathematical proofs, among others. But mathematical proofs themselves can also be conceived as being primarily about action. Hamami and Morris (2021) proposed the correspondence displayed in Fig. 1 between the static notions of deductive step and mathematical proof and the dynamic notions of deductive inference and proof activity which belong to the realm of action. That deductive inferences are first and foremost actions of an epistemic nature has been emphasized by several logicians and philosophers (see, e.g., Sundholm 2012; Prawitz 2012; Boghossian 2014; Wright 2014). Hamami and Morris introduced the term *proof activity* to refer to the sequence of deductive inferences corresponding to a mathematical proof. In this section, we will review contributions that propose an action-based perspective on mathematical proofs, focusing in turn on the notions of deductive inference and proof activity.

Larvor (2012) has argued that, in order to better understand the nature of informal proofs, it is not sufficient to approach them as bodies of propositions connected in specific ways. Rather, one should see a proof as a sequence of dynamic transitions, that is, one should focus on *inferential actions*. This change of perspective is particularly fruitful because there is no reason to think of inferential actions has

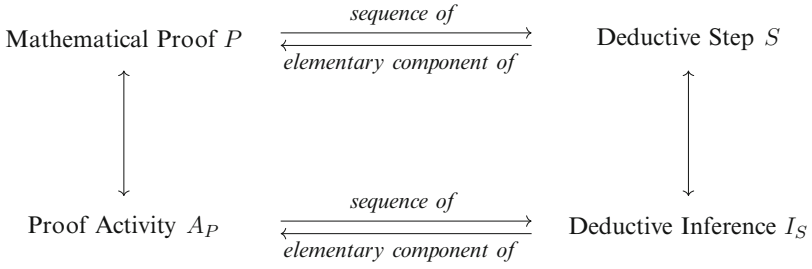

Fig. 1 Mathematical proof, proof activity, deductive step, and deductive inference

[12] By "mathematical proofs" I mean here the kind of proofs one commonly finds in mathematical practice, also commonly referred to as "informal proofs."

being restricted to linguistic representations – inferential actions can operate on different kinds of representations such as diagrams, symbolic expressions, physical models, computer models, etc.[13] Larvor builds on this observation to argue that the validity or invalidity of informal proofs can depend on their content. The main reason being advanced is that inferential actions are not always possible in all domains; only inferential actions that consist of logical inferences are. This means that the validity of these inferential actions must depend somehow on features of the domain under consideration. Larvor argues that inferential actions that are context-dependent can perfectly be rigorous insofar as they come with means of control which govern the inferential actions that are possible and legitimate in a given domain. In this respect, Manders' analysis of Euclid's diagram-based geometric practice (Manders 2008) is an archetypal example of a study aiming to make explicit the means of control governing inferential actions operating on text and diagram in the context of Euclid's geometric proofs. Larvor points out that this perspective shapes and organizes a research program on informal proofs in the philosophy of mathematical practice: the task is to identify the various types of inferential actions, to isolate the features of the domain on which they operate that are responsible for their validity, and to identify the means of control that govern them.[14]

If it is particularly fruitful to approach individual deductive steps as inferential actions, then it must be equally fruitful to approach entire mathematical proofs as sequences of inferential actions, i.e., as *proof activities* (see Fig. 1). Hamami and Morris (2021) have undertaken a detailed analysis of proof activities and the form of agency underlying them. Their investigations start from the observation that proof activities have two noticeable characteristics, namely they are goal-directed and temporally extended activities. They are goal-directed in the sense that any proof activity is always directed towards a specific goal, namely to prove or establish the mathematical proposition at hand. They are temporally extended in the sense that any action in a proof activity depends on what happened before and constraints what will happen next, that is, any action is fully integrated into the temporal structure of the activity taken as a whole. In this respect, proof activities are similar to many of our ordinary activities such as travelling or cooking which are obviously goal-directed and which unfold over time. Now, the philosopher of action Michael Bratman (1987) has observed that, for human agents, the realization of goal-directed and temporally extended activities most often requires a form of planning agency. This means that the agents engaged in goal-directed and temporally extended activities are guided by a plan that they construct, revise, and execute over time. In the case of proof activities, this means that the sequence of actions does not come from nowhere but is the result of the execution of a plan that has been constructed rationally. This has some interesting consequences for the epistemology of mathematical proofs in practice. First, it means that mathematical proofs possess what Poincaré (1908) called an *architecture* or a

[13] There is here a direct connection with the topic of agency and mathematical artifacts discussed in the previous section.

[14] This line is further pursued in Larvor (2019).

unity that can be grasped as a whole (see also Detlefsen 1992). This is due to the fact that a mathematical proof is the result of the execution of a plan produced by a mathematical agent, in the same way as a building is the result of executing the plan of an architect. Second, because proof plans are rational constructs, this also means that mathematical proofs produced by rational planning agents possess what Mac Lane (1935) called a *rational structure* – a mathematical proof in practice is not a "mere" sequence of deductive steps. Hamami and Morris (2022a) have argued that this notion of rational structure can be fleshed out by identifying the norms of rationality governing the construction of proof plans. Third, if we accept proof plans as meaningful epistemological entities, then we may expect that some of the activities carried out with proofs will have to do with proof plans. Indeed, several authors have pointed out an intimate connection between proof plans and proof understanding (e.g., Poincaré 1908; Robinson 2000; Folina 2018). Following along this line, Hamami and Morris (2022b) have advanced an account of proof understanding according to which understanding a mathematical proof amounts to being able to rationally reconstruct the proof's underlying plan. Finally, Hamami and Morris (2021) have also argued that proof plans play an important role in the activities of presenting and communicating mathematical proofs.

The action-based perspective on mathematical proofs fits very naturally with the general idea of approaching mathematics as a human activity. As we saw in this section, the static and agentless notions of deductive steps and mathematical proofs can profitably be analyzed through their active counterpart, namely the notions of deductive inferences or inferential actions and proof activities. This perspective is particularly suited to study the spectrum of activities carried out in interaction with mathematical proofs. As an illustration, we saw here that Larvor's view on inferential actions naturally leads to an account of what it means to evaluate the validity of mathematical proofs, while Hamami and Morris' analysis of proof activities can be used to shape an account of what it means to understand, present, and communicate mathematical proofs. But these are only some of the many activities related to mathematical proofs. An obvious research program to foster this action-based perspective will be to pursue and extend the analysis of these different activities. This, in turn, can shed light on the nature of agency involved when interacting with mathematical proofs.

6 Agency and Mathematical Texts

Mathematical texts are a privileged vehicle for the transmission of mathematical knowledge.[15] If we approach the nature of mathematics through the lens of mathematical practice, a key issue is then to understand how mathematical agents can

[15] This is not to say that mathematical knowledge cannot be transmitted by other means. Agent-to-agent communications through oral transmissions, eventually accompanied by gestures and external representations, have been historically dominant in some mathematical cultures and are certainly very important in present-day mathematical practice. Thanks to José Ferreirós for suggesting this clarification.

realize mathematical actions and activities on the basis of mathematical texts. In this section, we will review studies in the field that address exactly this question. As we shall see, such investigations can yield important insights on key questions in the philosophy of mathematical practice.

Computing and proving are two archetypical mathematical activities. The former is central to certain mathematical traditions such as those of Mesopotamia, ancient China, and the Indian subcontinent, while the latter has been privileged in other traditions such as that of ancient Greece (Chemla 2012). Some commentators have downplayed the activity of computing as compared to that of proving for several reasons (e.g., Hacking 2000), a main one being that computations can be carried out blindly, in a step-by-step fashion, without any form of mathematical understanding. Chemla (2015) argues against this view by undertaking a detailed investigation of how texts of mathematical procedures in ancient China prescribe mathematical actions. The focus is on two key mathematical texts, namely the *Writings on mathematical procedures* and *The Nine Chapters on Mathematical Procedures*. Her analysis yields two important results. The first one is that procedures in these texts cannot be executed in a step-by-step fashion because the specification of certain steps require to attend to other instructions appearing later on in the sequence. This means that a certain form of knowledge is required to "circulate" – Chemla's term – within these texts of procedures. This circulation is necessary to infer from the text the actual sequence of actions to be carried out in specific cases or situations. Chemla argues that this feature witnesses to the generality of the procedures – i.e., the fact that the same procedure can be applied to a wide range of different cases and situations. It is thus essential that the reader be able to infer from the text which actions to take in her specific situation, a competence that goes beyond a blind step-by-step following of the procedure. The second result is that, to infer the sequence of actions to be carried out, the reader needs a certain understanding of the reason(s) why certain steps are carried out. This follows from a meticulous analysis of what it takes to interpret steps in procedures that involve the term "likewise," that is, steps that require an understanding of what exactly is to be replicated. Taken together, this analysis of the way actions are prescribed in texts of mathematical procedures challenges, according to Chemla, the view that computations are mathematical activities that are carried out blindly without any understanding.

Tanswell (forthcoming) has offered an analysis of imperatives in mathematical proofs – introduced by terms such as "let," "assume," "solve," "observe," etc.[16] – which, he argues, yields important insights into the nature of informal proofs. Imperatives issue instructions or commands to carry out mathematical actions. Tanswell identifies three kinds of imperatives in mathematical proofs. The first kind are imperatives which directly refer to the activity to be carried out, for instance, "solve" this equation, "differentiate" or "integrate" this function, "multiply" these two matrices, etc. The second kind are imperatives corresponding to standard

[16] See the chapter by Inglis and Tanswell in this Handbook (Inglis and Tanswell 2022) for a corpus analysis of imperatives and instructions as they occur in mathematical texts.

instructions, but for which some information is left implicit, such as an "assume" clause without stating exactly what the goal is (e.g., to establish a conditional, to reach a contradiction, to do a reasoning by cases, etc.). The third kind are imperatives whose formulation does not correspond exactly to what is to be done and, for this reason, require background and expertise to be interpreted appropriately. As an example, Tanswell mentions a situation where one is told to "using the Axiom of Choice, for each *n* choose an enumeration," while "the whole point of the Axiom of Choice is that we cannot actually go about choosing infinitely many times" (Tanswell forthcoming, p. 7). Acknowledging the importance of imperatives in mathematical proofs motivates, according to Tanswell, what he calls the *recipe model* of informal proofs.[17] The model is introduced through a number of analogies between proofs and ordinary cooking recipes. It is noted that proofs, like cooking recipes, (1) employ the imperative mood, (2) are secondary to the associated activities, and (3) involve a clear distinction between the process the author(s) went through to produce them and the way it is being used by the readers or consumers. Tanswell argues that this recipe model of informal proofs is particularly adapted to account for the role of diagrams in proofs for the main reason that diagrams are used to provide instructions in many contexts, and so there is no particular reason to see diagrams as more problematic than texts when it comes to yield instructions.

The studies by Chemla (2015) and Tanswell (forthcoming) show that much is to be learned by conducting detailed analyses of how mathematical texts can lead to mathematical actions and activities. Here, we have seen that this can provide evidence for revising received views on the relation between computation and proof as well as on the nature of informal proof.[18] But, more generally, such investigations are a privileged way to better understand mathematical activities themselves. In fact, for many (most?) mathematical traditions, mathematical texts are all we have. A key task for the historians of mathematics is thus to reconstruct past mathematical activities on the basis of the mathematical texts that came down to us. As Chemla's study illustrates here, this should not only consist of identifying the actions constituting these activities, it should also amount to characterizing the knowledge, competence, and understanding that mathematical agents need to possess to carry out the relevant mathematical activities. From this perspective, the issue of mathematical agency necessarily arises whenever one undertakes to analyze or reconstruct mathematical activities, and more generally mathematical practices, on the basis of mathematical texts.[19]

[17] See Weber and Tanswell (2022) for further developments of this model and its applications to issues in mathematics education.

[18] In this respect, the studies by Chemla and Tanswell fit perfectly within the action-based perspective on mathematical proofs discussed in the previous section.

[19] Here, mathematical texts should be understood in the broad sense encompassing all the different kinds of representations used in mathematical communication, namely texts but also diagrams, symbols, graphs, etc. There is then a direct connection between the theme of this section and the ones developed in Sect. 4 on agency and mathematical artifacts.

7 Conclusion

What does it mean to *do* mathematics? Doing mathematics obviously involves doing a wide range of different things, and so the only way to progress on this question is to decompose the problem into chunks amenable to philosophical investigations. As we saw in this chapter, philosophers and historians of mathematical practice have made significant progress in this direction by investigating what it means to carry out mathematical activities, do things with mathematical artifacts, engage with mathematical proofs, and perform mathematical actions prescribed by mathematical texts. But this may only be the tip of the iceberg, and it is likely that the question of agency in mathematical practice covers a vast research territory that remains to be uncovered and explored. In this conclusion, I will suggest potential avenues for future work in this direction.

Perhaps one of the most pressing issues is to reflect on what mathematical agents are, a problem that should be addressed for every specific mathematical activity and practice. One of the few authors who have tackled this question directly is Ferreirós (2016), the notion of mathematical agent being central to the philosophical view he advances.[20] For Ferreirós, mathematical agents are first and foremost human agents with ordinary cognitive abilities and limitations, and immersed in a physical, social, and cultural world. Ferreirós argues that all those aspects are relevant to his account of mathematical knowledge and mathematical practices. Taken together, the contributions reviewed in this chapter already highlight many salient aspects of mathematical agents. In addition to the features identified by Ferreirós, mathematical agents are also planning agents (Hamami and Morris 2021, 2022a), powered with a faculty of manipulative imagination (De Toffoli and Giardino 2014, 2015, 2016), capable of performing inferential actions (Larvor 2012, 2019), grasping and understanding the reasons behind mathematical actions (Chemla 2015), and following recipes (Tanswell forthcoming; Weber and Tanswell 2022). A challenge for the philosophy of mathematical practice is to develop an account of mathematical agents capable of articulating these different dimensions in a systematic way.

Research on agency in mathematical practice has so far focused mainly on individual human agency, but several other forms of agency are present in mathematical practice – the most obvious ones are social agency, computer agency, and extended agency. Social agency is present whenever mathematical agents are doing things together, typically when several mathematicians are collaborating to prove a theorem. This raises the question of what it means for a *group* of mathematical agents to do mathematics *together*. As philosophers of action have shown,[21] social agency most often require subtle mechanisms of coordination and interaction. Investigating these

[20] In Ferreirós' words: "The thesis that multiple practices coexist and are interrelated, in a way that is crucial for the conformation of mathematical knowledge, has one interesting consequence. It means that my analysis of mathematical knowledge has to be crucially centered on the agents" (Ferreirós 2016, p. 59).

[21] See Roth (2017) for a review of the literature on social agency in the philosophy of action.

mechanisms in the context of mathematical practice will certainly lead important insights into the social dimension of mathematical practice. Additionally, it may be interesting to investigate the agency displayed by the mathematical community or subgroups thereof, for instance, when attributing credits and rewards (see, e.g., Jaffe and Quinn 1993; Rittberg et al. 2020). Similarly, the increasing role of computers in mathematical practice raises the questions of what it means *for* computers to do mathematics, if at all, and what it means to do mathematics *with* computers.[22] These issues pop up concretely whenever one investigates cases of proving or discovering where computers are involved in an essential way – e.g., in the computer-assisted proof of the four color theorem. Finally, the many studies on mathematical artifacts in mathematical practice raises the question of what exactly the agent who does mathematics consists in. When a mathematical activity is carried out by a human agent relying on some mathematical artifacts, what is doing mathematics is a sort of integrated system composed of the coupling of the agent and the artifacts, in which case the mathematical agent may better be conceived as an extended agent. Such an approach could be developed, for instance, in the line of the cyborg conception of agency proposed by Clark (2003), following the famous extended mind thesis much discussed in the philosophy of mind (Clark and Chalmers 1998). Another challenge for philosophers and historians of mathematical practice is thus to identify and characterize the different forms of agency at play in mathematical practice.

The question of agency in mathematical practice is both a theoretical and a methodological issue for the philosophy of mathematical practice. It is a theoretical issue in the sense that any account of what it means to do mathematics may be expected to say something about the agents doing mathematics. But it is also a methodological issue in the sense that our underlying conception of mathematical agency guides, in part, our investigations into specific mathematical activities and practices. More specifically, it provides us with a "template" to address questions such as: What does this mathematical activity or practice consists in? What does it take for an agent to be able to properly engage in it? These two aspects are intimately intertwined: progress on the theoretical front may yield new tools and perspectives to investigate specific mathematical activities and practices;[23] in turn, these investigations may yield new empirical data to constrain and revise our theoretical conceptions. Given that the nature of agency is one of the outstanding issues spanning the Humanities, progress in the case of mathematical agency can certainly be made by recruiting concepts and resources from other fields, both within philosophy – especially from the philosophy of action, philosophy of mind, epistemology, and the philosophy of science – but also from other areas of the social sciences such as sociology and anthropology. Understanding the nature of agency in mathematical practice is thus likely to require the full interdisciplinary perspective that was claimed as a characteristic feature of the philosophy of mathematical practice.

[22] See Avigad (2008) for some investigations in this direction.

[23] A perfect illustration of this is provided by the studies in Chemla and Virbel (2015) which build, in part, on the theoretical framework developed by Virbel and colleagues (Grandaty et al. 2000; Virbel 2000).

Abstract

A common description of a mathematical proof is as a logically structured sequence of assertions, beginning from accepted premises and proceeding by standard inference rules to a conclusion. Does this description match the language of proofs as mathematicians write them in their research articles? In this chapter, we use methods from corpus linguistics to look at the prevalence of imperatives and instructions in mathematical preprints from the arXiv repository. We find thirteen verbs that are used most often to form imperatives in proofs, and that these show up significantly more often within proofs than in the surrounding

mathematical writing. We also show that there are many more verbs used to form a diverse selection of instructions in proofs. These findings are at odds with the view of proofs as sequences of assertions. Instead, we argue in favour of the *recipe model of proofs*: that proofs are like recipes, giving instructions for mathematical actions to be carried out.

Keywords

Proof · Mathematical language · Corpus linguistics · Instructions · Imperatives

1 Introduction

One of the central principles of the philosophy of mathematical practices is to embrace, analyse, and understand the real (and often messy) features of mathematics as a living subject. A project like this is necessarily interdisciplinary, relying on history, sociology, anthropology, psychology, cognitive science, education, argumentation studies, etc. to identify and study the salient features of mathematics. Here, we will use methods from *corpus linguistics* to study the language used in modern mathematics, and especially proofs.

Despite the central importance of attending to the realities of practices, our understanding of what proofs are really like is, in the existing literature, typically only informed by modern and historical case studies, and often by anecdote and personal familiarity. While we do not dispute the value of these, they can only provide part of the picture. In this chapter, we instead perform a systematic, large-scale, computational analysis of mathematical texts. Specifically, we will analyse texts from the *arXiv*, a preprint server for mathematics research articles.

We will investigate the relationship between the language used in written, textual mathematics, and how to best understand what proofs are. In particular, we will look at the use of instructions in proofs. One way that instructions are issued in mathematics texts is in sentences in the imperative mood. A sentence in the imperative mood instructs or commands that some action be carried out, such as "Go to your room"; "Eat your greens"; and "Do as you'd be done by." The use of the imperative mood can also be found in mathematics, such as "Suppose that the inductive hypothesis holds"; "Let I be a proper ideal of A"; and "Notice that x is a member of y." While the presence of instructions and imperative mood sentences in mathematical writing has been observed and discussed to some extent, there has been no systematic investigation of their relative frequency in modern mathematical proofs, and only to a limited extent the philosophical implications they have.

The central questions we will address through corpus linguistics concern the *frequency* and *diversity* of the instructions given in proofs in modern mathematical writing. In other words, we are asking how common various imperatives are, and how broad the range of permissible imperatives is.

There are several reasons to look specifically at the use of the imperative mood in mathematics. First of all, it contributes to philosophical debates on the nature of

proof and rigour, since it tells us about how written proofs are currently presented in research articles. Secondly, it is relevant to the epistemology of mathematics, since the potential ways that knowledge is gained from imperatives, which instruct us to carry out actions, might be importantly different to knowledge from other kinds of sentences. Thirdly, the existence of imperatives in mathematical writing points us to a different class of speech acts being used in proofs, and thereby raises questions about what the function of written proofs might be. Fourthly, it contributes to an overall picture of mathematical style and the language used in professional mathematics, which has impacts in mathematics education on how students are taught to read and write proofs. Finally, it adds to the practical efforts to embed computer assistants into mathematical practice, by showing what computers need to be able to read and produce in order to engage in mathematics alongside mathematicians.

The structure of this chapter is as follows. In Sect. 2, we outline the recipe model of proofs, under which a proof provides a recipe of instructions for the reader to follow. In Sect. 3, we look at the background of existing literature discussing the use of instructions and imperatives in mathematics. In Sect. 4, we present our corpus study: Sect. 4.1 explains corpus linguistics more generally and the body of texts we are working with; Sect. 4.2 offers our hypotheses to test based on the recipe model and the existing literature; Sect. 4.3 describes the methods; and Sect. 4.4 goes through the various results we obtained. Section 5 will offer an empirically informed discussion of the philosophical questions in light of the results.

2 The Recipe Model of Proofs

In this section, we describe the *recipe model of proofs*, as defended by Tanswell (forthcoming). This model stands in contrast to the *standard model of proof*, on which proofs are seen as sequences of assertions, which are stepwise inferences from premises to a conclusion, and all of which are declarative statements. From that perspective, all of the activity is reduced to acts of inferring, and the steps in the proof represent the results of those inferences. The standard model of proof has many virtues; however, it also often mischaracterises both what proofs look like in practice and how they are engaged with by practitioners. The recipe model of proof is intended to more faithfully account for these aspects of mathematical proofs. This alternative model develops an analogy that mathematical proofs are akin to cooking recipes. This section will fill out the important aspects of this analogy. Our summary of the recipe model will focus on four key points: (1) the instructions given by the text; (2) the language used to issue them; (3) the relationship between the text and the activity it tells you to carry out; and (4) the epistemic significance of proving. In this section, we discuss these four points.[1]

[1] As we are interested in written, purely textual proofs here, we set aside a fifth point by Tanswell (forthcoming) concerning the use of diagrams to issue instructions.

On point (1), the reason to compare proofs to recipes is that this emphasises the ways in which proofs are used to issue instructions, either explicitly or implicitly, for us to carry out a series of mathematical actions. On the recipe model, we propose that the actions that a proof instructs the audience to perform are far more diverse than inferring alone, and can include instructions for constructing useful mathematical objects, for manipulating objects and equations, for hypothetically considering mathematical assumptions, for fixing notations, for directing the readers' attention, for structuring their reasoning, and for many more possible epistemic actions.

For point (2), the emphasis of the analogy to recipes is on the similarity of the language used to issue instructions. There are, of course, large variations in the presentation of both cooking recipes and mathematical proofs. However, in cooking recipes the predominant mood is usually the imperative mood, directly listing instructions to follow to carry out the recipe.[2] The recipe model thus predicts that proofs will similarly include imperative sentences to offer instructions to the reader. However, two disanalogies are salient. First of all, recipes might sometimes include elements describing the state of the food, but in mathematics there is reason to find more declarative content because we are likely to see some aspects of the traditional view of proofs, where they do contain declarative statements with inferences from one to the next. Secondly, as a matter of style, cooking recipes tend to use more purely imperatival language, while in maths we can also make use of the "We [verb]" constructions. Nonetheless, in both disanalogies the instructions are still there: in the latter case explicitly, but in the case of inferring from statement to statement, the proof is still implicitly instructing the reader to undertake those mathematical acts of inference.[3] This means the recipe model is not dependent on there being many imperatives but does certainly look more plausible if there are. We expect that there are plenty of proofs without imperatives, but if there are very few proofs that contain any imperatives at all, that would be a bad sign for the recipe model generally.

The next point (3) is about how both proofs and recipes should be understood in terms of the relationship between a written text and the actions they describe. A recipe is intrinsically linked to the activity of making, and by this analogy we should understand proofs to be the same. A proof is a device for recording and communicating how to carry out some piece of mathematics, but it is the correct performance of the relevant actions that constitutes mathematical practice. On this model, therefore, we prioritise the doing of mathematics over the written artefact of a proof itself. Putting it another way: the recipe model makes proofs secondary to proving. Here,

[2] Detailed considerations of the language used in cooking recipes in different contexts can be found in Gerhardt et al.'s (2013) edited volume.

[3] What will "implicit instructions" look like? It will not be the case that all verbs are used to give implicit imperatives. Rather, the idea is that declarative sentences can carry with them instructions for, say, inferences (or other things) to be carried out. It may be that one needs a certain level of mathematical expertise and know-how to understand what these implicit instructions are exactly. Analysing the verbs in certain ways, as we will do, is one way to access these instructions, but we don't assume that all verbs correspond to instructions.

the activity of proving is construed broadly, such that the authors of the proof have proved the theorem, then use a proof to communicate to their readers how to carry out the mathematical activity, and thereby establish the truth of the theorem. Similarly, we expect the author of a recipe to have cooked it themselves, then use the recipe to enable the audience to reproduce it.

The final point (4) concerns epistemology: one of the central functions that proofs play in mathematics is epistemic: a correct and rigorous proof is meant to establish a theorem to be known with certainty.[4] But an important question for the standard model is: how does a presented proof link to knowledge at all? What is connecting the proof on the page (or wherever) with the knowledge in your head? A plausible story would already have to be recipe-like, where the proof tells you exactly which inferences to carry out. But as soon as the proof has any inferential gaps (Fallis 2003; Hamami 2014; Andersen 2020), which many proofs do, an additional account is needed. The recipe model's answer to this question is more direct: that knowledge is gained through the mathematical activity that we are instructed in by proofs, with this activity acting as a key intermediary to explain the epistemic functioning of proofs. Furthermore, the recipe model also expands the traditional conception of mathematical knowledge, which is largely about propositional knowledge, to also include mathematical knowledge-how. In order to cook from a recipe, one needs to *know how* to perform the relevant actions; likewise, to carry out a proof one needs to *know how* to perform the mathematical actions it tells you how to do. In fact, the mixture of imperative and declarative forms suggests that the knowledge gained from proving will be a combination of knowledge-how and knowledge-that. (For a longer development of this epistemic picture see Tanswell (2016, Chap. 4) and Tanswell (forthcoming, Sect. 6).)

The recipe model of proofs gives us concrete predictions on our two main areas of investigation, concerning the frequency and diversity of imperatives, namely that they should be common and diverse. They should be common because the issuing of instructions is one of the primary functions of proofs. They should be diverse because the possible space of mathematical activities that one could be instructed to carry out is large. These hypotheses are set out in Sect. 4.2 and tested in Sect. 4.4.

3 Background on Mathematical Language

In this section, we survey previous discussions of the use of instructions and imperatives in mathematics. We group these into two broad categories, based on the sources of the discussion: (1) mathematics education and philosophy; and (2) formalised mathematics.

[4] This is again a rather strong traditional conception of the epistemic function of proofs, and we agree with De Toffoli (2020) that this needs to be tempered to properly reflect practice.

3.1 Mathematics Education and Philosophy

Researchers in mathematics education and philosophy have both, at times, noted the use of the imperative mood in mathematical proof texts. However, in many cases this has just been done parenthetically or tangentially. We will set out a number of examples from these literatures chronologically.

David Pimm, in *Speaking Mathematically* (1987), analysed the kinds and effects of the language used in the mathematics classroom. As an aside, he remarked on mathematical imperatives:

> There is also the equally common use of the imperative in mathematical discourse (e.g. *consider*, *suppose*, or *define*) [...]. Another form is 'Let x be the number of . . .' Who is giving permission for this to be done? The mathematical imperative [. . .] is a topic worthy of considerable attention. (Pimm 1987, p. 72)

However, Pimm does not go on to give them any such attention, merely suggesting that the impersonal style allows mathematics texts to suppress and omit the agent who is carrying out the actions. This is a clear case of a parenthetical mention of the imperative mood in mathematics.

The work of Brian Rotman (1988, 1993) included the unusually careful examination of imperatives in mathematics. His broader project is one of semiotic analysis of mathematical signs, which is the analysis of how signs come to have meaning in mathematical texts. He considers imperatives to be a major feature of mathematical writing, and in establishing the shared meanings used in mathematics:

> But proof in turn involves the idea of an argument, a narrative structure of sentences, and sentences can be in the imperative rather than the indicative. [. . .] Mathematics is so permeated by instructions for actions to be carried out, orders, commands, injunctions to be obeyed — 'prove theorem T', 'subtract from y', 'drop a perpendicular from point P onto line L', 'count the elements of set S', 'reverse the arrows in diagram D', 'consider an arbitrary polygon with k sides', and similarly for the activities specified by the verbs 'add', 'multiply', 'exhibit', 'find', 'enumerate', 'show', 'compute', 'demonstrate', 'define', 'eliminate', 'list', 'draw', 'complete', 'connect', 'assign', 'evaluate', 'integrate', 'specify', 'differentiate', 'adjoin', 'delete', 'iterate', 'order', 'complete', 'calculate', 'construct', etc. that mathematical texts seem at times to be little more than sequences of instructions written in an entirely operational, exhortatory language. (Rotman 1988, p. 8)

He argued that imperatives in mathematics can be separated into two distinct kinds: *inclusive* imperatives, which are for creating shared mathematical discourse (by introducing shared standards, notations, referents etc.), and *exclusive* imperatives, which take a shared mathematical discourse for granted and operate within it. Rotman takes "consider," "define," "prove," and synonyms of these to be inclusive, constructing a shared domain of meaning, while other mathematical verbs merely tell us to operate on the shared domain of meanings that is already established. For example, "consider the metric space *(X,d)*" tells us to use X as a set with a distance measure d obeying the definitions of a metric space, constructing shared meanings for the author and reader for the coming mathematical text, while "add the distances d_1 and d_2" merely instructs the reader to carry out an operation

within the space, where meaning for the variables has already been established. This distinction is important for understanding the semiotics of a mathematics text and how some imperatives work to create shared mathematical discourses, but we don't think the distinction coincides with the epistemic and pragmatic functions of different kinds of imperatives. We also note that while Rotman listed many potential mathematical instructions, there is no study as to how common these actually are. We will carry out such a study below.

Besides the creation of shared meaning in mathematical texts, another feature of the use of imperatives in mathematical texts is to mark who is part of the mathematical community, something discussed by Candia Morgan (1996). She says:

> One common characteristic of academic mathematics texts (and some school texts) is the conventional use of imperatives such as *consider, suppose, define, let* x *be*. Like the use of we, these implicate the reader, who is addressed implicitly by the imperative form, in the responsibility for the construction of the mathematical argument. The use of imperatives and of other conventional and specialist vocabulary and constructions characteristic of academic mathematics marks an author's claim to be a member of the mathematical community which uses such specialist language and hence enables her to speak with an authoritative voice about mathematical subject matter. At the same time it constructs a reader who is also a member of the same community and is thus in some sense a colleague (although the nature of this relationship may vary according to the type of action demanded). (Morgan 1996, p. 6)

Her analysis was primarily focused on how these issues of community membership work for students of mathematics who are not yet members of the community but are in the process of being inducted and enculturated into it. However, she did not further concern herself with imperatives in particular.

Paul Ernest has also discussed imperatives in mathematics in multiple places. For example, in his book *Social Constructivism as a Philosophy of Mathematics* (1998), he stated:

> Thus mathematical texts comprise specific assertions and imperatives directed by the writer to the reader. (Ernest 1998, p. 170)

We are broadly sympathetic to this view of proofs as, at least in part, functioning as communicative devices to transfer knowledge of mathematical reasoning from author to reader. In more recent work, citing Rotman, Ernest went so far as to say:

> Imperatives are orders that instruct or direct actions either inclusively, such as: let us ..., consider ..., or exclusively, such as: add, count, solve, prove, etc. Imperatives occur more frequently in mathematics than in any other academic school subject. (Ernest 2018, p. 191)

We note that this is a direct empirical claim, offered without evidence, and one that could potentially be refuted by other disciplines which use imperatives in their written work such as chemistry, philosophy, or geology (cf. Swales et al. 1998). Below we carry out one study of the frequency of imperatives in proofs in mathematical research articles.

The work of Rotman was also extended and challenged by Roy Wagner (2009, 2010) in his detailed semiotic study of Gödel's proofs of the first incompleteness

theorem. Wagner discussed the imperatives both explicit and implicit in the text, and incorporated these into a nuanced picture of the mathematical subject, agency, and the relationship these have to a mathematical text. One major difference from our findings below is that Wagner finds very few explicit imperatives:

> First, there are very few imperatives in these texts. Perhaps the imperative mood was considered ill-suited for civilised written communication in the Vienna and Princeton circles. Perhaps it never occurred to writers in these circles to dominate a mathematical text with the imperative mood. Instead of imperatives, we have the frequent use of the indicative mood in both active and passive voices, often attributed to the character we. (Wagner 2009, p. 48)

It is notable, but maybe not surprising, that the modern writing style is different in some ways to Gödel's in the 1930s. Wagner's work also provides a nice contrast for what can be achieved with different methodological approaches: Wagner uses detailed analysis of a single mathematician's writing, while the corpus linguistics approach below looks for patterns across thousands of papers by thousands of authors.

A notable difference related to action-based vocabulary was also found by Mejía-Ramos and Inglis (2011). On a proof-evaluation task with undergraduate students, they found that changing the question from "Does the argument prove the claim?" to "Is the argument a proof of the claim?" had a significant impact on how the students evaluated a specific visual argument. The students were more willing to agree that the argument proved the claim than that it was a proof for the claim. The researchers built the case that the verb form was more connected to judgments of conviction, while the noun form was more connected to judgments of validity. They related this to issues of semantic contamination: where the everyday meanings of words affect our understanding of them in more formal and technical settings like mathematics (cf. Tanswell 2018, Sect. 4).

As a final example, Lew and Mejía-Ramos (2019) investigated the norms of mathematical writing by testing the reactions of mathematicians and students to cases where those norms were flouted. One of their stimuli was an ill-formed imperative: "Suppose $(S \cdot R)^{-1}$ such that [...]." They found that professional mathematicians especially responded very negatively to the ungrammatical phrasing of this. For the mathematicians, imperatives must be used correctly and grammatically, and they appear to have strong conventions on how that is achieved. In contrast, students often did identify that the construction didn't sound right but could not clearly express why (Lew and Mejía-Ramos 2019, p. 134).

From a different direction, Paul Halmos (1970) provided a classic style guide for mathematics and discussed both imperatives in maths and the use of the first-person plural "we." Regarding imperatives, he said: "A frequently effective and time-saving device is the use of the imperative. 'To find P, multiply q by r.' 'Given p, put q equal to r.'" (Halmos 1970, p. 141).[5] He also proceeded to explain using the first-person plural to convey instructions on how a proof goes:

[5] Somewhat amusingly, the immediately prior sentence is: "Most (all?) mathematical writing is (should be?) factual; simple declarative sentences are the best for communicating facts." (Halmos 1970, p. 141).

> There is nothing wrong with the editorial "we", but if you like it, do not misuse it. Let "we" mean "the author and the reader" (or "the lecturer and the audience"). Thus, it is fine to say "Using Lemma 2 we can generalize Theorem 1", or "Lemma 3 gives us a technique for proving Theorem 4". (Halmos 1970, p. 141)

Indeed, it is discussions of the first-person plural "we" that are found most often in mathematical style guides. For example, Krantz likewise stated that "The custom in modern mathematics is to use the first person plural, or "we." It stresses the participatory nature of the enterprise, and encourages the reader to push on." (Krantz 1997, p. 33). A similar point was made by Knuth et al. (1989, p. 2).

3.2 Formalised Mathematics

There is a large area of research dedicated to formalised mathematics, where the central goal is to provide formalised counterparts of informal proofs that can be formally verified in one of the proof-checkers, such as Lean, Coq, Mizar, or Isabelle. Standardly, these come with their own language, software, and libraries of completed formal proofs that can be called on in later proofs. There are two obvious goals to this formalisation project: firstly, to check the existing mathematical literature, and secondly, to develop software that can assist mathematicians in new work.

Especially for the second goal, it is important that the formal language used by the computer is accessible to human mathematicians. For this reason, there is some research on the language of everyday mathematics focusing on how to formalise it. Oddly enough, researchers here sometimes seem to downplay the significance of imperatives in proofs. We look at three examples of work in this area, and what they say with regard to imperatives in mathematical writing.

The oldest we consider is the work of de Bruijn (1994). His goal was to set out the "mathematical vernacular," which is meant to be the native language of mathematics, described as "[...] the very precise mixture of words and formulas used by mathematicians in their better moments" (de Bruijn 1994, p. 865). This is immediately contrasted to the "official," purely formal language of mathematics. De Bruijn then claimed that this mathematical vernacular is in essence the same as the rigorous part of mathematics:

> Roughly speaking, the [mathematical vernacular] part of a piece of mathematics will be the rigorous part. (ibid., p. 867)

This is then used to exclude various common parts of mathematical texts from the mathematical vernacular as he sees it, such as historical remarks, textual signposting, references to the syntactical form of the presented equations, and indications of how to reproduce omitted material. Included in this list is "Commands, like `show that'." (ibid., p. 867). Hereby de Bruijn excludes imperatives from the domain of rigorous mathematics.

This exclusion is also present in the book *The Language of Mathematics* by Mohan Ganesalingam (2010). The purpose of the book was to analyse the language used in

mathematical texts in keeping with a broadly generative tradition, to give a formal, objective, and precise syntactic structure and associated semantics. Ganesalingam said that he will restrict himself to the language used in "more rigorous, careful textbooks" (ibid., p. 7) and only the part in the *formal mode*, where "[a] sentence is in the formal mode if and only if it consists only of assertions about mathematical objects and about mathematical facts, so that its semantic content is purely truth-conditional and can be completely captured in an appropriate logic" (ibid., p. 7). This clearly precludes imperatives, since they are not assertions, nor do they have a purely truth-conditional semantics.[6] Ganesalingam thus stated that:

> [T]he language of mathematics consists purely of assertions about mathematical objects. As a result, textual mathematics predominantly uses the third person singular and third person plural, to denote individual mathematical objects (or propositions) and collections of mathematical objects (or propositions) respectively. The first person plural ('we') is also used in a more restricted capacity, with a limited and potentially closed class of verbs, typically to refer to the mutual intent of the author and reader. (ibid., p. 21)

This seems to allow constructions similar to imperatives (e.g., "We suppose," "We assume," "We obtain," etc.) but not the imperative forms ("Suppose," "Assume," "Obtain"). Of course, if we restrict ourselves to the formal mode, which by definition is exclusively about mathematical assertions, then the absence of imperatives must follow. Nonetheless, this doesn't justify these bolder claims about *the language of mathematics* being limited to this class of sentences, nor even claims about rigorous textbooks.[7]

Below we will demonstrate that imperatives are present in mathematical writing as found on the *arXiv*. Whether any given article on the *arXiv* is part of rigorous mathematics or not must surely be debatable, but there is no doubt that such a corpus must represent a collection of paradigm examples of the language of mathematics.

In contrast to de Bruijn and Ganeslingam's claims about rigorous mathematics, formalised mathematics does not need to exclude imperatives. Here is an example of a simple proof in Lean[8]:

---

[6] The formal mode is contrasted with the *informal* mode: "The informal mode consists of commentary on the ongoing mathematics. Individual sentences in the language of mathematics tend to be either entirely formal or entirely informal, though there are exceptions. It is worth noting that mathematicians have very strong intuitions about the distinction between these two modes." (p. 7). Below we show that imperatives are a part of normal mathematical language, but it bears emphasising that no evidence is provided for the existence or reliability of these intuitions, and even if mathematicians do have robust intuitions about the difference between doing the mathematics and commentary on it, that does not necessarily align with the characterisation he gives of the difference between the formal and informal modes.

[7] A similar criticism can be levelled concerning another exclusion: that of *modality* in mathematics. Ganesalingam said: "[...] textual mathematics is much more restricted than natural language. [...] Mathematical truths are true in all possible worlds, and therefore there is no modality." (pp. 22–23). However, Hodges (2013) demonstrated that there are many uses of modals in mathematical writing but that these don't refer to metaphysical necessity and possibility.

[8] This example is taken from https://leanprover.github.io/introduction_to_lean/ written by Jeremy Avigad, Gabriel Ebner, and Sebastian Ullrich (Accessed 11/02/2021).

```
theorem even_add : ∀ m n, even m → even n → even (n + m) :=
  take m n,
  assume ⟨k, (hk : m = 2 * k)⟩,
  assume ⟨l, (hl : n = 2 * l)⟩,
  have n + m = 2 * (k + l),
  by simp [hk, hl, mul_add],
  show even (n + m),
  from ⟨_, this⟩.
```

The details of how the system works are not important here; all we need is to see the imperatives at work in the proof. What is remarkable is that the imperatives serve the dual functions of both acting as imperatives in a proof in the sense outlined above for the human mathematician, and acting as imperatives as commands for the computer (in the imperative programming tradition).

The system Naproche-SAD (De Lon et al. 2020) similarly incorporates many imperatives into its "controlled natural language," a fact notable because of the system's explicit aim to emulate normal mathematical language. Here is an example of Naproche-SAD text taken from Frerix and Koepke (2018, p. 3):

Theorem 1 *Assume f is holomorphic and the domain of f is a region. If f has a local maximal point then f is constant.*

Proof *Let z be a local maximal point of f. Take ε such that Bε(z) is a subset of Dom(f) and |f[w]|≤|f[z]| for every element w of* $B_\varepsilon(z)$*. Let us show that f is constant on* $B_\varepsilon(z)$*. Assume the contrary. Then* $f[B_\varepsilon(z)]$ *is open. We can take δ such that* $B_\delta(f[z])$ *is a subset of* $f[B_\varepsilon(z)]$*. Therefore there exists an element w of* $B_\varepsilon(z)$ *such that* $|f[z]|<|f[w]|$*. Contradiction. end. Hence f is constant.*

Again, observe the natural use of imperatives to construct the proof here. The creators of *Naproche* are amongst a relatively small set of researchers who also use linguistics to study mathematical language, and we hope that our empirical work below will support its further development.

4 A Corpus Linguistics Study

4.1 Corpus Linguistics

The driving idea underlying the philosophy of mathematical practice is to ensure that our philosophical claims about mathematics are true and accurate of real mathematics, not just some idealised version of it. This means that we need to give empirical grounding to any factual claims about mathematical practice that we rely on (e.g., Aberdein and Inglis 2019). In this chapter, we are focused on the language of mathematics, and especially on the language used in proofs. In our review of the literature, however, the main evidence used by previous authors is their own experience as mathematicians (e.g., Ganesalingam 2010) or the detailed analysis of isolated

texts (e.g., Wagner 2009, 2010). Here, we take a very different approach: we examine a large number of mathematics texts using the tools of corpus linguistics.

A corpus in this sense is a substantial body of texts that are machine-readable to allow for computational analysis. In our case, we are using the corpus assembled by Alcock et al. (2017) and used by Mejía-Ramos et al. (2019) in their study of language relating to explanation in mathematics. The corpus is made up of all of the papers uploaded to the arXiv in the first 4 months of 2009 to the *Mathematics* category. The arXiv is an online repository for texts from mathematics, physics, computer science, and various related disciplines, which acts as the main preprint server for large sections of research mathematics, especially in English-speaking mathematics communities. Many mathematicians upload copies of their academic papers as preprints to make them freely accessible online. There is a level of selection before papers can appear on the arXiv, partially moderated by volunteered and partially by an automated system, and the assigned category for the paper does have social implications, as described by Reyes-Galindo (2016).

Texts on the arXiv are predominantly written in the TeX/LaTeX mark-up language, then compiled into pdf format. In order to process these into a form useable for computational linguistics (plain texts without extraneous code), the texts were processed to strip out the TeX/LaTeX code while preserving the structure of the written language, as described by Mejía-Ramos et al. (2019, p. 249–250).[9] This posed the challenge of what to do with inline mathematics, such as "Let f: X →Y be a bijection." The problem is that the same mathematics can be coded in many different ways in LaTeX, which speaks against leaving the code as is because the linguistics software would not be able to identify the different codes as representing the same syntactic unit. However, simply removing it would interfere with some of the linguistics tools (measuring word proximities, for example). As such, they opted to replace all inline mathematics with the tag "inline_math." For the above example, this gives us "Let inline_math be a bijection." The result of this processing is sufficient for our needs too because we are interested in the natural language components and not the mathematical content.[10]

In total, the corpus then contained 6,988 files and 30,892,695 words of mathematics (with 231,400 distinct words). As a useful subset of this for our purposes, we also have a corpus that is made up of only the proofs found in these papers, containing 3,268 files and 4,973,892 words of mathematics (with 48,025 distinct words).[11] This will allow us to focus specifically on the mathematical writing found

[9] This process was automated, and Chris Sangwin has made the code available online at https://github.com/sangwinc/arXiv-text-extracter (accessed 23/02/2021).

[10] The decision of how to treat the mathematical content of the papers does affect the kinds of results we get. If we were to instead convert mathematical content to verbalised counterparts (i.e., x^2 + 5 becoming "x squared plus five"), this would lead to different frequencies, and "dilute" the natural language parts in the corpora. However, there is certainly no unique or uncontroversial algorithm for this process of verbalisation, so our approach here is the pragmatically obvious one.

[11] Selected automatically, using everything between "\begin {proof}" and "\end{proof}." This is the most common way to write proofs but may have left out a small minority of written proofs coded differently.

in written proofs in these papers. Simple subtraction then also lets us compare the proof-only corpus to the non-proof parts of the mathematical texts. The non-proof part therefore contains 25,918,803 words. Henceforth, we refer to the main corpus as the *All-math* corpus, and the proof only part as the *Proof-only* corpus, and the result of subtracting the *Proof-only* from the *All-math* will be called the *Non-proof* corpus.

Something important to be sensitive to in analysing these texts is how representative they are of textual mathematical proofs more generally. Since the arXiv is the standard repository for preprint papers for many mathematical researchers, we do take it that the corpus is fairly representative. However, this must come with some caveats. The first is the most obvious: we are conducting this research in English, and so our results apply to mathematical texts written in English. They may still be applicable to nearby languages, where we believe many similar linguistic conventions apply for mathematical writing, but the current study would not reveal that. Secondly, language and other factors will in turn affect who submits their papers to the arXiv, and there are obvious demographic and geographic biases likely to arise in whose work we are seeing.[12,13] Thirdly, since these are preprint articles primarily from professional mathematicians, the mathematical language we are analysing is theirs and not, say, that of mathematics students or teacher, nor the language used in proofs in maths textbooks or other media (such as spoken proofs, or proofs on blackboards in seminars). Finally, the papers are all from 2009 and so represent a snapshot of proof writing from that year.[14] We do not believe there has been any substantial change since then, but writing and presentational styles are always changing to some degree. Obviously, the results of our study will not immediately generalise to historical mathematical writing either.

4.2 Hypotheses

Based on the previous sections, we can form various hypotheses about the prevalence of instructions and imperatives in our corpus.

In the literature from mathematics education and philosophy, we saw that the researchers like Pimm (1987), Rotman (1988, 1993), Morgan (1996), and Ernest (1998, 2018) broadly claimed:

[12] The arXiv themselves do have various statistics about submissions and downloads at https://beta.arxiv.org/help/stats (accessed 23/02/21), but these do not include demographic or geographic data.

[13] For more on how social features of mathematics can involve epistemic exclusion, see Rittberg et al. (2018) and Tanswell and Rittberg (2020). Indeed, Reyes-Galindo (2016) examines how the automated filtering of the arXiv is partially based on linguistic analysis, and can lead to the exclusion of certain researchers.

[14] They are also from only the first 4 months of 2009. We do not believe that the time of year makes a significant difference to writing styles, though it is possible it affects the demographics of who is submitting their papers to some small degree.

(H1): Imperatives are common in mathematical proof texts.

The recipe model of proof also predicts that (H1) will hold.

In the works of De Bruijn (1994) and Ganesalingam (2010), however, the opposite claim was made regarding imperatives. They saw rigorous proofs as only containing assertions about mathematical objects. So, the opposite hypothesis can be considered:

(H2): There are no imperatives in mathematical proof texts.

The recipe model of proof will predict that (H2) will not hold.

Next, consider the first-person plural in mathematics, which we saw was mentioned in various style guides for mathematics. This can be used with the same verbs to form "We [verb]..." sentences, which can potentially also be used to give instructions for the reader to follow. We will test how common this is as the following hypothesis:

(H3): The construction "We [verb]..." is common in mathematical proof texts.

The recipe model of proof again predicts that (H3) will hold.

Ganesalingam did note the use of the "We [verb]..." constructions (like "We suppose...," "We assume..." etc.) but states that they are only used for a "limited and closed class of verbs." Generalising to cover imperatives too, and putting this as a hypothesis:

(H4): The verbs used in imperatives and the "We [verb]..." constructions in mathematical proof texts are drawn only from a limited and closed class of verbs.

On the recipe model of proofs, proofs contain many instructions (be they explicit or implicit), and therefore the more diverse the selection of verbs the better for the model. As such, the recipe model of proofs predicts that (H4) does not hold.

In sum, (H1) and (H2) are about the *frequency* of imperatives in mathematical texts, while (H3) is about "We [verb]..." constructions. The hypothesis (H4) is about the *diversity* of verbs used to form mathematical imperatives. We believe that both of these can be used in mathematical texts to give instructions so will investigate both below.

4.3 Methods

We used Laurence Anthony's *AntConc* software (Anthony 2020) and Yasu Imao's *CasualConc* software (Imao 2018) to analyse the corpora.[15]

[15] The *AntConc* software is available online at https://www.laurenceanthony.net/software/antconc/ (accessed 24/02/21) and *CasualConc* is available at https://sites.google.com/site/casualconc/ (accessed 06/03/21).

We had two primary targets for investigation from our hypotheses: explicit imperatives and "We [verb]" constructions. Both of these have textual markers that we could use. For explicit imperatives, we could perform a case-sensitive search for capitalised verbs, as this is a reasonable and conservative operationalisation that will capture many imperatives (e.g., "Let...," "Assume...," "Suppose...," and "Construct..." all are formed with a capitalised verb to start the imperative sentence.) A drawback of this is that it will miss any imperatives constructed in different ways, such as "Firstly, suppose...," but we did not have a systematic way to predict the idiosyncratic ways sentences may be constructed, and we believe that missing these did not alter our findings. For "We [verb]" constructions, the software allowed us to search for these strings directly.

For both explicit imperatives and "We [verb]" constructions, we needed to identify the specific verbs we will investigate in the first place. We required some way to select these systematically, but the verbs most likely to be used in mathematical imperatives are typically mathematical keywords; we shouldn't expect, for instance, that common mathematical imperatives would use the same verbs as imperatives in general English, so couldn't use that as a guide. To solve this, we produced a list of the 500 most common words in the *All-math* corpus and selected all of them that can ever be verbs in English. This gave a total of 91 possible verbs, listed in Table 1. One obstacle we faced was that many of the words have multiple meanings, for example, the word "set" is ambiguous between the verb form and the noun form and is used in both senses in the corpora. The same held for many of the terms for mathematical objects, such as "group," "ring," "field," and "structure." A second obstacle is that some of these words were extremely unlikely to be used as verbs in the current context, such as "stable," "like," and "hand." Finally, some of the verbs have existing functions in mathematics papers, such as "claim," "step," and "remark."

To separate out the verbs used as imperatives in the corpus, we generated a file for each of the 91 verbs containing all capitalised instances of that verb in the *All-math*

Table 1 The 91 potential verbs among the 500 most common words in the *All-math* Corpus

Action	Construct	Free	Lie	Order	Satisfy	Step

corpus and their contexts (which shows six words either side of the verb). For example, an entry from the file for the verb "choose" is:

```
     [circle of a copy of inline_math.  Choose a base point
inline_math on inline_math,]
```

By examining these files, we separated the 91 verbs into three classes: (1) those where the capitalised form was used exclusively (or almost exclusively) as an imperative; (2) those where there was a mixture of imperatives and other uses; and (3) those where there were no imperatives. Separating the verbs into the three lists using the context files gave us the three categories reported in Table 2.

From here, we performed a selection of analyses using the corpus linguistics software, reported below.

4.4 Results

4.4.1 Comparing Imperatives in the *Proof-Only* and *Non-Proof* Corpora

To test (H1) and (H2) on explicit imperatives, we compared the frequency (per million words) of the capitalised verbs in our *Proof-Only* and *Non-Proof* corpora. We used only the verbs from the first category of Table 2 so that our operationalisation of using capitalised verbs to track sentences in the imperative mood will be accurate. Recall that the third category contained no imperatives, and the second category contained a mixture of imperatives and non-imperatives, which would interfere with the goal of the study. The results are displayed in Table 3. What we see is that the total frequency per million words for our selected verbs is 9406 in the *Proof-only* corpus and 6854 in the *Non-proof* corpus, a highly significant difference, Fisher's exact test, $p < 0.001$.

These results demonstrate that imperatives using common mathematical verbs appear more commonly within proofs than outside of proofs. If mathematical texts

Table 3 Comparing imperative frequencies per million words in the *Proof-only* and *Non-proof* corpora

Verb	Proof-only	Non-proof
Let	4523	4035
Suppose	944	512
Note	929	681
Consider	570	314
Assume	556	339

Conclude	0	0
TOTAL	9406	6854

outside of proofs, as in the *Non-Proof* corpus, are a reasonable baseline for imperatives in mathematical writing, then these results provide evidence for (H1) and against (H2).

The results here also show major variation in the prevalence of imperatives using different verbs. By far the most common is the imperative using "Let," followed by "Suppose" and "Note," then by "Consider" and "Assume." The imperatives using "Recall," "Define," "Fix," "Denote," "Observe," "Choose," "Take," and "Write" were also relatively common. Other capitalised verbs we searched for were all present to some degree but were less common overall. The only three capitalised verbs that showed up as a higher frequency per million words in the *Non-Proof* corpus were "Show," "Prove," and "Conclude."

4.4.2 Comparing "We [verb]..." Constructions in the *Proof-Only* and *Non-Proof* Corpora

To test (H3) concerning the "We [verb]..." constructions, we took all 91 of the (possible) verbs from the top 500 most common words in the *All-math* corpus (i.e., all of the verbs found in Table 1) and looked for the "We [verb]" string in the

Table 4 Comparing "We [verb]" construction frequencies per million words in the *Proof-Only* and *Non-Proof* Corpora.

			TOTAL	2923	2522

Proof-Only and *Non-Proof* corpora. We made this case-sensitive to only look at instances where the "We" is capitalised, thus indicating the start of a sentence. The results are reported in Table 4.[16]

[16] We have omitted all the verbs that returned no results. As such, the zero entries that do appear in the table are the result of rounding.

The results here are more mixed than in the previous section. The two biggest entries are from "We have" and "We will," used to form the past and future tenses, so they are not in and of themselves giving implicit instructions, but could be used that way. Especially "We have" has a diverse range of potential uses: it could describe carrying out an action in the past tense, as in "We have applied...," or can be used to summarise as in "We have seen...." It can be used in the present tense to emphasise tools, facts, or mathematical objects at our disposal at that point in the proof, as in "We have that...." It can also be used to point forwards to set a shared target, as in "We have to [achieve some goal/carry out some procedure/etc.]." These constructions can also be used in the abstracts of the papers, describing what the authors do in the paper, in which case the "we" is not being used to include the reader, unlike within a proof. Examining the corpus revealed examples of all of these constructions.

While the totals overall again find more "We [verb]" constructions in the *Proof-Only* corpus than the *Non-Proof* corpus (and this difference is again significant, Fisher's exact test, $p < 0.001$), most of the difference can be accounted for just by the "We have" construction, which we just noted can be used in a variety of ways, and so does not tell us much about instructions being issued.

Looking more at the specific verbs, the more common imperatives we found above do not appear to be anywhere as common in the "We [verb]" form: none of the verbs used in the thirteen most common imperatives appear in this form more than 100 times per million words in the *Proof-Only* corpus. Nonetheless, several other verbs are more common in this form, especially "We claim," "We conclude," "We prove," "We show," and "We use." What is notable about these constructions is that they appear to be more structural than the verbs we found as imperatives, in that they are used to structure where the proof is aiming to get to, or (in the case of "We use") what method or fact will be employed to get there.

With regard to (H3), we did find plenty of "We verb" constructions in the *Proof-Only* corpus, suggesting that they are not uncommon, but we also didn't find them to be overall more common than in the more general mathematical texts, as represented by the *Non-Proof* corpus. The lack of more substantial finding here may be because of the restriction to the start of a sentence, as identified with starting capital letters. We will return to this concern in Sect. 4.5 and look at these constructions in an example from the corpus.

4.4.3 Imperative Frequency in *Proof-Only* Files

In Sect. 4.4.1, we tested (H1) and (H2) by looking at the frequency of imperatives in proofs relative to their frequency in mathematical texts outside of proofs. To provide another angle on how common imperatives are, we now investigate the percentage of files they appear in. Recall that our *Proof-Only* corpus consists of 3,268 files. A file in our corpus contains all of the proofs from one file uploaded to the arXiv. Barring a minor complication, we can thus take this to give us a representation of

what percentage of papers that contain proofs at all also contains a given imperative somewhere in those proofs.[17]

Once again, to look for imperatives we searched for the capitalised verbs from the first category in Table 2 using a case-sensitive search such that, for example, it will count "Consider" and "consider" separately.

The results are found in Table 5 in the left columns. To put the percentages in some context, we have included an arbitrarily selected word which appears in a similar percentage of the papers, listed on the right.

The results agree with the findings from Sect. 4.4.1, with the same set of verbs serving most often as imperatives in proofs. The results also show that these

Table 5 Number of and percentage of files in the *Proof-Only* corpus containing the capitalised verb, alongside other keywords appearing at a roughly similar frequency for reference

Verb	Number of files	% of files	Nearby word	Number of files	% of files
Let	2692	82.4%	then	2706	82.8%
Note	1486	45.5%	function	1477	45.2%
Suppose	1250	38.3%	thus	1274	39.0%
Consider	1186	36.3%	So	1186	36.3%
Assume	1085	33.2%	bounded	1053	32.2%
Recall	844	25.8%	know	843	25.8%
Define	712	21.8%	simple	722	22.1%
Fix	606	18.5%	action	598	18.3%
Choose	541	16.6%	length	553	16.9%
Denote	538	16.5%	precisely	544	16.7%
Take	459	14.1%	always	465	14.2%
Observe	447	13.7%	less	455	13.9%
Write	343	10.5%	derivative	348	10.7%
Apply	173	5.3%	block	173	5.3%
Use	104	3.2%	convenient	122	3.7%
Call	57	1.7%	congruent	54	1.7%
Introduce	44	1.4%	Lagrangian	42	1.3%
Construct	34	1.0%	walk	32	1.0%
Say	27	0.8%	adopt	27	0.8%
Check	7	0.2%	Nash	7	0.2%
Show	5	0.2%	Method	5	0.2%
Prove	5	0.2%	functionally	5	0.2%
Obtain	2	0.1%	unpruned	2	0.1%
Conclude	1	0.0%	Hamiltonianly	1	0.0%

[17] The minor complication is that if a paper was uploaded as multiple files, then it will remain as multiple files in our corpus. However, only files containing proofs at all will be included in the corpus, which reduces the frequency of this. Only a small minority of the files were uploaded this way, and this is conservative such that the effect on our results is that the percentage of files we report is a slight underestimate of the percentage of papers a given word appears in.

imperatives are not only common relative to non-proof mathematical texts, but also common in general, appearing in a substantial proportion of the files of the corpus, and therefore in a substantial percentage of the papers containing proofs.

4.4.4 Imperative Diversity

Our final hypothesis (H4) concerned the diversity of verbs used in imperatives and "We [verb]" constructions in mathematical proofs, alluding to Ganesalingam's claim that they are drawn only from a limited and closed class of verbs. Our more fine-grained results from the previous sections already address this hypothesis to some degree.

Of course, the truth of (H4) depends on what that class is. For example, the English language is finite, so on one reading the claim could be trivially true. We propose that a natural reading of Ganesalingam (2010) in light of our results would be to have the "limited and closed class of verb" be those that we found to be most common in Sects. 4.4.1 and 4.4.3, namely, "let," "consider," "assume," "denote," "note," "define," "suppose," "recall," "write," "take," "choose," "fix," and "observe." From our results in the previous sections, then, it is correct to say that a large number of the instructions in proofs are given with these verbs. This is clearer in the case of imperatives from Sects. 4.4.1 and 4.4.3, but also occurs in the "We [verb]" constructions.

However, the hypothesis of (H4) states that these verbs are the *only* ones used in instructions given by imperatives and "We [verb]" constructions. Above, we found many other instances of verbs being used both as imperatives and in "We [verb]" constructions. Here, we offer two more pieces of evidence for there being a diverse number of instructions issued in mathematical proofs.

First of all, in Sect. 4.3 we set aside 22 of our 91 verbs because in the *All-Math* corpus they were used in their capitalised form both as imperatives and in some other ways, which would have obscured the above studies. These were the verbs listed in the middle column of Table 2. Returning to these verbs, we searched for them in their capitalised forms in the *Proof-Only* corpus. Of these, 16 returned results that were clearly imperatives.[18] For each of these, we selected a clear example, displayed in Table 6. Given that these examples sound like normal written mathematics, this demonstrates further diversity of the verbs used as imperatives in the *Proof-Only* corpus.

The second way we chose to look at the diversity of verbs used as imperatives in proofs was using the mathematical verbs listed by Rotman in the quote in Sect. 3.1. We omit all of those that overlapped with the previous analysis. Like in Sect. 4.4.1, we compared the frequency per million words of the capitalised versions of the verbs between the *Proof-Only* and the *Non-Proof* corpora. The results are displayed in

[18] We avoid giving the numbers of imperatives because not all of the cases were clear, and mostly the numbers were low. That is not important, though, as here we are interested in diversity of imperatives rather than the frequency.

Table 6 Examples of imperatives from the *Proof-Only* corpus for the verbs found in the middle column of Table 2

Verb	Example
Set	Set the total degree equal to the sum of the bidegrees.
Group	Group the non-constant linear generators of inline_math so that [. . .]
Map	Map this product to a neighborhood inline_math of the torus knot as follows [. . .]
Form	Form the commutative cube in which the front and back faces are pullbacks, so that [. . .]
Order	Order the eigenvalues of inline_math so that the inline_math eigenvalue of the spectrum of inline_math is [. . .]
Number	Number the elements of inline_math.
Get	Get rid of the self-intersection as before to obtain as before.
Give	Give the knot inline_math an orientation inline_math.
Find	Find a partition of unity inline_math on inline_math subordinate to the cover inline_math.
Sum	Sum the estimates in the previous corollary.
Do	Do the above coarsening process for every element inline_math with inline_math.
Complete	Complete this elimination process, ending with inline_math.
Pair	Pair these elements and return to inline_math and repeat the process, skipping over any letters already paired.
Estimate	Estimate the difference on the right hand side of [. . .] by the triangle inequality to find [. . .]
Study	Study the case inline_math.
Factor	Factor inline_math as a product of prime ideals inline_math in inline_math.

Table 7. These verbs appeared significantly more often per million words in proofs than outside of proofs, Fisher's exact test, $p = 0.006$.

One striking feature here is that the verbs suggested by Rotman are orders of magnitude less common than those selected by our method above, suggesting that while these may be mathematical words broadly speaking, they are not particularly common ones. More importantly for (H4), we did find that many of them were present as imperatives in our *Proof-Only* corpus. Once again, this result suggests that many more verbs are amenable to being used as imperatives in mathematical proof texts. We thus reject (H4), as the class of verbs does not appear to be closed or limited.

4.5 An Example

It is easy to lose oversight of what these results look like in practice. To address this, and provide some reflection on the methodological choices made above, we will now demonstrate the use of imperatives and instructions in our corpus with an illustrative example. We will look at the preprint of the paper by Mazzeo and Rowlett (2015), selected as the chronologically first paper in our corpus to contain at least one proof.

Table 7 Comparing the Rotman verb imperative frequencies per million words in the *Proof-Only* and *Non-Proof* Corpora

Verb	Proof-only	Non-proof
Add	2.01	2.28
Adjoin	0	0.08
Assign	1.81	1.12
Calculate	0.80	1.50

Multiply	7.84	0.93
Reverse	0.20	0.58
Specify	0	0.46
Subtract	1.21	0.12
TOTAL	27.74	21.22

Here is an excerpt from the introduction section of the paper. This contains three imperatives ("For simplicity, suppose," "Let," and "Note") of which our analysis using capitalisation would have found two. There are also two "We [verb]" constructions ("We now explain" and "We assume"), of which we would have found one. Interestingly, in the context of an introduction, the "We [verb]" phrases are not acting to include the reader in epistemic actions but instead are simply describing what the authors are doing. What is also noteworthy is that this paragraph is relatively high in instructional language, but is also *proof-like* in the sense that it is describing a piece of mathematical reasoning. Looking further through the paper, this seems to be the case for a large number of the imperatives being used. Direct imperatives appear in theorem statements, lemma statements, numbered remarks, and in the long paragraphs of description of mathematical reasoning. Since our analysis placed all of those in the *Non-proof* category, the results we have described are likely to understate the extent to which imperatives are characteristic of proofs in research papers, since this style of proof writing can spill over into the surrounding text (Fig. 1).[19]

[19] Our thanks to a referee for pushing us to be explicit about this important point.

We now explain the desingularization more precisely. For simplicity, suppose that Ω_0 and Ω_ϵ all lie in some slightly larger ambient open surface $\widetilde{\Omega}$, and that the metrics g_ϵ on Ω_ϵ are all extended to metrics (still denoted g_ϵ) on this larger domain. We assume that this family of metrics converges smoothly on $\widetilde{\Omega}$. Let p be a vertex of Ω_0 and consider the portion of Ω_ϵ in some ball of fixed size around p, $B_c(p) \cap \Omega_\epsilon$. Our main assumption is that the family of pointed spaces $(B_c(p) \cap \Omega_\epsilon, \epsilon^{-2} g_\epsilon, p)$ converges in pointed Gromov-Hausdorff norm, and smoothly, to a noncompact region $Z \subset \mathbb{R}^2$ with smooth boundary, such that at infinity, ∂Z is asymptotic to a cone with vertex at 0 and with opening angle α, the same angle as at the vertex p in (Ω_0, g). Note that this is actually pointed Gromov-Hausdorff convergence for the ambient space $(\widetilde{\Omega}, g_\epsilon, p)$.

Fig. 1 An excerpt from the introduction of Mazzeo and Rowlett's (2015) preprint

Proof of Theorem 1.6: We first construct a particular family of parametrices for the heat kernel on Ω_ϵ. For any $0 \leq \epsilon < \epsilon_0$, decompose

$$\Omega_\epsilon = \Omega_{\epsilon,1} \cup \Omega'$$

where $\Omega_{\epsilon,1} = \Omega_\epsilon \cap B_1(p)$, and $\Omega' = \Omega_\epsilon \setminus (\Omega_\epsilon \cap B_1(p))$. Note that Ω' is independent of ϵ. Lemma 2.2 shows that

$$H^{\Omega_\epsilon}(t,z,z) = \chi_1(z) H^{\epsilon Z}(t,z,z) + \chi_2(z) H^{\Omega_0}(t,z,z) + K(t,z), \qquad (3.1)$$

Fig. 2 An excerpt from the proof of Theorem 1.6 of Mazzeo and Rowlett's (2015) preprint

The first substantial proof is of Theorem 1.6, which spans over several pages. The opening lines of this proof can be seen in Fig. 2.

The proof contains eight direct imperatives (using the verbs "decompose," "note," "write," "set," "choose," and "let"), of which our analysis would have found five. In fact, we have not looked for imperatives using the verb "decompose" above, so this reinforces our finding of diversity of imperative phrases. The proof also contains ten instances of using "we" with a verb to indicate activities (using the verbs "construct," "denote," "see," "defer," "examine," "write," "prove," "appeal," and "find"). Surprisingly, only two of these were in the exact "We [verb]" form, and most were embedded in much more complicated sentence structures. This is coherent with our analysis that we did find "We [verb]" phrases in both the *Proof-only* and the *Non-proof* corpora but suggests that further analysis might reveal a richer picture. Indeed, this proof also contains several phrases that suggest epistemic and mathematical actions in other ways: "For that, we may as well replace the upper limit of integration by [...]," "To finish the proof, we must analyze the behaviour of [...]," and "The decay of each of term as $|\lambda| \to \infty$ is straightforward, so we can write [...]."

These three all make use of modal language, something examined by Hodges (2013). Computational corpus linguistics may be a suitable method for capturing these more complex constructions, but would require more advanced tools than we have used here.

We also note that at the time of writing, Keith Weber (submitted) has carried out a smaller scale analysis of the use of instructions and imperatives, examining the entirety of Kunen's classic textbook *Set theory: An introduction to independence proofs* (1980). This will provide a useful piece of methodological triangulation for our results, something which Löwe and Van Kerkhove (2019) have argued is centrally important for empirical approaches to mathematical practice. While our computational analysis allows us to examine trends across a large number of papers, Weber's approach does not rely on automation and thus allows him to find and analyse instructions our methods wouldn't catch. Indeed, Weber is able to carry out an interesting investigation of the different kinds and functions of instructions he finds, providing different insights into the instructional language of proofs. Nonetheless, Weber's results largely confirm our results, finding both a high frequency and broad diversity of instructions and imperatives in Kunen's text. There are some differences in the exact distribution of the imperatives he finds, but this is easily explained by the fact that this is a single author with certain stylistic preferences. In light of Weber's work, we can feel more confident that the various small methodological choices we have made above have delivered reliable results.

5 Conclusion

Our analysis of the language used in a large number of mathematics papers allows us to make empirically informed contributions to the philosophy of mathematical practice, and especially questions concerning the nature of real, modern mathematical proofs. We now relate our findings to the philosophical debates discussed earlier in the chapter.

Recall that we were interested in the recipe model of proofs, which tells us that proofs are akin to recipes, commanding that we undertake various kinds of mathematical actions to perform a piece of reasoning. These actions were not limited to inferential actions, but also include constructing and manipulating mathematical objects, fixing notations, entertaining hypotheticals, structuring their reasoning, and more besides. Viewing proofs in this way has important implications for understanding the nature of proofs, the epistemology of proofs, the functions of proofs, how to best educate students to engage with proofs, and how to best integrate formal proof checkers into mathematical practice. As such, while it may appear to be a mere stylistic variation, we hold that the specifics of how proofs can be written is of substantial importance in the philosophy of mathematical practice.

Based on the recipe model, we predicted that imperatives and instructions are both common and diverse in mathematical proof texts. The results of our study certainly lend support to the recipe model because we did indeed find that imperatives and

instructions are used often and use a broad range of verbs. However, there were a core set of more common imperatives using the verbs "let," "consider," "assume," "denote," "note," "define," "suppose," "recall," "write," "take," "choose," "fix," and "observe." This core set of verbs make up the bulk of the imperatives we found in our study, suggesting that these imperatives are used in fairly standardised ways for particular mathematical instructions. Nonetheless, we found many different verbs used as imperatives in our corpus. While many of these were used less frequently, it does indicate that there is also the flexibility in written proofs to deploy a diverse selection of instructions using imperatives.

Finding broad empirical support for the recipe model of proofs is also beneficial for the epistemic picture underlying it. If proofs are giving us instructions to carry out, then mathematical knowledge is more intimately tied to knowledge-how than is standardly recognised.

Our results should also be of interest to the formal mathematics community. If part of the aim of formal proof checkers is to gain widespread use among mathematicians by making the formal tools better at reading and producing natural-sounding proofs, then we will need accurate information on how those proofs do and ought to look. The results in this chapter suggest that such natural-sounding formally-verifiable proof should contain imperatives and "We [verb]" constructions, especially those most common verbs.

We should re-emphasise a note of caution from above. Our results are for papers from the arXiv and so represent a particular kind of mathematical text. It is thus not clear whether they would generalise to other contexts, such as proofs in textbooks, classrooms, or seminars. We can speculate that journal proofs may be at the more formal end of mathematical language, and therefore we might expect greater flexibility in terms of the verbs used to form instructions in other contexts. Research articles are also a context where one assumes a great deal of competence from the reader, so we might also hope that proofs aimed more at teaching will include more imperatives as a communicative aid.

To conclude, we have made progress in investigating real mathematical proofs in a systematics and large-scale way. If we truly want our philosophy of mathematics to attend to the realities of practice, then these methods should be integral to uncovering what those realities are.

Acknowledgments Work by the first author was funded by the Research Foundation – Flanders (FWO) – Project G083620N: *The Epistemology of Data Science: Mathematics and the Critical Research Agenda on Data Practices*. We are grateful to Lara Alcock, Kristen Lew, Pablo Mejía-Ramos, Paolo Rago, and Chris Sangwin for the assembly and processing of the corpus with which we conducted this work. We would also like to thank Laurence Anthony for the creation and free distribution of the *AntConc* software with which we carried out our main analysis. Likewise, we thank Yasu Imao for the creation and free distribution of *CasualConc*, with which we carried out some subsidiary analyses. We thank audiences in Prague and online via Copenhagen for helpful feedback. We are grateful to Valeria Giardino and Roy Wagner for the careful refereeing of this chapter. We also had comments and suggestions from a large number of friends and colleagues, to whom we also extend our thanks.

Abstract

The philosophy and history of mathematical practices have brought the study of mathematical language and signs to the forefront of contemporary mathematical thought. However, despite the fruitfulness of this research trend, a comprehensive and unified account of its various aspects and the diverse approaches taken to explore it remains elusive. Recognizing this gap, we have undertaken the task of editing the present section of the Handbook of the History and Philosophy of Mathematical Practice as a much-needed remedy. Before providing an overview of the various contributions to the section, this introduction provides some context for the subject matter and a few conceptual clarifications.

1 Introduction

The purpose of the following pages is to present the section "Semiology of Mathematical Practices" in this Handbook of the History and Philosophy of Mathematical Practice (Sriraman 2020). The section provides a comprehensive account of the philosophical and historical approaches to the study of mathematical *signs* and *language* from the viewpoint of mathematical practice. Conceived as a whole, the series of contributions that make up this section demonstrate the consistency and diversity of these approaches, offering a unified yet plural perspective on this important dimension of the history and philosophy of mathematical practices.

The section is composed of nine chapters written by leading specialists, providing a rich account of the state of the art in most areas of this research field. The initial chapters present the philosophical and historical underpinnings of a practice-driven theory of mathematical signs. They are followed by compelling case studies, which demonstrate the fruitfulness of the semiological approach in analyzing the historical and conceptual aspects of mathematical practices. Finally, the section offers fresh insights into current and upcoming challenges where a theory of mathematical signs can play a critical role.

The authors of this section have done an exceptional job of enriching their unique perspectives with a comprehensive introduction to the respective topics, along with a presentation of the necessary context and conceptual tools. Consequently, attempting to provide a detailed introduction to the semiology of mathematical practices here would lead to redundancy. Instead, the goal of these pages is to offer a concise presentation of all the contributions, accompanied by a few elements of context and some conceptual clarifications that could only be addressed from the general standpoint enabled by the completed work.

2 What Do You Mean, "Semiology"?

An initial clarification is in order concerning the term "semiology." While some may find the term either unknown or outdated, it addresses a precise object of inquiry that no other alternative seems to capture entirely. At its core, semiology is the *theory of signs*. The study of signs has a rich history, stretching back to ancient medical practices where signs and symptoms were essential in diagnosing ailments. Building upon this foundation, the Stoics further developed the concept of the sign within the context of logical thought. In modern philosophy, John Locke drew upon this tradition to characterize one of the three divisions of science as "σημειωτική" (*semeiotiké*), concerned with "the nature of signs the mind makes use of for the understanding of things, or conveying its knowledge to others" (Locke 2013, p. 720). In contemporary thought, semiology has two primary roots that have significantly shaped its present understanding. One of these roots can be traced back to Charles Sanders Peirce (1839–1914) within the tradition of Boolean logic. Peirce retained the term "semiotics" or "semeiotics" to refer to the philosophical study of the semiosis process, whereby a sign, a signified object, and an interpretant

are related. Parallelly, within the linguistic tradition, Ferdinand de Saussure (1857–1913) introduced the term "semiology" as a key component of the ideas leading to the structuralist revolution in the field. At the opening of his influential *Course in General Linguistics* (Saussure 1959), Saussure stated:

> *A science that studies the life of signs within society* is conceivable; it would be a part of social psychology and consequently of general psychology; I shall call it *semiology* (from Greek *sēmeîon* 'sign'). Semiology would show what constitutes signs, what laws govern them. Since the science does not yet exist, no one can say what it would be; but it has a right to existence, a place staked out in advance. Linguistics is only a part of the general science of semiology; the laws discovered by semiology will be applicable to linguistics, and the latter will circumscribe a well-defined area within the mass of anthropological facts. (Saussure 1959, p. 16)

As Saussure explains in the passages following these lines, postulating semiology as a scientific discipline was crucial for successfully "assigning linguistics a place among the sciences" (p. 16). The reason is that a semiological approach to language seeks to determine the "true nature of language" by examining its similarities and differences with other sign systems, rather than deferring the task to the study of individual behaviors or social institutions. In this way, semiology affords the theory of language independence from fields such as psychology or sociology.

It is this specific feature that our use of the term "semiology" would like to emphasize.[1] More precisely, our choice seeks to highlight the idea that there exists a consistent region of phenomena *akin to language*, which cannot be fully understood by relying solely on current linguistic analysis without missing crucial aspects of them. Yet, attempting to approach those phenomena from extra-linguistic perspectives can lead to even worse reductions to the principles of other disciplines such as psychology, sociology, logic, biology, physics, or even mathematics. If we agree to call "*signs*" those nonlinguistic entities with language-like characteristics, the term "semiology" refers to the idea that these signs, irrespective of their connections to other domains of knowledge, are *things* that deserve independent and thorough study *in and of themselves*.

A less pedantic way of expressing the same idea is to say that the perspective adopted here considers semiology as a form of *generalized linguistics*, encompassing languages other than natural language. Hence its relevance to addressing the problem of what is usually referred to, for lack of a better expression, as *mathematical language*. Throughout its documented history, mathematical practice has employed all kinds of semiotic artifacts and principles to express the specific contents at stake. Those artifacts involved natural language in significant ways. Yet, crucially, they also transcended those resources in an equally essential manner. In its minimal expression, the idea of a semiology of mathematics is that all those expressive means and their relationship to their respective contents should be studied

[1] For a more comprehensive approach, the reader can consult Barthes (1988); Sebeok (2001); Robering et al. (1996).

as such from a perspective that leaves room to explore the similarities and differences with other linguistic phenomena.

A second point of clarification concerns the distinction between the terms "semiology" and "semiotics." While these terms are often used interchangeably, our focus on the idea of a generalized linguistic in this section motivates a slight preference for "semiology," as evidenced by our choice of the section title. Other arguments stemming from the evolution of the structuralist tradition could be also summoned. In particular, Louis Hjelmslev, following Saussure's program, offered explicit definitions precisely characterizing the relation between the two notions. In Hjelmslev (1975), we can find the following definitions for both terms:

> A *Semiotic* [. . .] is a Hierarchy, any of whose Components admits of a further Analysis into Classes defined by mutual Relation, so that any of these classes admits of an analysis into Derivates defined by mutual Mutation. (Df. 24, p. 11)

> A *Semiology* [. . .] is a Metasemiotic that has a Non-Scientific Semiotic as an Object Semiotic (Df 47, p. 15)

Although Hjelmslev's definitions may appear obscure – in particular, each capitalized expression has been previously defined in his treatise – his idea is simple: the term "semiotic" is reserved to refer to any sign *system*, while "semiology" denotes those sign systems that take other semiotics as their objects of analysis. These definitions have at least the merit of replacing the alternative between both terms with a joint and coherent characterization. In our case, this would mean characterizing mathematics as a semiotic, and our theories about mathematical signs as semiologies.[2]

However, although these and other arguments could be put forth to justify the choice of either term, it is crucial to keep in mind that our intention from the outset of this project was to take a minimalistic and nonprescriptive stance. Above all, our primary aim for this section was to enable a pluralistic approach to the study of mathematical language and signs, granting authors the freedom to expose their unique perspectives on this fundamental aspect of mathematical practices. Accordingly, we intentionally refrained from any standardization in the use of the terms "semiotics" and "semiology," nor did we encourage specific conceptual choices or theoretical preferences that the use of one term or the other might implicitly entail. Hence, as a rule, both terms are to be read as synonyms across the different chapters of this section, and any variations should be attributed to the authors' reflective choices or individual tastes.

[2] The fact that semiologies are defined as having "non-scientific" semiotics as objects should not lead us to assume that mathematics cannot be studied as a science from a semiological perspective. For Hjelmslev, a "scientific semiotic" is merely a semiotic organized as a specific analytical procedure. If mathematics were to fall into this category, its study as a sign system would be termed a "meta-(scientific semiotic)" according to Hjelmslev's view (cf. Hjelmslev 1975, Df. 41,46).

Notwithstanding the plurality of perspectives represented in this section, there is one significant feature setting the semiological standpoint apart from other philosophical approaches to language, such as logicism, or generative linguistics, with which all our authors seem to agree to some extent. This crucial aspect is the key role attributed to *practices* in the study of signs. This will come as no surprise in a Handbook on the history and philosophy of mathematical practices. However, from a semiological viewpoint, the relationship between signs and practices is not an accidental feature. Given its significance, it might be helpful to provide some conceptual insight on this point.

The emphasis on practices is a component of both the Peircean and the structuralist traditions. However, it is the latter that has given a more prominent role to it, as evidenced by the development of Saussure's semiological project within various disciplines such as anthropology, psychology, sociology, and history, each one addressing specific dimensions of human practices. Within this tradition, the notion of practice is consubstantial to that of sign. We have seen how Saussure's semiological project placed language as part of "the life of signs within a society," determining "a well-defined area within the mass of anthropological facts" (Saussure 1959, p. 16). Yet, a more systematic account of the internal connection between signs and practices is provided by Hjelmslev and Uldall. In Hjelmslev and Uldall (1936), the authors write:

> A language consists of three concentric parts [. . .]: A central part, the *system*, i.e. the elements arranged in a pattern of mutual relations; the *norm*, i.e. a set of rules based on the system and fixing the limit of variability for each element; the *usage*, i.e. a set of rules based on the norm and fixing the limit of variability tolerated in a given community at a given time. It is necessary to distinguish between language as an institution, and the use to which it is put by the individual speaker; this is called the *practice* (Saussure's *parole*). (Hjelmslev and Uldall 1936)

Figure 1 offers a possible illustration of Hjelmslev and Uldall's (1936) views. In their text, the authors propose the example of the English phoneme /r/, which, as an element of the English linguistic *system*, is defined through a complex array of oppositions with respect to all the other phonological units of the system. Yet, as well specified as this phoneme may be, it leaves significant room for variability within those limits, thus defining a *norm* for English determined by all the possibilities of pronouncing the letter *r* without it being mistaken for another element of the phonetic system. Specific *usages* of English, such as the Scottish, Victorian, or Jamaican, exploit only a restricted region of that norm. Finally, individual *practices* represent singular manifestations of those collective usages, like the unmistakable accent of Bertrand Russell. These conceptual distinctions can be easily imported into the analysis of mathematical language. An unimaginative example is provided by arithmetic, where numbers, defined as elements of a system, can be expressed in a myriad of ways without violating elementary requirements of the assumed arithmetical system. However, different historical and geographic numeral systems (Roman, Arabic, binary, etc.) restrict the variability of that norm to only a few writing usage principles, which will then be practiced by individuals in their own style.

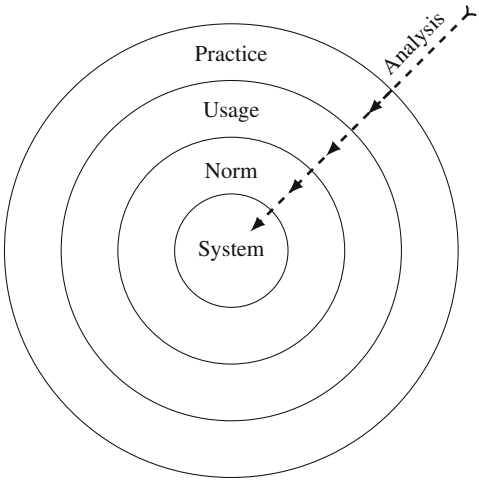

Fig. 1 Illustration of Hjelmslev and Uldall's (1936) view of semiological analysis through the various dimensions of language

Interestingly, Hjelmslev and Uldall affirm that the true object of a theory of language and signs is the exhaustive description of a language *as a system*. However, the key point is that the elements and rules composing semiotic systems *are not observable as such*. In their most fundamental nature, *languages and signs are only given in individual practices*. As long as the analysis of signs is to remain empirical, its task is to infer systematic features from idiosyncratic and constantly evolving practices. As Uldall and Hjelmslev say:

> The [. . .] system is found inductively through a series of ascending abstractions: an empirical study of the practice leads to the recognition of the usage, a study of the usage to the recognition of the norm, and a study of the norm to the recognition of the system. (Hjelmslev and Uldall 1936)

A semiology of mathematics is, therefore, inseparable from the analysis of mathematical practices, even as it aims to reveal the underlying system. Nonetheless, a semiological approach must also characterize the distinctiveness of mathematics compared to all other sign systems. In this regard, it is not impossible that part of what makes mathematical practice different from most semiotic practices is its recurrent endeavor to explicitly articulate systematic features of its own language. Admittedly, these features are themselves conveyed through signs and are, as such, the object of individual practices. Peano axioms can certainly be taken as a characterization of the *system* of arithmetic. But this cannot erase the fact that such a system is the result of multiple systematization practices (including but not restricted to Peano's), involving a complex interplay with norms and usages. What is more, the stabilization of one system cannot entirely preclude the emergence of new and nonentirely equivalent systematizations in the future. The chapters in this section provide numerous examples of such a phenomenon. However, the explicit pursuit of systematization as a critical aspect of mathematical practices can motivate alternative

original trajectories in the semiotic space, distinct from the ones traditionally conceived for the study of other sign systems. These and other specificities of mathematical practices indicate the potential contribution a semiology of mathematics can offer to a general theory of signs.

3 Semiology in History and Philosophy of Mathematics: Contributions to This Section

In 1902, Bertrand Russell reproached Frege for not having "clearly disentangled the logical and linguistic elements of naming" (Russell 2010, p. 519). Half a century later, the young Noam Chomsky opposed any attempt to understand natural language as logical systems such as Caranap's:

> But in the case of the artificial 'languages' investigated by Carnap in his logical laboratory, there is little if any antecedent reason for regarding these as in any way comparable to the actual languages of the outside world. (Chomsky 1955, p. 43)

These cross-accusations involving the most prominent figures in the fields of logic and linguistics serve as a compelling illustration that despite the so-called "linguistic turn," insofar as the philosophy of mathematics has been governed by a classic logical approach, the true problems of language have been kept at arm's length. The tutelary figure of the late Wittgenstein only confirms this circumstance, as it demonstrates how a multitude of new problems linked to mathematical signs emerge once the strict logical perspective is subject to critical examination.

As a consequence, strictly semiological approaches have occupied a relatively marginal position in contemporary philosophy of mathematics. As the new century emerged, alternative approaches to the language of mathematics, distinct from strictly logical accounts, were limited to only a few rather disconnected and not necessarily converging individual works originating from both philosophy and history (cf., for instance, Rotman 1988, 2000; Netz 1999; Vinciguerra 1999; Herreman 2000; Serfati 2005; Kvasz 2008; Macbeth 2005; Chemla 2004). However, as a result of the "practical turn" in the philosophy of mathematics over the past decades, numerous studies have been pursued to explore various facets of mathematical knowledge as products of human practices rather than solely arising from abstract logical properties. Accordingly, a significant portion of research within the field involves the analysis of various mathematical corpora. These corpora encompass a wide range of materials, including actual mathematical texts, experimental data, historical and contemporary works, whether authored individually, institutionally, or collectively, and comprising both published and unpublished sources. The problem of mathematical signs – inscriptions, symbols, marks, diagrams, expressive means, representations, etc. – has thus regained prominence in the field. Drawing on insights from classical semiological theories, important aspects of mathematical knowledge have been shown to be intricately related to regularities and emergent patterns identifiable at the level of signs. From a philosophical viewpoint, these

works have contributed to bridging the traditional gap that separated mathematical from natural language by demonstrating the many ways in which mathematical signs, classically assumed to be purely formal, are conditioned by empirical and historically determined human practices. This shift in perspective has further facilitated the avoidance of anachronistic and ethnocentric biases in the philosophical and historical study of mathematical knowledge.

The philosophy and history of mathematical practices have thus brought the study of mathematical language and signs to the forefront of contemporary mathematical thought. However, despite the fruitfulness of this research trend, a comprehensive and unified account of its various aspects and the diverse approaches taken to explore it remains elusive. Recognizing this gap, we have undertaken the task of editing the present Handbook section as a much-needed remedy.

As emphasized earlier, our primary aim was to prioritize the richness of diverse perspectives rather than impose artificial uniformity and systematicity in the practice-driven study of mathematical language. To achieve this goal, we sought to include a wide array of viewpoints and topics in our selection of contributions. Despite the varied nature of approaches, the resulting series of chapters exhibit a cohesive structure. The section commences with papers that tackle the problem of mathematical signs from a broad and overarching perspective, both philosophically and historically. These pieces set the stage for the exploration of case studies that vividly demonstrate the fruitfulness of a semiological approach in analyzing various historical and conceptual dimensions of mathematical practices. Finally, the section concludes by offering fresh perspectives that confront new challenges, paving the way for further developments that can build upon and expand the rich insights showcased in this section.

The first chapter of this section is **David Waszek**'s *Signs as a Theme in the Philosophy of Mathematical Practice*. This contribution is conceived as a detailed introduction to the whole section. Waszek provides a comprehensive *survey* of the diverse works that delve into the problem of mathematical signs within the tradition of the history and philosophy of mathematical practice. His insightful analysis explores the reasons behind this apparent convergence in the field toward the study of signs, revealing that it conceals a diversity – and sometimes even a disparity – of perspectives and motivations, each with its own agenda.

Waszek identifies three main trends within this landscape. The first trend aims to reveal the norms of informal mathematical practices, suggesting that mathematics is characterized by specific manipulations of signs rather than solely relying on classic logical inference. The second trend focuses on exploring the boundaries of rigorous norms, such as ambiguity and polysemy, to underscore the openness of mathematical practices to sociohistorical conditions. Lastly, the third orientation investigates the cognitive aspects associated with the manipulation of signs by individuals, raising questions about the cognitive conditions that shape mathematical knowledge and the design choices that can enhance or hinder the efficiency of mathematical practices.

Notably, the three trends identified by Waszek align, at least to some degree, with the three external layers of semiotic systems presented earlier: abstract norms, sociohistorical usages, and individual practices. One can hardly conceive of a better

account of how the current research on the semiology of mathematical practices is distributed across the landscape of a theory of signs, encompassing multiple trajectories.

After Waszek's comprehensive survey, **Roy Wagner** proposes a theoretical introduction to the topic in the chapter titled *Structural Semiotics as an Ontology of Mathematics*. Wagner's specific approach revolves around the *structuralist and poststructuralist theories of signs*, building upon the foundational works of Saussure, Lévi-Strauss, and Derrida. His analysis conceptually reconstructs the historical evolution of this major current of semiological thought, skillfully extracting the elements and principles relevant to the study of mathematical practices. In particular, Wagner centers his account around the *commutation test*, which allows to identify semiotic units through correspondences between signifier and signified substitutions. Wagner's reconstruction is both precise and accessible, making the chapter an exceptional resource for readers seeking an initial foray into the semiology of mathematics.

However, Wagner's contribution goes beyond the sole presentation of this theoretical framework; he also puts the corresponding conceptual tools to the test through a historically informed mathematical example – the history of the numeral 0. This example not only showcases the strengths of the approach but also highlights its limitations. Through this elaboration, Wagner advances a crucial thesis: the semiological perspective in question can offer more than just methodological tools or epistemological insights to the history and philosophy of mathematics; *it can offer an ontology*. In other words, the analysis of mathematical signs involves a way of answering the question of what mathematics *is* or what it is *about*.

Crucially, Wagner avoids falling into a naïve position holding that everything is a sign. Instead, he crafts a formula that is rich with subtleties: everything is *also* a sign. This implies that everything, including everything mathematics is supposed to be about, is at any time subject to the displacement operations necessary to determine it as a sign through the commutation test. Departing from classic ontologies of mathematics centered around fixed referents and concepts, Wagner concludes, supported by various examples, that this perspective offers an insightful image of mathematics as a series of signs determinable only through the regularities found amidst multiple changes of context. Consequently, mathematical knowledge becomes inherently reliant on practices in a central and inescapable manner.

The next chapter reminds us that the role of history in fostering a renewed awareness of the significance of signs for the study of mathematical practices cannot be overstated. Notably, Reviel Netz's *The Shaping of Deduction in Greek Mathematics* (1999) stands as a landmark and an exemplar in this regard. The reader will certainly recall Netz's celebrated "two lanes" thesis, positing that the two components of deduction in Greek mathematics – necessity and generality – were shaped through a complex articulation between two semiotic devices: the lettered diagram, and the formulaic language. While the semiotic aspects of these "cognitive tools" were expounded with remarkable detail and erudition, the methodological and epistemological underpinnings of the analysis ended up appearing scarce in the face of the increasing fruitfulness of the approach.

The significant impact of this historical study led to a growing need for further theoretical and methodological elaboration guiding the replication of the same historiographical gesture in other contexts. In the third chapter of this section, **Reviel Netz** willingly embraced the challenge of revisiting his celebrated work after almost a quarter of a century since its publication. In *Shaping, Revisited*, Netz embarks on a remarkable endeavor of retroactive methodological and epistemological reflection, directly addressing the semiological dimension of this and subsequent works. Reviewing a rich series of historical cases, he probes the attributes that can be attributed to strictly semiotic properties in each case. This reflective exercise reveals that the study of mathematical signs, from a strictly semiological perspective, is inextricably intertwined with two other dimensions: the "culturally and historically malleable" cognitive apparatus and, more crucially, a materialist approach to the history of culture. Thus, we see the name of Marx joining that of Lévi-Strauss to indicate the plausibility of a materialist-structuralist perspective in the history of mathematics, yet only as a provisional orientation contingent on the empirical conditions of particular historical explanations.

The intricate connection between textual practices and culture in the historical study of mathematical practices has been a focus of an intense research program led by Karine Chemla and her colleagues for over two decades (Chemla 2004). In the fourth chapter of this section, titled *Mathematical Practices and Written Evidence: General Reflections Based on a Historian's Experience*, **Karine Chemla** returns to this question through a theoretical lens, offering critical insights into the *nature of textuality* in the history and philosophy of mathematical practice.

Beginning with a clear distinction between texts, documents, and inscriptions, Chemla builds on a comprehensive survey of recent works on the topic, drawing from a historically grounded theoretical discussion on how these forms of textual evidence can inform our understanding of mathematical practice. She first challenges the prevailing notion that the primary function of texts is communication. While this may be true for many published texts, historical investigations reveal that communication is not an immutable property of textuality but rather a situated practice that demands proper contextualization. Yet, the universality of communication can also be questioned at a deeper level, particularly when the notion of textuality is extended beyond published sources. Historical records offer numerous instances where texts serve other purposes than communication, such as exploration, learning, or computation.

By meticulously surveying these diverse cases, in which cultural variability plays a pivotal role, Chemla convincingly demonstrates how different conceptual and philosophical perspectives on the nature of writing can shape our understanding of texts. Emphasizing the importance of looking beyond published, communicative documents and considering the materiality of texts, she reveals a wealth of mathematical practices and sheds light on the social conditions that enabled their existence.

The first four chapters of the section offer an overarching perspective on how philosophical considerations about signs and language can ground the analysis of concrete, historical mathematical practices, while simultaneously showcasing how historical analyses of practices can inform and shape philosophical perspectives. With **Lucien Vinciguerra**'s contribution, *What Happens, From a Historical Point of*

View, When We Read a Mathematical Text?, the section takes a step further by presenting a series of three contributions that exemplify this virtuous circle in action, combining conceptual elaborations with detailed case studies.

Vinciguerra's chapter is a testament to his rich and original contributions, where he extends Foucault's archaeological program to the history and philosophy of mathematics (cf., in particular, Vinciguerra 1999). Here, he provides a compelling example of how such a perspective can yield critical tools for a theory of mathematical signs, emphasizing the inseparability of philosophy and history in this context. The central focus is on the act of *reading* mathematical texts, which becomes pivotal in addressing the classic Husserlian question concerning the stability of mathematical truth within an ever-evolving history of mathematical objects and concepts.

Intriguingly, as entangled as philosophy and history may be, the nature of mathematics itself introduces a tension between both, which Vinciguerra embraces as productive without the need of taking a definitive stance. He proposes to view texts as continuous but divisible spaces, where partitionings are effectively enacted through reading practices. Specifically, Vinciguerra explores three distinct ways in which the act of reading can redistribute the lines within a text: partitioning what is true and false, partitioning what is text and what is image, and partitioning what is mathematical and what is not in a text.

Mobilizing these critical tools, the second part of the chapter presents a meticulous case study centered around the reading of equations in Descartes' *Geometry*, skillfully drawing insights from other Cartesian texts like *The World* and the *Dioptrics* to reveal hidden partitioning lines. Vinciguerra's original focus on the philosophical conditions of reading historical texts uncovers essential differences between the historicity of mathematics and that of experimental sciences.

Moving forward in history, **Ladislav Kvasz** proposes a stimulating perspective in his chapter *Symbolic Algebra as a Semiotic System*, by delving into the *dynamic effects* that sign systems can exert on mathematical practices. Building on his prior work (Kvasz 2008), which associates crucial dimensions of the evolution of mathematical knowledge with different features of mathematical language, Kvasz's contribution focuses on the invention of symbolic algebra during the sixteenth and seventeenth centuries. He contends that understanding the changes occurring during this period requires attention to two dimensions of algebraic symbols: compositionality and referentiality, which characterize pivotal components of any semiotic system. To elucidate both aspects, Kvasz draws upon the works of Frege and Wittgenstein, respectively. Both references are surprising in their own way, determining the originality of Kvasz's approach. The first one because, unlike classic analytic approaches, Frege is here summoned to study the functioning of signs, and not of logical properties. Kvasz's use of Wittgenstein's philosophy, on the other hand, is doubly innovative. At odds with the usual references to the late Wittgenstein in this area of research, Kvasz returns to the early Wittgenstein. Yet, instead of relying on the *Tractatus*'s logical apparatus, the referential dimension of mathematical language is elaborated through the pictorial theory of signs. The result is a thought-provoking chapter proposing a framework wherein analytical properties of mathematics emerge from historical developments.

Concluding the series of case studies and shifting the focus to the nineteenth century, **Anna Kiel Steensen**'s chapter titled *Reading Mathematical Texts with Structuralist Semiotics* adopts the principles and tools of structuralist semiology, building on Wagner's presentation in this section, to conduct a *close reading* of a historical mathematical text. Steensen's proposes a proper operationalization of the commutation test, which enables her to identify semiotic units by examining substitutions within mathematical expressions and their corresponding contents. The specific text under scrutiny is Dedekind's *Über die Composition der binären quadratische Formen*, initially published in 1871. With exceptional precision, Steensen's analysis of this famous piece tackles the genesis of the mathematical notion of "ideal" from the internal perspective of the text.

Through the lens of structuralist semiology, Steensen convincingly shows that the progressive specification of expressions within the text's narrative structure engenders a series of productive ambiguities requiring the intervention of the reader. The irreducible underspecification of certain signifiers thus revealed allows her to suggest two intriguing properties of mathematical signs which could be extended beyond this particular text. First, a mathematical text can – and sometimes must – be read before its content is rigorously established. Second, in this process, important dimensions of mathematical content are determined as the effect of the interaction between strictly expressive means. Looking ahead, while Steensen's analysis remains circumscribed to a single text, her contribution can have broader implications in the use of distributional analyses for the study of mathematical text and corpora.

The last two chapters of the section redirect the attention from historical analysis to current and future challenges in mathematical sign practices. In the first of these chapters, *The Design of Mathematical Language*, **Jeremy Avigad** addresses the question of the *design choices* that arise when conceiving mathematics as a *semi-formal language*. Retrieving the theme of the previous chapter, Avigad observes that traditional formal languages used to represent mathematical content often face the issue of being underspecified in comparison to ordinary mathematical language. While the control and precision offered by formal methods are arguably essential for meeting the inferential requirements of mathematics, other features that are absent in formal specifications are equally necessary or desirable when considering mathematical language as the object of collective practices. Such features encompass, among others, principles and tools for effective error checking by a community, fostering creativity, ensuring efficiency, and maintaining reliability.

In addition to drawing on examples from the mathematical literature – particularly textbooks – Avigad's exploration of this problem crucially incorporates insights from the design of computational proof assistants and their libraries. This constitutes one of the principal originalities of Avigad's contribution, as it brings contemporary mathematical practices into play to reflect on the nature and conditions of mathematical language. While his approach is not necessarily limited to contemporary mathematics, Avigad's focus in this case centers around contemporary mathematical language. The outcome is an impressive survey of various features of mathematical language that are subject to design choices, ranging from the different categories

used to organize mathematical objects to various abstraction principles, theory-building tools, and other aspects of mathematical language, such as diagrams, algorithms, and heuristics.

Avigad's *catalogue raisonné* is an insightful and useful tool for analyzing past practices and making informed decisions in current and future contexts. As computer-assisted mathematics gains prominence, Avigad's contribution provides essential guidance for effectively leveraging the benefits of formal methods while preserving the richness and flexibility of mathematical language as a dynamic and evolving tool for collective mathematical practice.

Finally, in *How to Do Maths With Words. Neural Machine Learning Applications to Mathematics and Their Philosophical Significance*, **Juan Luis Gastaldi** tackles one of the most pressing issues facing the mathematical community today – the widespread proliferation of *machine learning applications to mathematical knowledge*, stimulated by the development of Deep Neural Networks (DNNs) and Artificial Intelligence (AI) in the past decade. Gastaldi's primary goal is to demonstrate that these applications hold profound implications worthy of the attention and interest of historians and philosophers of mathematics, despite the natural skepticism that may arise toward current AI branding. Gastaldi bases his claim on two compelling reasons: the potential impact of these new technologies on mathematical practices and, more profoundly, the emergence of a new perspective on mathematical knowledge bearing a new and surprising relationship with the principles of natural language.

After providing a concise presentation of DNNs, Gastaldi conducts a meticulous survey of the work in this booming research area, unveiling its main identifiable orientations. Significantly, those trends tend to be spontaneously organized according to the AI researchers' implicit assumptions as to what particular practice characterizes the production of mathematical knowledge, namely: finding proofs, manipulating objects, acquiring skills, or supporting heuristics. Through this survey, Gastaldi highlights that despite the pronounced differences among various machine learning applications, they all share a distinct and novel perspective on mathematical language, at odds with the conventional view that understands mathematical expressions as simple notations for existing contents or as an arbitrary syntax for a predefined semantics. The reason is that the successful performance of tasks requiring the manipulation of mathematical content is grounded on the processing of textual data alone. Yet, this does not bring neural models closer to a formalist approach to mathematical knowledge and language, because the language implied both in the training data and in the learning models is no other than natural, informal language. Challenging a clear-cut distinction between natural and artificial languages, natural language datasets and models are thus mobilized to address tasks involving mathematical content in a way that no existing philosophy of mathematics could have foreseen.

The implications of this new role for natural language raise numerous open questions and challenges that demand attention from a pluralistic, critical, and historically informed theory of mathematical language – precisely like the one outlined in this entire section.

Inevitably, every publication comes with its share of *regrets*. Despite our best efforts, some approaches representing significant contributions to a practice-driven theory of mathematical signs and language could not find a place in this section. Four of them deserve to be briefly mentioned here, thus inviting the reader to explore these topics further and fill in the gaps left by their absence in this work. The first one concerns the study of mathematical language and other semiotic artifacts from the perspective of *ethnomathematics*. The work of Barton (2008) offers a beautiful example of what this approach can contribute to the study of mathematical language. The stimulating work of Vandendriessche (2015) also provides original insights in this regard. Second, it barely deserves to be mentioned how much a philosophy of mathematical *notations* has to offer to a theory of mathematical signs. While Waszek's survey addresses some of this work, this section would have greatly benefited from a chapter dedicated to this important subject matter. We refer the interested reader to the references in Waszek's chapter. Thirdly, the intersection of *digital humanities*, *corpus linguistics*, and mathematical practices is an area of growing importance, where the automatic processing of mathematical texts plays a fundamental role. Insights from this research orientation can be particularly insightful to articulate many dimensions of semiotic practices in mathematics. Fortunately, this Handbook features a chapter by Tanswell and Inglis providing an example of this interesting line of research. Finally, it is worth mentioning the combined efforts of the research communities gathered around the Conference on Intelligent Computer Mathematics (CICM). The results exhibited in the processing of many mathematical tasks assessed by this community – such as informal-formal translation, information retrieval, classification, formula parsing, OCR, digital edition, typesetting systems, automatic proof generation, etc. – constitute valuable resources for the study of mathematical signs within the tradition of the history and philosophy of mathematical practice. We refer the reader to the series of proceedings of the Conference (CICM 2008–2022).

4 Conclusion

The culmination of our endeavor is a comprehensive work comprising over 250 pages, skillfully crafted by confirmed and emerging specialists in the field. We are confident that the collective efforts invested in this work will significantly enhance our understanding of the intricate connections between mathematical knowledge and semiotic practices. By providing a diverse, consistent, and historically informed account of this important dimension of the history and philosophy of mathematical practices, we aspire to contribute to unraveling the distinctiveness of mathematics as a human practice. Ultimately, the aim of this work is to forge innovative pathways that bridge the realms of formal and natural sciences with the rich domain of the social sciences and the humanities, fostering a harmonious integration of knowledge across diverse disciplines.

Abstract

Why study notations, diagrams, or more broadly the variety of nonverbal "representations" or "signs" that are used in mathematical practice? This chapter maps out recent work on the topic by distinguishing three main philosophical motivations for doing so. First, some work (like that on diagrammatic reasoning) studies signs to recover norms of informal or historical mathematical practices that would get lost if the particular signs that these practices rely on were translated away; work in this vein has the potential to broaden our view of the specific normativity of mathematics beyond logical proof. Second, some work focuses on signs to highlight the open-ended and "nonrigorous" aspects of mathematical practice, and the role of these aspects in the historical development of mathematics. The third motivation is based on the following observation: the reason differences in

signs matter in mathematics is that humans are finite agents, with cognitive and computational limitations. Accordingly, studying signs can be a way to study how human computational constraints shape the mathematics that we do, and to tackle the topic of mathematical understanding.

1 Introduction

That mathematical texts do not solely consist of arguments conducted in natural language is obvious: Geometrical diagrams and symbolic formulas routinely serve as emblems for the discipline. Yet, in a sense, much of twentieth-century philosophy treated this fact as *inessential*, assuming that mathematics could be recast in some uniform mold – say, first-order logic, itself often seen as little more than a regimentation of natural language – and that nothing philosophically crucial about the nature of mathematical knowledge would be lost in the process. In contrast, recent years have seen a surge of philosophical interest in the various "signs" or "representations" (more on terminology below) actually employed by mathematicians. My goal in this chapter is to explain why: Philosophically, what is there to gain by focusing on mathematical signs?

First, more needs to be said about the mathematical and philosophical context that made the variety of signs actually used in mathematics seem unimportant. One aspect of this context, namely the rejection of diagrams in "rigorous" proofs, has been much discussed – and debated – over the past thirty years. However, the attitude toward diagrams is but one part of a broader story: As we shall see, there has been a concomitant tendency to also treat symbolic notations as a superficial matter. Sect. 2 offers a brief and tentative sketch of this background.

The chapter then presents recent work that takes mathematical signs seriously by distinguishing three broad reasons, or philosophical agendas, for doing so. Some work looks to the signs (and in particular to diagrams) to recover norms of informal or historical mathematical practices; attempts to draw philosophical conclusions from such efforts often look to the (broadly speaking Peircean) thesis that what makes mathematical knowledge special is not logical inference in the traditional sense, but the reliance on the construction and manipulation of signs (Sect. 3). Some work studies signs as a way to highlight the heuristic, or more generally the "nonrigorous," aspects of mathematical practice, emphasizing how the ambiguity and openness to reinterpretations of mathematical signs is crucial to the historical development of the discipline (Sect. 4). Finally, the work surveyed in Sect. 5 focuses on what may, at first, appear to be psychological or pragmatic features of mathematical signs: the way they leverage human cognitive abilities, the way they make certain tasks more or less efficient. One reason why such a study matters

philosophically, as we shall see, is that questions of computational efficiency – and hence, the signs we use – shape our mathematics quite deeply, constraining which mathematical objects end up being salient for us.

With respect to the existing literature and to other papers in this volume, my focus here is distinctive in two ways. On the one hand, I restrict myself to external, *nonverbal* signs (like diagrams and symbolic notations), excluding mere written text. While this choice reflects recent trends, and makes sense as a reaction to the philosophical context alluded to above, one should keep in mind that there is no clear dividing line between verbal and nonverbal signs – between, say, introducing new terminology and introducing a new piece of symbolic notation. The language of mathematical texts, even when it does not rely on specific symbols and looks just like, say, English, ancient Greek, or Chinese, can in fact be quite specialized, constrained, and in a sense "artificial," as emphasized by historians (see Netz 1999; Chemla 2006); indeed, the close parallel between questions of terminology or concepts on the one hand, and questions of notation or representation on the other, will come up repeatedly below. Accordingly, some authors choose a broader scope from the outset, discussing "mathematical language" (Avigad, ▶ "The Design of Mathematical Language") or the "semiotics of mathematics" (Wagner, ▶ "Structural Semiotics as an Ontology of Mathematics") without separating the seemingly verbal from the seemingly nonverbal (for a short general introduction, see also Colyvan 2012, chap. 8). On the other hand, as mentioned already, I focus on nonverbal signs *in general*, including symbolic notations; many surveys are more restricted, covering only visualization (Mancosu 2005; Giaquinto 2020) or diagrams (Shin et al. 2013; Giardino 2017) (Giardino, "Diagrammatic Proofs in Mathematics").

Before getting started, a terminological remark is in order. How should one refer, generically, to diagrams, graphs, formulas, matrices, and so on – in short, to the many nonverbal inscriptions used in mathematical practice? An obvious choice is to call them *representations*, which is in line with well-established usage in philosophy of science.[1] It is not without problems, however; among other things, the term already has technical uses in mathematics. In keeping with the title of this section of the *Handbook*, on the *semiology* of mathematics, I decided to call them *signs* instead, though no substantive position should be taken to hinge on this.

2 The Ideal of Signless Mathematics

It would be hopeless to survey the entirety of twentieth-century thinking about mathematics here, and preposterous to claim that all of it was marked by a dismissal of the role of signs: there certainly have been major countervailing tendencies (some varieties of formalism, Wittgenstein's late philosophy of mathematics, and much of "post-structuralist" continental philosophy come to mind). Nevertheless, it is a crucial background for the rest of this chapter that some of the main currents of

[1] See, e.g., Frigg and Nguyen (2020).

thought of the period *have* made the issue of mathematical signs decidedly marginal. To bring home this point, I highlight two suggestive elements of context, one philosophical and one mathematical.

In the philosophy of mathematics, it is the conjunction of two widely held views – inherited from the intense work on the foundations of mathematics in the first half of the twentieth century – that presents the most significant obstacle to the study of mathematical signs. The first view is that mathematical proofs, and hence mathematical knowledge, can be adequately captured as derivations in some formal system. The general notion of a formal system, of course, is very broad: It includes systems that encode the legal moves in chess, rewriting systems that encode algebraic computations, the lambda calculus and its derivatives, and indeed the systems that encode the construction and manipulation of diagrams that we'll meet in Sect. 3. But this first view is often conjoined with a second one, namely that the formal systems appropriate for mathematics are *logical*, roughly in the sense that their derivation steps regiment, model, or capture logical inferences. The prototypical examples of such systems are the various formulations of first-order logic (in which set theory is standardly phrased), typical inference rules of which are *modus ponens* and universal generalization. Such rules are meant to be general rules of reasoning, which could be formulated in words just as well as in symbols.

In combination, these two theses yield a view of mathematics in which, *in principle*, any proof could be replaced by a formal derivation in some logical system, and this formal derivation in turn by a piece of reasoning conducted in natural language. It is often conceded that such a reduction is not practical, but the impression remains that, as far as the nature of mathematical knowledge goes, little is lost *philosophically* by focusing on natural language arguments and idealizing all the rest away. The result is not just to exclude diagrams and other ostensibly nonlinguistic signs from serious consideration, but also to downplay the distinctiveness of symbolic calculi and computations by assimilating them to verbal reasoning.

While some philosophers of mathematical practice might be inclined to reject both theses at once, notice – anticipating the next section – that the first thesis, formalizability, does not on its own preclude a substantial investigation of the variety of mathematical signs. Nothing in the concept of a formal system, at least as understood in mathematical logic or computer science, immediately prevents its application to ostensibly nonlinguistic signs like diagrams, or more broadly to sign manipulations of any kind that do not obviously track verbal proof steps. In particular, we shall encounter a range of efforts at formalizing diagrammatic reasoning in Sect. 3; tellingly, many have come from researchers trained in mathematical logic or computer science rather than from philosophers.

The second element of context are attitudes, prevalent in parts of pure mathematics in the twentieth century, according to which the discipline should become "conceptual" in some sense, working from intrinsic definitions of its objects rather than relying on notations and computations. As a signpost to broader developments, let me focus on a few suggestive remarks by members of the influential Bourbaki group in the middle of the century.

At the heart of Bourbaki's outlook (as presented in their manifesto *The Architecture of Mathematics*[2]) is what they call the "axiomatic method," which invites identifying and separating out, axiomatically, the elementary structures that are normally mixed together in any given mathematical theory or problem. Their ideal is that, once the right structures have been isolated and the crucial ideas properly encoded in the theory, the proofs should flow easily, in what may be called a purely "conceptual" way – that is, without recourse to opaque calculations or geometric intuitions not adequately captured by the axioms. As they famously phrased it (taking up a slogan from Dirichlet that is typically associated with a purported nineteenth-century German school of "conceptual mathematics"[3]), an overarching goal of theirs was to "substitute *ideas* for *calculations*";[4] in the retrospective words of Chevalley, one of the founding members of the group, "anything that was purely the result of a calculation was not considered by us to be a good proof."[5]

This is where the connection with signs arises: From such a perspective, the real mathematical action ought to take place at the conceptual level, so that, once the appropriate structures have been worked out, the particular signs used ought to be inessential. An offhand remark by Weil, another founding member of Bourbaki, is particularly telling in this respect. In a famous (and famously nasty) polemical reply to Unguru – a historian of mathematics who had insisted that, to obtain a proper understanding of ancient Greek mathematics, it was crucial to refrain from transcribing ancient results into modern algebraic symbolism and, instead, to respect ancient phraseology and notations – Weil wrote, as though it were self-evident, that "the content of a theorem does not change greatly, whether it is expressed in words or in formulas; the choice, as we all know, is mostly a matter of taste and of style."[6] In Weil's view, what marks out real mathematicians is precisely their competence and ability to *see beyond the signs*.

Again, the two trends just discussed – in academic philosophy, a focus on logical formalization; among some mathematicians, a preference for "conceptual" methods – should not be taken to represent the entirety of thinking about mathematics in the twentieth century. Nevertheless, they played a major role in making the diversity of signs actually used in the practice of mathematics seem peripheral. Explaining how and why the tide has now turned, at least in some parts of the philosophy of mathematics, is the goal of what follows.

[2] Bourbaki (1950) = Bourbaki (1948).

[3] For a first introduction, see Ferreirós (2007, 24–38); but see Haffner (2014, chap. 1) for a good overview of the difficulties involved in identifying such a school, or in tracing the origins and meaning of this slogan.

[4] Bourbaki (1950, 231) = Bourbaki (1948, 47); emphasis in the original French.

[6] Weil (1978, 92).

3 Proof Beyond Logic: The Norms Governing Nonverbal Signs

Mathematical practice is a peculiarly constrained activity: There seem to be rigid norms – more rigid, at least, than in most other human pursuits – governing which statements and justifications practitioners take to be correct. At first sight, formalizations in logical systems offer an explanation for this rigidity: A mathematical proof is correct, one might say, if and only if it can be routinely formalized in a suitable logical system. However, such formalizations are far removed from mathematics as it is actually found in the classroom or in research: Proofs there might contain diagrams, say, or algebraic calculations; even when they look like a purely logical argument, they are not usually couched in a formal language like that of first-order logic, nor are they formally correct – and formalization can prove quite difficult. And yet it is clear that generations of pupils have found their mathematics teachers more exacting and rigid in their expectations than any others. Prima facie, it is not clear how formalizations that are neither used, nor even accessible in practice, can nevertheless account for the manifest rigidity of practitioners' judgments.

Accordingly, one motivation for looking at the particular signs used by mathematicians is to describe the *surface* norms, so to speak, that govern their practices. One possible goal can be to provide a *bridge* to underlying formalizations: If we take formalizability as the criterion for correctness of mathematical proofs, a full account of mathematical practice requires explaining how *informal* proofs are actually judged to be correct, and how such informal correctness judgments manage (at least in many cases) to track formalizability. We shall discuss efforts of this kind with respect to both a much-studied historical example, namely elementary plane geometry in the style of Euclid, and more contemporary uses of diagrams.

A more radical goal, as we shall see, can be to account *directly* for the rigidity and distinctiveness of mathematics, bypassing formalization accounts altogether: Work on diagrams (and on nonverbal signs in general) has the potential to broaden our vision of proof beyond logical inferences as standardly construed, or at least – if one prefers to keep the usual meaning of "proof" fixed – to broaden our view of the distinctive normativity of mathematics beyond (logical) proof. One can end up arguing that what makes mathematics unique is not its link to logical deductions, but the fact that it is based on strictly normed sign manipulations.

3.1 A Historical Example: Euclid's Geometry

First, consider the historical example – much discussed in the recent literature – of elementary plane geometry, with its *diagram-based* proofs that the angles at the base of an isosceles triangle are equal, that the angles in any triangle sum to two right angles, and the like. Under various guises, such proofs have been a mainstay of mathematics in the West at least since Euclid's *Elements*, often serving until recently as *the* exemplar of mathematics. Paradoxically, though, their use of diagrams makes

them difficult to accommodate for contemporary philosophical views, a discrepancy that has of late spawned a fairly large literature.[7]

Let us first clarify the problem. Roughly speaking, from a contemporary point of view, elementary geometry studies what can be deduced logically from fundamental, verbally formulated assumptions about space ("axioms") – where, as a rough approximation, one can think of logical deduction as corresponding to the use of a handful of simple rules like *modus ponens* and universal generalization. But, though Euclid's text does appear axiomatic – with "postulates" and "common notions" that, at first sight, play the role of axioms, and an apparent commitment to prove everything on the basis of these – his proofs come with diagrams and *crucially rely on them*, in the straightforward sense that if the diagrams are removed, some claims in the proofs no longer appear supported by preceding ones.[8] From the vantage point of contemporary mathematics, we can only see this as a flaw, since it is not clear whether or how those steps that rely on the diagram could be deduced logically from the hypotheses, postulates, or common notions. Hence, insofar as we accept Euclid's theorems or proofs as correct at all, it can only be because *we* are able to *patch them up* according to our standards, eliminating any use of diagrams in the process – or so it seems to the modern observer. While one could try to argue that our patched-up proof is, in some sense, "essentially" the same as the ancient one, it seems clear that such "corrections" import later tools and standards into the earlier proofs instead of assessing them on their own terms.

This perspective on Euclid, based on modern views of proof, raises two crucial problems. First, the use of diagrams obviously does not mean that "anything goes." In ancient Greece – just as today – geometry was seen as a distinctively rigorous enterprise, with uniquely little room for disagreement among practitioners: It is clear that ancient geometers had their own norms as to what counted as a correct proof, which we cannot hope to describe by invoking standards inaccessible to them. Second, even admitting that we need to patch up Euclid's proofs before we can accept his theorems as correct, how is it that we are able to do this for pretty much *all* of Euclid, without stumbling upon clear mistakes? We need to explain this fact, unless we are prepared to conclude that ancient geometers were incredibly lucky, or that later mathematicians were so committed to making the *Elements* come out as true that they found creative ways of reinterpreting and correcting them so as to *make*

[7] Of course, there is no unitary practice spanning the two millennia and counting from Euclid to today's classrooms; for the sake of precision, the literature has mostly focused on the first books of the *Elements* themselves, usually without attending too closely to the details of the text.

[8] See Netz (1999, esp. chap. 5, 175–182) for a careful investigation of the various ways diagrams are used and relied upon in Euclid's proofs. In some cases, the diagram only serves as a kind of shortcut, in the sense that unproblematic chains of logical inferences could easily be added to the text to "fill in" the apparent justificatory blank left by the removal of the diagram; in others, such a "filling in" would require adding postulates; in others still (proposition 35 of book I is a simple example), Euclid's proposition seems general, as does the beginning of its proof, but at a certain point the proof turns out to be about a particular case displayed by the diagram (i.e., about particular relative positions of the relevant points and lines), so that, absent the diagram, some statements in the proof no longer follow from preceding ones at all – the proof would have to be reorganized.

them correct (but see Vinciguerra, ▶ "What Happens, from a Historical Point of View, when we read a Mathematical Text?").

These two problems motivate much recent work, the goals of which are, accordingly, the following: first, to describe the norms that governed Euclidean geometric practice as the practitioners themselves understood them; and second, to account for the fact that these norms, old-fashioned though they may be, largely produce conclusions that are *correct by contemporary standards*. The most philosophically sophisticated discussions along these lines are those by Manders (2008a, b) and by Panza (2012) (see also Netz 1999 for a philological perspective, and Ferreirós 2016, chap. 5 for a helpful introduction).

On the picture of Euclid that emerges, diagrams are not – as the modern perspective would have it – mere illustrations, sometimes used spuriously in the course of proofs, of a subject matter that could be specified axiomatically independently of them. Instead, they are a full-fledged part of the practice and are subject to precise norms, much like the pieces of reasoning conducted in Euclid's text.

The norms governing the diagrams are, in the first instance, codified in Euclid's postulates, which turn out not to be axioms in the modern sense: instead, they serve to codify how diagrams can be *constructed* and *enlarged* – if one insists on an analogy with modern logic, they are more akin to *formation* and (to a certain extent) *transformation* rules than to axioms. Once the diagrams are constructed, one can draw conclusions based on their appearance. While codified nowhere explicitly, this, too, turns out to be done only in very constrained and controlled ways. Equalities of lengths or angles, for example, are not (and indeed could not) be deduced from the appearance of diagrams. One *can*, however, rely on other features of diagrams, for instance on the fact that two circles that are partly inside each other have a point of intersection (like in Euclid's infamous first proposition) – features that turn out to be such that they can be reliably reproduced by different practitioners, working on different and imperfect diagrams. Other aspects of the practice also seem designed to secure agreement among practitioners: The division of the text into propositions whose proofs are kept relatively short by a systematic reliance on previously proved propositions, for instance, ensures that diagrams remain simple and uncluttered enough to be reliably reproduced, checked, and inspected.

In sum, a close inspection of Euclid's practice shows that there are clear and substantial norms governing how diagrams can be constructed, transformed, and exploited, and that these norms seem designed to ensure – as far as possible – univocal agreement among experienced practitioners.

A question then remains: Since Euclid's diagram manipulations are not justified by reference to other principles – in the sense that the diagrams are not illustrations of a subject matter that Euclid had means to define independently of them, and that, therefore, the norms governing their use could not be reduced to properties of this independent subject matter – what is Euclid's geometry *about*? Historians emphasize that it is a theory of figures (line segments, triangles, squares, circles, etc.) and *not*, as today's geometry, a theory of space.[9] But then, what exactly are these figures that

[9] On the transformation of geometry from a theory of figures to a theory of space, see, for instance, De Risi (2015).

cannot be defined independently of the diagrams yet are not reducible to them? Netz (1999, Sect. 2.3.2) explains the problem well: On the one hand, Euclid's geometry – full of expressions like "let a circle have been drawn," "let the given bounded straight line be AB" – appears to be *about the diagrams themselves*, or at least to identify the objects it talks about with the concrete lettered diagrams that are referred to within the text. On the other hand, this cannot be quite right, as the diagrams clearly do not exactly have, and are not meant to exactly have, the properties ascribed by the text to its objects.

Panza (2012) (▶ "Platonism, *De Re*, and (Philosophy of) Mathematical Practice") articulates and defends the most straightforward answer: Euclid's geometry is about abstract objects that are *individuated*, and some properties of which are *determined*, by the concrete diagrams. (This makes these objects *quasiconcrete* in the sense of Parsons, like the "expression types" familiar from the type-token distinction for languages: They "have an intrinsic relation to the concrete," in the sense that they "are determined by their concrete embodiments."[10]) In other words, Euclid's constrained practice with concrete diagrams gives rise to a *sui generis* domain of abstract objects.

Instead, Manders (2008b) suggests focusing on the inferential norms governing the practice and doing away with any talk of geometrical objects, arguing in particular that Euclid's use of "impossible" diagrams in proofs by contradiction – like the diagram with squished circles that is used to prove, in proposition 10 of book III, that two circles cannot cut in more than two points – puts too much pressure on accounts of diagrams as representations for them to be viable. (For an analysis of this argument, see Waszek 2022.)

3.2 Norms of Nonverbal Signs in Contemporary Mathematics

In contrast to Euclid, contemporary mathematicians typically do possess resources to define their subject matter independently of diagrams (e.g., by defining its objects axiomatically or constructing them from set theory). Nevertheless, controlled uses of diagrams do still make their way into widely accepted proofs; as we shall see, this seemingly threatens common contemporary views about mathematical rigor.

Here are some examples from the recent literature. De Toffoli, partly in collaboration with Giardino (De Toffoli and Giardino 2014, 2015a; De Toffoli 2017, 2023), explores the use of various kinds of diagrams in knot theory and more broadly in low-dimensional topology, as well as in homological algebra: knot diagrams, polygons representing surfaces, arrow diagrams, etc. Giardino and Patras (n.d.) examine the role of Feynman diagrams in a proof from a recent research paper straddling algebra and mathematical physics.

[10] Parsons (2008, 33, and the entirety of §7).

In these cases, diagrams may be eliminable *in principle*, but in practice they are crucial to the way practitioners assess proofs as correct or incorrect. They may even, at least in the Feynman diagrams case study, be in some sense *more fundamental* than any nondiagrammatic definition of the relevant subject matter: While there is no doubt that an appropriate nondiagrammatic definition of "Feynman diagrams" could be provided, it would be cumbersome and, more importantly, it seems that the standard by which its *adequacy* would be judged would precisely be the diagrams themselves. For contemporary (informal) proofs too, then, attending to the signs actually used allows one to describe *surface* norms governing the practice.

Such diagram-based practices from contemporary mathematics put pressure on what is sometimes called the "standard view" of mathematical rigor, most carefully spelled out by Hamami (2022): On this view, (1) an informal mathematical proof is *rigorous* if it can be *routinely translated* into a formal proof; (2) practitioners *judge* whether informal proofs are rigorous by recognizing what one might call "syntactical shortcuts," essentially higher-order inference rules; which (3) ensures that practitioners' rigor judgments track actual rigor, that is, *track translatability into formal proofs*. If in fact practitioners – at least sometimes – judge proofs on the basis of sign manipulations that do not straightforwardly correspond to logical inferences or sequences thereof, one will have to offer another account of whether and how informal proofs that are judged correct by practitioners manage to track formal proofs.

One might hold that correct informal proofs do not, in fact, track formal proofs at all; see for instance Rav (1999, 2007). Alternatively, one might maintain that formalizability holds, but articulate other accounts of the relationship between informal proofs and formal proofs. Burgess and De Toffoli (2022) map out some possible options. One well-known proposal comes from Azzouni (2005, 2009) (► "The Algorithmic-Device View of Informal Rigorous Mathematical Proof"). He introduces the notion of "inference packages," of which the use of diagrams in elementary geometry is the prototypical example: According to him, these function as "black boxes," allowing practitioners to extract consequences *reliably* from sets of assumptions while hiding from them the precise logical relations linking hypotheses and conclusions.[11]

3.3 Philosophical Ramifications

Let us take stock: Practices prototypically called "mathematical" sometimes – perhaps even frequently – rely not only on logical inferences in the usual sense, but also on controlled manipulations of nonverbal signs (prominently including diagrams). What should we make of this? On the one hand, historians or sociologists

[11] For an attempt to apply this idea to a contemporary example, see again Giardino and Patras (n.d.) on Feynman diagrams.

of mathematics would do well to adopt a broad notion of "proof" that can accommodate such phenomena. This is precisely the move made by Chemla (2012), who suggests that a misplaced philosophical obsession with absolute certainty and hence logical proof has truncated and distorted our perception, not only of contemporary mathematics, but also of its ancient counterparts:

> By the term 'proof' [. . .] we simply mean texts in which the ambition of accounting for the truth of an assertion or the correctness of an algorithm can be identified as one of the actors' intentions.[12]

On the other hand, philosophically, doing this leaves us with a puzzle: If any justification appearing in a mathematical context can be called a proof, what – if anything – distinguishes "mathematical" practices from other practices? If the peculiar rigidity of mathematics does not come from a specific method of demonstration, where does it come from?

One might answer that the question is misguided. Perhaps so-called mathematical practices are only special insofar as they rely on logical inference, which they normally do to a partial extent at best; as soon as one would leave behind the firm ground of logical proof, there would be nothing but a continuum of practices with no natural boundary for what should properly count as a mathematical justification. In particular, the various diagram-based practices discussed above would be nothing but more or less imperfect relatives of logical deduction.

The work just surveyed, however, suggests a different answer, one that has been most explicitly articulated by Peirce: Perhaps the peculiar character of mathematics comes not from logical inference but from controlled sign manipulations. Peirce's account has, for this reason, undergone a revival in the philosophy of mathematical practice (see in particular Carter 2014, 2020). For him, mathematics is about drawing "necessary consequences" from hypotheses, but in contrast to more standard deductivist positions, this drawing of necessary consequences does not proceed by logical inference in the usual sense, but by the construction and manipulation of signs:

> [I]n drawing those [necessary] consequences, the mathematician uses what, in geometry, is called a "construction," or in general a diagram, or visual array of characters or lines. Such a construction is formed according to a precept furnished by the hypothesis. Being formed, the construction is submitted to the scrutiny of observation, and new relations are discovered among its parts, not stated in the precept by which it was formed, and are found, by a little mental experimentation, to be such that they will always be present in such a construction. Thus the necessary reasoning of mathematics is performed by means of observation and experiment, and its necessary character is due simply to the circumstance that the subject of this observation and experiment is a diagram of our own creation, the conditions of whose being we know all about. (Peirce 1931–1958, §3.560)

[12] Chemla (2012, 18).

In fact, for Peirce, logical inference is *itself* a species of the broader genus of reasoning through the construction and observation of signs – a broader genus which Peirce variously calls *deduction* (in a broad sense) or *diagrammatic reasoning*, it being understood that his use of "diagram" includes such things as algebraic formulas and the schematic sentences of syllogistic logic.[13]

Further discussion of Peirce's views goes beyond the scope of this chapter; for a helpful introduction written from the perspective of mathematical practice, see Carter (2020).

3.4 The Problem of Reliability and Diagrammatic Formal Systems

Views of the normativity of mathematics that, like Peirce's, center on sign manipulations face an apparent roadblock in the oft-repeated (though distinctively modern) idea that diagrams are a source of fallacies. Indeed, it is often supposed that mathematics is made distinctive by its certainty and reliability – so is it not counterintuitive, from a modern point of view, to model one's *overall* account of mathematics, including logical inferences and simple algebraic computations, on something so reputedly unreliable as diagrammatic reasoning?

On the face of it, the work discussed above does show that even geometrical diagrams can be used in controlled and (at least to some extent) reliable ways. As for nongeometrical diagrams, many of those used in contemporary mathematics (like the arrow diagrams used in homological algebra or category theory) do not seem to threaten reliability at all. Might it nevertheless be the case that the use of diagrams, or at least of some of them, is inherently less safe than purely deductive reasoning?

In Euclid's geometry – to again use it as an example – one faces the so-called *generality problem*: One proves a *general* statement by constructing and inspecting a *particular* diagram, but is the particular diagram adequate to the general claim, or are there other, substantially different diagrams in which the claim might be wrong, or for which a further proof would be required? Applying Peirce's remarks, quoted above, to the case of Euclidean diagram-based proofs (which were, for him, a prototypical example), one needs to ensure "by a little mental experimentation" that the conclusions drawn from the constructed diagram are "such that they will always be present in such a construction." This, however, cannot be done according to mechanical rules; It requires tact and care, and leaves one exposed to the risk of an oversight – a risk that, in the common image of mathematics, bulletproof logical deductions are meant to avert.

There are two complementary strategies to mitigate such worries. On the one hand, one can emphasize that run-of-the-mill, nondiagrammatic proofs *too* are fallible (though often very reliable); De Toffoli, for instance, was led – after her

[13] He writes that "all deductive reasoning, even simple syllogism, involves an element of observation" and that, for instance, the "syllogistic formula, All M is P, S is M ∴ S is P" is "a diagram of the relations of S, M, and P" (Peirce 1885, 182).

work on diagrams, though her motivations are broader – to a fallibilist account of mathematical knowledge (De Toffoli 2021). On the other hand, one can bolster diagrams' claim to reliability by attempting to *formalize* (instances of) diagrammatic reasoning, which by now has been done in a number of cases, including for the simplest parts of a reputedly difficult case, namely Euclid's geometry (for surveys, see Mancosu 2005; Shin et al. 2018; Giaquinto 2020).

The first strategy ties in with broader discussions about the nature of informal proofs. Above, I wrote as if diagrammatic proofs raised a unique challenge to the "standard view" of mathematical rigor (Hamami 2022) – i.e., as if there were questionable proofs using diagrams on the one side and rigorous deductive proofs on the other, the latter basically being similar to formal proofs, just with *gaps* that correspond to the application of higher-order inference rules and hence can routinely be filled. However, much recent work has argued that informal mathematical proofs are often *not* like that, especially in research contexts. This is not to say that informal proofs are unreliable. Rather, the disagreement concerns where the reliability of informal proofs comes from. On the "standard view" as articulated by Hamami, informal proofs reliably track formal proofs because they are *sketches* of formal proofs and are *recognized as such* by practitioners; their reliability then comes directly from the unimpeachable solidity of the underlying formal proofs. In contrast, the argument made in papers, such as Avigad (2021) and De Toffoli (2021), is that the reliability of informal proofs – the fact that they *do* track formal derivations – comes from a host of features of mathematical practice that allow for effective communal error checking. On such views, informal proofs do not straightforwardly inherit their solidity from the formal derivations they track; the relationship between the two can be quite complex.[14]

From such perspectives, the fallibility or defeasibility that some diagrammatic proofs might display comes to be seen as typical, but it is compatible with high reliability: The remaining question is merely one of degree. In Manders's vocabulary, does a certain practice afford us enough *control* – by way of error-checking and dispute-resolution mechanisms – to avoid a fall into *disarray*, with recurrent errors and endless controversies? As Mancosu (2005) already concluded, this will have to be adjudicated on a case-by-case basis, whether there are diagrams or not. Euclid-like diagram use, for instance, certainly seems to offer sufficient control for elementary geometry, if not in more advanced settings; in many contemporary cases, diagrams do not seem to threaten reliability at all, and in fact might sometimes *increase* it by introducing helpful error-checking mechanisms (see Avigad 2021, 7392–7393 for such an argument).

The second strategy is to argue for the reliability of (some uses of) diagrams by developing *diagrammatic formal systems*. These come in two broad flavors, which face different challenges.

[14] See again Burgess and De Toffoli (2022) for a survey of the various ways of understanding this relationship.

Systems of the first kind have a syntax that is truly diagrammatic, in the sense that it is *not* made up of strings of symbols; instead, the formation and transformation rules instruct one to draw, erase, or transform geometric objects like lines or curves. Systems of this kind were mostly developed around Barwise and Etchemendy's diagrammatic reasoning program (see Allwein and Barwise 1996 for an overview), and include the first attempt at a diagrammatic formal system for plane geometry (Luengo 1996); the best known of them is Sun-Joo Shin's (1994) system for Venn diagrams. By explicitly codifying how diagrams can be constructed and manipulated, such systems are meant to allow – as usual formal systems do – conducting consistency or soundness proofs, as well as performing "move by move" checks of the correctness of purported proofs.

In systems of this kind, however, issues like the generality problem are still lurking. Setting them up or reasoning about their properties requires being able to survey the totality of possible diagrams that could be constructed using certain rules. But, in contrast to standard formal systems – whose inductive formation rules give us a sufficient grasp on possible formulas to reason about them – diagrams may have nonobvious spatial properties: We may have difficulty picturing the full range of possible cases, and may make mistakes by having only simple and unrepresentative examples in mind.[15] It does seem that genuinely diagrammatic systems, despite their appearance of perfect codification, raise problems of control that do not arise with standard formal systems.

Diagrammatic formal systems of the second kind – for instance, those developed by Miller (2007), Mumma (2006, 2019), and Avigad et al. (2009) for Euclid's geometry – have a more familiar syntax that is made up of strings of symbols, but is meant to *model* the diagrams and the reasoning conducted on them. Since their syntax is not itself diagrammatic, these systems are no less reliable than the standard ones found in logic textbooks. Instead, the challenge they face is one of *goodness of fit*: Do they closely track the preexisting diagrammatic practice, or are they more akin to *reconstructions* that eliminate the difficulties involved in diagram use? Consider again the case of Euclid. Rabouin (2015, note 33) points out that the extant systems for formalizing the *Elements* all end up rejecting at least a few of Euclid's proofs. The problem comes from those *reductio* proofs that require drawing apparently "impossible" diagrams (like the impossible diagram for proposition 10 of book III, with two "circles" that cut in four points): Formalization, because it requires stipulating exactly what kind of diagrams can legally be drawn, is liable to block at least some of these proofs.

A thorough assessment of diagrammatic systems lies beyond the scope of this survey. However successful such formalizations may be, and whether or not one ends up accepting a Peircean view of mathematics, one conclusion is clear.

[15] Shin's original system turned out to contain a mistake of this kind: It had a transformation rule permitting the erasure of any curve in a Venn diagram, which overlooked the fact that in complex diagrams (having more than four curves), though not in simpler ones, such a transformation can, for topological reasons, lead to a diagram that is not well formed (see Scotto di Luzio 2002; Howse et al. 2002).

Diagrammatic formal systems demonstrate that formalizing does not necessarily mean logicizing, at least not in the traditional sense: One can formalize norms of mathematical sign manipulations that do not correspond to logical inferences as usually construed. Note, though, that one can express the same conclusion in a different vocabulary: Instead of talking of sign manipulations that are not logical, one can attempt to redefine logic so as to cover diagram manipulations, as suggested in particular by Barwise, Etchemendy, and Shin on the basis of a semantic view of logical consequence (see for instance Barwise and Hammer 1994 and Shin 2004).

4 The Open-Endedness of Signs and the Historical Development of Mathematics

Let us now turn to work that, instead of looking to mathematical signs to recover *norms* of informal or historical mathematical practices, does – if anything – the very opposite, emphasizing the ambiguity and incidental features of signs, their openness to reinterpretation and change, and the way these drive the historical development of mathematics. The main thrust of such work, which often goes hand in hand with discussions of mathematical discovery and of the historical growth of mathematical knowledge, is to combat a vision of mathematics as an isolated and inward-looking realm governed by strict rules, and instead to emphasize its plasticity and open-endedness. My aim here is to give a quick feel for the relevant literature; the topic is covered in much more detail in Wagner's survey (this section).

The simplest point to be made will be familiar to everyone who has studied mathematics: It is not unusual for definitions, theorems, or proofs to be motivated by a visualization or a heuristic computation, only to be rigorously formulated or established in a different way. Such bifurcations between demonstration and heuristics – where the heuristics often rely on diagrams or other sign manipulations – go at least as far back as the work of the ancient Greek mathematician Archimedes (see, e.g., Detlefsen 2008, Sect. 2 for a historical survey), and reflect the norms in force as to what counts as an acceptable proof. In the recent literature, Carter (2010) and Starikova (2012) nicely document examples of diagram-driven discovery in contemporary mathematical research (see also Giaquinto 2020, Sect. 4 for a survey).

Perhaps most interesting, however, are cases in which the line between the demonstrative and the heuristic – between what is a legitimate sign manipulation, sanctioned by clear rules, and what is an unintended representational artifact – is not so clear-cut.

As a first example, consider the derivatives of a function f. In principle, it should not matter much whether they are written f', f'', etc. (Lagrange's notation) or $\frac{df}{dx}, \frac{d^2f}{dx^2}$, etc. (a descendant of Leibniz's notation); there may be "pragmatic" differences, of a kind we shall return to in Sect. 5 – the Lagrangian notation may be more economical, and the Leibnizian one better suited for remembering the chain rule, say – but the rules of the differential calculus themselves should remain the same whether they are couched in one notation or the other. From this point of view, the fact that differential operators $\frac{d}{dx}, \frac{d^2}{dx^2}$ appear separately from the function f in the Leibnizian case is merely

an artifact of the notation. Heuristically, though, this apparent artifact matters: It invites officially illicit, but sometimes productive, algebraic manipulations of the differential operator itself. This seems to have given rise historically to the collection of methods called the "operational calculus," in which differential operators *are* used algebraically. While the manipulations in question do not follow any preestablished norms, they depend on particular features of the signs previously in use, by creatively exploiting analogies these signs suggest or opportunities they afford.

Note that caution is required here: The idea that a mere artifact of notation is what led to the operational calculus is a caricature. Rarely if ever does it happen that an incidental feature of a notation adopted for unrelated reasons is solely responsible for a major breakthrough, however tempting the idea may be. Nevertheless, this caricature gets something right: Notations can matter in exploratory contexts. For a cautious attempt at seeing how much of a role notational changes did play in the earliest attempts, by Leibniz and Johann Bernoulli, at an algebraic treatment of differential operators, see Waszek (n.d.).

Importantly, there is already more at play in this example than a disjunction between discovery and justification; it is not merely a case where something was discovered at some point based on incidental features of previously used signs, but was then justified by a different route. Methods associated with the "operational calculus," defined by their algebraic use of differential symbols, ended up being used in a *systematic fashion* over extended periods of time, often with no more than partial and piecemeal justifications available. (On the history of the operational calculus, see Koppelman 1971 and Lützen 1979; for an engaging and mathematically sophisticated survey of various instances in which sketchy algebraic manipulations turn out to be surprisingly and systematically helpful, see Cartier 2000. Feynman diagrams are a well-known analogous case, but with diagrams rather than symbolic formulas; see, e.g., Kaiser 2005.)

The operational calculus – especially methods developed in the late nineteenth century by the electrical engineer Oliver Heaviside[16] – is one of the favorite examples of Wilson (2006, in part. chap. 8; 2021), who emphasizes that scientific and mathematical progress often comes by way of exploratory sign manipulations that, at first, cannot be justified nor fully understood. His broader point, which is pragmatic in spirit, is that it often takes a lot of scientific developments before we are able to understand why and how our successful methods work, and that insisting prematurely on perfect rigor is counterproductive.

Crucially, though, Wilson sees the operational calculus merely as an extreme and obvious instance of a phenomenon that is pervasive throughout scientific practice. He argues through numerous examples that signs (and more broadly, concepts) tend to shift in meaning in subtle and often unrecognized ways depending on context – even in core scientific work that is not considered heuristic by practitioners – and that this allows for successful and efficient methods whose underpinnings we only *think* we understand.

[16] On these, see Lützen (1979).

Work by Grosholz (2007) and Wagner (2017) on the role of ambiguity in mathematics bolsters such claims. Wagner's study of generating functions (2017, chap. 4) provides us with a particularly clear example coming from contemporary mathematical practice. Generating functions are series of the form $\sum a_n x^n$ that are used to solve combinatorial problems. What Wagner shows is that the various techniques commonly used in this field require interpreting the symbol x in different ways: Sometimes x has to be a real or complex variable, sometimes a mere placeholder defining a formal power series, and sometimes a (transcendental) element of an extension of the field to which the coefficients belong. While any particular technique – save perhaps for delicate cases at the frontier of research – can be justified satisfactorily, the interpretations and mappings between interpretations that would be required to do this are not usually spelled out, and often could not be except by sophisticated practitioners. In effect, under a veneer of rigor, the field thrives on ambiguity.

More radically, Wagner and collaborators emphasize that signs permit circulations, not just between different mathematical contexts, but also between mathematical and nonmathematical ones. (For ease of exposition, I take for granted that there is a clear boundary between the mathematical and the nonmathematical, but of course the point of such work is to call this into question.) Wagner (2010, 2017, chap. 2) focuses on Italian abbacist treatises of the sixteenth century; he argues that the way they conceptualized and handled (what we would now call) negative numbers, fractional numbers, and square roots was closely related to *economic* practices of currency conversion. In other work (2009; 2017, chap. 4), he studies a specific combinatorial problem that, in the mathematical literature, is often phrased in terms of marriages; he argues that, through such choices of terminology and notations, gender stereotypes can end up shaping how the problem is framed and what kind of questions are asked about it.

In sum, and in contrast to the image of perfect rigor that mathematics often enjoys, the work we surveyed in this section argues that the open-endedness of signs – their ability to function ambiguously, to be experimented upon beyond what is allowed in principle, to be reinterpreted, and to allow circulations from contexts apparently far removed from mathematics – plays a crucial role in the practice and historical development of the discipline.

5 Mathematics for Finite Agents: From Psychology to Understanding

Our last motivation for studying the signs actually used in mathematics is to explore how finite human beings, with their specific cognitive makeup and computational limitations, can practice mathematics and attain mathematical knowledge.[17] Indeed, while in principle, one could practice arithmetic using the symbols of set theory or do

[17] As such, it is an instance of what Carter (2019) has called the "agent-based" strand of the philosophy of mathematical practice.

geometry without any diagrams, both are effectively impracticable: For humans, the particular signs used matter considerably.

It may seem that such differences between signs are merely "psychological" or "pragmatic," in the sense that they do not impact the *justification* or *content* of mathematics: They are irrelevant – one might think – to whether a theorem is true or to what kind of objects (if any) it is about. It is true that part of the literature rests content with fitting mathematical knowledge into a reasonable account of cognition and ignores ontological questions altogether. But as we shall see, the stakes are higher than this. Some recent work clearly suggests that human computational limitations, and the representational tools that allow us to make do with these limitations, deeply shape our mathematics, including in its justifications and its ontology.

Note that similar questions have long been discussed in relation to the philosophically central topic of *infinity*. Indeed, one way of formulating Hilbert's foundational program (at least in its mature formulations, from the second half of the 1920s) is as aiming to justify all talk of the actual infinite on the grounds that it ultimately provides an *efficient* (though in principle eliminable) way of talking about the finite (see Zach 2023, Sect. 3), thus seemingly grounding our mathematical ontology on concerns of pragmatic accessibility. Later on, questions about how different notations impact practical feasibility have been raised in the context of discussions of strict finitism (see Dean 2018). Early efforts at developing an explicitly semiotic account of mathematics were also largely motivated by the problem of infinity (Rotman 1993, 2000; on this, see also Van Bendegem 1996). Despite its obvious relevance, however, the question of infinity has not had a central role in recent work on mathematical signs; moreover, it would deserve an extended discussion. This topic is therefore best left for elsewhere. (For a starting point, see Easwaran et al. 2021.)

5.1 Mathematical Cognition

Let us start from a few examples of psychologically oriented research that explores how human cognitive abilities constrain, and take advantage of, the various signs used in mathematics. Landy, Goldstone, and collaborators have shown experimentally that perceptual cues, like spacing, impact accuracy and performance in symbol manipulation tasks – e.g., that $a + b*c + d$ is easier than $a+b * c+d$ to parse (properly) as $a + (b * c) + d$ – and, more broadly, that fluency in parsing symbolic expressions relies on a kind of *perceptual training*.[18] Wege et al. (2020) show that even the most superficial aspects of mathematical signs, like symmetry, can impact performance. Experiments by Hamami et al. (2021) suggest that human reasoners typically assess the validity of elementary geometric claims through a diagram-based search for counterexamples. Finally, in a more phenomenological (rather than

[18] See Landy and Goldstone (2007); Landy et al. (2014); Marghetis et al. (2016).

experimental) vein, De Toffoli and Giardino (2014) argue that the practice of topology often relies on the use of sophisticated visuospatial skills to imaginatively manipulate diagrams of three-dimensional objects.[19]

Such work reintegrates mathematics into cognition and, at its best, has the potential to reveal unexpected ways in which mathematics taps into the strengths of the human sensorimotor apparatus. Its core message is that the practice of mathematics involves the body – the eye and the hand – in many ways. As such, its target is less traditional philosophy of mathematics than, on the one hand, a certain cultural image of mathematics as abstract and disembodied, and, on the other hand, broad theories of cognition that conceive of thinking as a computational process taking place "inside the head" – showing, instead, how much mathematics relies on the body, with its specific sensory apparatus, as well as on external signs.[20] In this context, mathematics is discussed less for its own sake than as a strategic battleground in broader debates on the embodiment of cognition – a position mathematics owes to the fact that it is typically seen as *the* paradigmatic instance of abstract thought.

However, it is clear that differences between signs are not just a matter of psychology. Think of algebraic symbolism: Details of the perceptual system may determine, in part, what kind of symbolic expressions (including spacing, the shapes of symbols, the spatial encoding of hierarchical structure, and so on) are easy for humans to process. Nevertheless, the fact that the calculus used in modular arithmetic, say, makes the solution of many divisibility problems much more accessible than run-of-the-mill algebra, which is symbolically quite similar, cannot have much to do with psychology at all.

Admittedly, the boundary between the psychological and the nonpsychological is sometimes subtle. For instance, given three sets A, B, and C such that $B \supseteq A$ and $C \cap B = \emptyset$, noticing that $A \cap C = \emptyset$ may be easier on an Euler diagram (which represents the sets A, B, and C as circles, with circle A located inside circle B and circle C disjoint from the others) than on the symbolic relations just given. Presumably, this is partly due to our visual ease at perceiving the containment and noncontainment of shapes (though even this is tricky to make precise: it might be due to human ease at processing spatial relations rather than to anything specifically visual, as Euler diagrams can be helpful even if perceived through touch). But even there, our visual abilities can only come into play because of an *antecedent*, *non*-psychological fact, namely that Euler circles systematically make set inclusion and set disjointness accessible in the form of geometric containment and noncontainment patterns, independently of the fact that we are good at visually picking up the latter – while conversely, a list of various relations such as $B \supseteq A$ and $C \cap B = \emptyset$, which could be phrased in a multitude of other ways, does not make inclusion and disjointness systematically accessible as single patterns.

[19] See also De Toffoli and Giardino (2015a, b).

[20] For general discussions of mathematical signs (diagrams as well as symbolic notations) in this spirit, see, for example, Giardino (2016); Vold and Schlimm (2020).

5.2 The Broader Issue of Computational Limitations

Wherever the boundary lies between factors that do and factors that do not depend on the peculiarities of the human sensorimotor apparatus, any mathematics practiced by *computationally limited agents* will be sensitive to the particular signs used, because these impact what is easily accessible. A study of how sign systems systematically reorganize accessibility – in theorem proving and problem solving, as well as exploration – can (and should) also be conducted independently of psychology, although both psychological and nonpsychological investigations will have to come together for a full account of mathematics as practiced by humans.

In this spirit, there are a number of recent case studies describing the advantages of particular mathematical signs in particular contexts, both historical and contemporary. To take just a few examples, De Toffoli (2017, 2023) discusses the use of commutative diagrams in homological algebra, and of arrow diagrams for representing closed connected surfaces; Feferman (2012) explores the use of some diagrams that contain ellipses (i.e., "...") to indicate that they could be continued indefinitely, including a commutative diagram used in homological algebra and a diagram often used to prove the Cantor-Bernstein theorem in set theory; Carter (2010) discusses the role an ad hoc diagram played in the discovery of particular concepts and later of a particular proof; and, in a more historical vein, Manders (1999) (an unpublished but widely shared manuscript) compares traditional geometry in Euclid's style, based on diagrams and verbal arguments, with Descartes' addition of algebraic equations.

So far in this survey, logic has mostly appeared as a foil – a provider of uniform symbolic languages that risk erasing the diversity of mathematical signs. However, logical notations too are designed for specific purposes (e.g., the perspicuous decomposition of sentences into constituents or of deductions into elementary inferences; the effective checking of the correctness of a deduction; the effective discovery of proofs; etc.). They are subject to psychological and computational constraints and can be analyzed in such terms. For example, Schlimm (2018) offers such an analysis of Frege's *Begriffsschrift* notation (or concept script); Waszek and Schlimm (2021) revisit the contrast between the notations of Boole and Frege, with an eye to their respective purposes and, relatedly, pragmatic advantages. There has also been work in this spirit on Peirce's many notations for logic, including his diagrammatic "existential graphs" (e.g., Schlimm and Waszek 2020; Bellucci and Pietarinen 2016).

The points made in the case studies just mentioned, be it in mathematics or in logic, usually boil down to the following: Using certain signs rather than others can make it more *efficient* for agents to perform certain tasks. The tasks in question are most often related to the discovery (or reconstruction) of proofs (or of solutions to problems). For instance, to borrow an example discussed by Feferman (2012) and De Toffoli (2017, 2023), using commutative diagrams rather than long lists of (symbolically formulated) commutation relations can make it considerably easier to reconstruct the proofs of many lemmas in homological algebra.

However, it is frequent to find such advantages phrased in a different idiom, namely in terms of gains in "understanding." In broad terms, one can make sense of such terminology if one explicates understanding in terms of the possession of *abilities* to perform certain tasks (to construct proofs, etc.); such an account is often endorsed at least implicitly in discussions of signs or representations (see, e.g., Feferman 2012), and is most explicitly articulated in Avigad (2008). To tighten the connection between understanding and the efficiency advantage of the signs used, however, one needs to clarify *which* tasks one has in mind and what these are good for.

Upon closer inspection, the precise tasks that certain signs make easier can be quite specific and varied. For example, they can make it easier to formulate a high-level sketch of the proof; to locate a particular step in such a sketch; to identify which steps one could possibly take next in a proof, and guess which is likely to help; etc. Intuitively, all of these are related to "understanding what one is doing" in a more precise sense than the mere ability to prove theorems efficiently. For attempts at identifying the most relevant tasks in particular examples, and at elaborating a suitable theoretical vocabulary, see Manders (1999, 2012) and Keränen (2005).

Trying to generalize, as just discussed, about the *kinds* of efficiency advantages that are most relevant to mathematical practice is one way of making case studies like the above more systematic. Another avenue of progress for going beyond the descriptive character of case studies lies in the following question: What exactly does it mean to say that, for certain purposes (solving a certain kind of problem, say, or proving a theorem), using certain signs offers advantages in efficiency? To give a clear answer to this question, one needs a *systematic way of comparing* different approaches, relying on different signs, to one and the same task. Though I cannot enter into details here, two broad strategies for making such comparisons more precise have emerged in the literature.

The first strategy to compare different signs, following Larkin and Simon (1987), is based on a computer model: problem solving is modeled by computer programs, and the signs or representations used in the problem-solving process are modeled by the data storage schemes used by these programs – in computer science terminology, by their "data structures." The idea is that different ways of storing the same data may lend themselves to different kinds of processing; in Larkin and Simon's terms, they may be "informationally equivalent" but "computationally different." Two ways of solving the same mathematical problem using different signs would then be modeled by two programs using different data structures, and their efficiency would be compared by counting the number of elementary operations they require before reaching a solution. (For a general discussion of this strategy, see Waszek 2023; for examples of recent attempts to apply this idea to mathematical signs, see Schlimm and Neth 2008 and Carter 2018.)

The second strategy boils down to treating different signs as the *syntax* of different *logical systems*, in order to quantify their efficiency for particular purposes by counting proof steps. In the case of diagrams, such efforts rely on diagrammatic formal systems as discussed in Sect. 3 (see Stapleton et al. 2017; Stapleton et al. 2018 for examples).

Both strategies rely on quantifying the efficiency of using certain signs by *counting* – elementary operations in one case, proof steps in the other – and both face a similar challenge, in that getting results for *particular* problems may seem of limited interest (and certainly has not much interested logicians), while getting *general* results, about the comparative efficiency of certain signs in a broad range of cases, is tricky. For instance, an obvious candidate for producing such general results would be computational complexity theory, but this approach requires identifying a class of similar problems of *arbitrarily large* size and yields only asymptotic results, which is of dubious relevance to practical concerns (see Dean 2019). Identifying classes of problems that are large enough to yield general results while still being relevant to the practice is difficult.

5.3 The Philosophical Stakes

Why should we care *philosophically*? Aren't the kinds of differences between signs discussed above, if not merely psychological, then merely "pragmatic" – in the sense that they are a matter of convenience or efficiency rather than substance? I believe that the very formulation of this question is wrong: For limited beings like us, considerations of efficiency end up shaping the substance. In particular, the signs we use for (at least partly) pragmatic reasons end up shaping what our mathematical objects and theorems are. Though research on this topic remains underdeveloped, two suggestive examples, one on notations and one on diagram use, will make this point clearer.

Before turning to examples, though, it may be helpful to notice that the parallel claim for *concepts* or *definitions* is easier to accept. Think of the central concepts in abstract algebra, say those of group, ring, or field. A main rationale for adopting them is surely efficiency – so much so, in fact, that the Bourbaki group famously referred to their axiomatic method, centered around isolating and studying such concepts, as the "'Taylor system' for mathematics"[21]: for instance, instead of studying related phenomena separately for numbers, permutations, geometric transformations, and so on, the theory of abstract groups allows focusing on them only once and then applying them to many cases (for a deeper analysis of this and related advantages, see Avigad 2020). But evidently, these concepts come with a change of subject matter: abstract algebra, even if applicable to number theory or geometry, is profoundly different from them – it is ostensibly about different objects, and its theorems are not reducible to their instances in other fields. Accordingly, the philosophical importance of conceptual or definitional choices is perhaps more evident than that of notational choices;[22] the Bourbaki group, one of whose main members (Weil) we have seen downplaying the role of notations, certainly staked its entire project on the importance of organizing mathematics around the right

[21] See Bourbaki (1950, 227) = Bourbaki (1948, 42).

[22] For discussion on this topic, see in particular Tappenden (2008a, b) and Lange (2017, chap. 9).

(structural) concepts. Nevertheless, the examples below suggest that choices of signs and choices of concepts or definitions lie on a continuum; both are perhaps best seen as species of the same genus. In practice, conceptual shifts often go hand in hand with changes in (nonverbal) signs, and both can end up reorganizing the subject matter. (For a further articulation of this parallel, see Waszek n.d.)

As a rough metaphor, think of people engaged in mathematical problem-solving, theorem proving, or mere exploration as travelers making their way through rough terrain. The signs or representations they use – and more broadly, their concepts and general organization of knowledge – trace paths and roads across the landscape, which privilege certain itineraries and make certain places *more accessible* to them than others. Nothing stops them from traveling cross-country once in a while (though some ravines may prove impassable without exceptional skill), it's just that taking the highway is more straightforward and efficient. But this "pragmatic" efficiency advantage ends up structuring most travelers' understanding of the land: which features of it are most salient, which places everyone visits, and which remain largely unknown. Of roughly this sort, I believe, is the impact of mathematical signs.

To make this more concrete, my first example comes from Avigad and Morris (2016), who discuss a famous theorem of number theory, first proved by Dirichlet: Any arithmetic progression whose terms do not all share a common factor contains an infinity of primes.[23] The proofs found in modern textbooks rely on the notion of *character* of a group; they involve summing over characters, the relevant sums being evaluated term by term based on the properties of the indexing characters. Dirichlet's original proof, however, does not refer to characters at all: His sums are indexed by intricate data and, while they contain what we can retrospectively recognize as the explicit algebraic expressions of the relevant characters, these are not the explicit focus of attention. In fits and starts, subsequent presentations of the proof progressively extricated what we now call characters, introducing specific *notations* for them and isolating their properties, thus making the proof much more surveyable.[24]

Dirichlet's original proof is just as valid as its successive reformulations, up to modern, character-based versions; in fact, there is an intuitive sense in which all of them are essentially the same. From this perspective, as Avigad and Morris note, it is tempting to dismiss the differences as "merely pragmatic." Yet in the historical arc they survey, these "pragmatic" differences had, as end result, a clear conceptual and even *ontological* change: The concept of character emerged, and characters became accepted as objects in their own right.[25] Notice the continuity, in this story, between

[23] For more historical detail, see also their companion paper, Avigad and Morris (2014).

[24] Among other things, introducing characters allows one to hide the complexity of the underlying explicit formulas, making the indexation of the sum easier to grasp, and making the proof more focused by spinning off the general properties of characters to separate lemmas.

[25] I should emphasize that the story is more complex than this sketch: treating (what we now call) characters as full-fledged objects, rather than just shorthands for parts of complex calculations, relies on a shift – associated with broader evolutions in nineteenth-century mathematics – from seeing them as algebraic expressions to seeing them as functions defined by their input-output behavior. Avigad and Morris (2016) deserves a full reading.

apparently simple *notational* abbreviations for characters and full-fledged conceptual developments.

My second example comes from Manders (1996), who uses the history of geometry to argue against the idea that "individuation of content, and hence *content*, is representation-neutral": in other words, he argues that the very content of our mathematical statements ultimately depends upon the representations (or signs) we use. His strategy is to contrast traditional geometry in the style of Euclid with *projective* geometry – more precisely, the form of it practiced by the nineteenth-century-mathematician Poncelet.

Euclid, Manders explains, proved two theorems that amount to the following: "when two lines through a point O meet a circle, say, one in A and B and the other in C and D, the rectangles (products) OA by OB and OC by OD are equal."[26] But Euclid did not state, and in fact did not have the means to handle, the result in this general form. Instead, he proved it separately for O inside and for O outside the circle.[27] This is because Euclid-style proofs always come with, and rely on, a diagram, and Eulidean diagrams *have to* settle such questions as whether a point is inside or outside a circle. Poncelet's projective geometry, on the other hand, does have means to state and prove all of these cases uniformly. So is there a single theorem here, or two? In Euclid-style geometry, the best we can say is that there are two somewhat analogous theorems with different proofs, one about "point inside circle" and one about "point outside circle." If instead we follow Poncelet, we can state and prove a single theorem about the undifferentiated content "point and circle," which Euclid cannot handle.

Before further analysis, two remarks will help forestall misunderstandings. First, there obviously *are* cases in which Poncelet's geometry goes beyond Euclid's. Manders's choice to focus on a case in which Poncelet and Euclid's theorems are intertranslatable is strategic: It is intended to bracket other phenomena so as to highlight the reorganization effected by the representational differences between them. Second, while Manders chose an example in which the focus is on the *diagrammatic* means of representation, similar points have also been made about the *conceptual* (or *definitional*) differences between Euclidean and projective geometry, highlighting again the continuity between representational and definitional differences. For instance, many of the unifications permitted by projective geometry turn upon accepting, on top of normal points, *points at infinity* at which parallel lines intersect – in other words, they turn upon redefining the

[26] Manders (1996, 396). In modern terms, these theorems are about what is sometimes called the "power of a point to a circle."

[27] The case with O inside is proposition 35 of book III of Euclid's *Elements*. The case with O outside is proposition 36, but with a further complication: the theorem still holds if one or both of the lines is *tangent* to the circle (e.g., if the first line is tangent, it will have a single intersection point A with the circle, and the theorem holds with the square on OA instead of the rectangle OA by OB), which means that there should be three cases to consider, depending on whether two, one, or none of the lines are tangents. Euclid proves only the case with one tangency, presumably because the others immediately follow.

concept of point. (The value of this redefinition is that any two lines, including parallel ones, will then intersect somewhere, which allows many theorems mentioning intersecting lines to also cover the case where the lines are parallel.) In practice, the concepts and the signs (or means of representation) are intertwined: The change in the concept of point is tied to a new way of seeing geometrical diagrams as invariant under projective transformations, some of which can send a run-of-the-mill point to infinity.

Returning to Manders's point, why does it matter if there is a single theorem (as in Poncelet) rather than two (as in Euclid)? Is it not the same knowledge, just packaged differently? Above all, the reorganization Manders analyzes matters because it alters what is *salient* for mathematicians in contexts of research and problem-solving. If using diagrams like Poncelet, one will, for instance, be attuned to any situation involving a point and a circle, irrespective of their relative positions, and may expect further theorems to also hold generally for points and circles. In other words, when faced with a problem, the signs one is in the habit of using – those in which one's theorems are phrased – determine what one pays attention to, what expectations one has, and what potential moves one thinks of first.

The metaphor of the traveler introduced above should be clearer by now: Much like concepts, the signs used trace privileged paths across the mathematical landscape, in a way that impact what kind of theorems, and even what kind of objects, are seen as structuring the land.

As a last point, note that these considerations have interesting connections to a different literature – one that did not originate in philosophy of mathematics, but in the *historiography* of mathematics. The question at issue is whether historians can legitimately use "anachronistic" mathematical notations and concepts to make sense of historical mathematics. Our discussion above – about the wide-ranging consequences that "pragmatic" differences between signs can have – should make the potential dangers of such a procedure clear: Summarily translating an ancient source into modern algebraic symbolism is like trying to retrace the winding itinerary of an ancient traveler by following the contemporary highway system; while convenient and doubtlessly useful for orientation, it is often inadequate in the details.

6 Conclusion

In recent years, a large literature has developed around "representations" or (as I have put it here) "signs" in mathematics, the aims of which – beyond that of offering precise descriptions of aspects of mathematical practice – are diverse and sometimes hard to discern. This survey attempted to clarify what is at stake.

Part of the literature discussed above is not much concerned with philosophy of mathematics in the traditional sense. Some authors investigate mathematical cognition; others mainly aim at altering our perception of mathematics, say by shifting the emphasis away from certainty, rigor, or abstraction and toward open-endedness, creativity, or embodiment.

For the rest, we encountered two main ways in which work on signs bears on more strictly philosophical questions. First, work on the norms governing nonverbal signs in various mathematical practices has the potential to revive views of the nature of mathematics that center on sign manipulations rather than on logical inference, perhaps along Peircean lines (Sect. 3.3). It is fair to say that such views remain marginal today, and are insufficiently discussed head-on. However, they will likely keep proving attractive to researchers wishing to accommodate the variety of mathematical practices without giving up on the specificity of mathematics. From an ontological perspective, discussions of how reference to abstract objects can emerge from sign manipulations – like those of Parsons for symbols and of Panza for Euclidean geometricals – will be relevant here (see Sect. 3.1).

Second, a focus on signs (including concepts, though my emphasis here has been on nonverbal signs like symbols and diagrams, where the issues can often be formulated more sharply) allows approaching the way human computational limitations shape the mathematics that we do, and in particular determine what our salient mathematical objects and theorems are (Sect. 5, esp. 5.3). Moreover, studying signs is a promising avenue for tackling in a precise way the topic of mathematical understanding, to which – under various names and guises – a large portion of the philosophy of mathematical practice literature is devoted.

Abstract

This chapter introduces a minimalist framework for structuralist and post-structuralist semiotics based on the work of de Saussure, Lévi Strauss, and Derrida. It then applies this framework to mathematical case studies. Finally, it explains what it means to consider semiotics as an ontology of mathematics and provides examples of this approach.

Keywords

Philosophy of mathematical practice · Structuralist semiotics · Post-structuralism · Ontology of mathematics

1 Introduction

As explained in the introduction to this section of the handbook, the terms semiotics and semiology are used in a variety of ways, loosely grouping together various extensions of linguistic methods beyond the context of natural languages. In the context of history and philosophy of mathematics, self-proclaimed semiotic approaches are few and far between, so a careful delineation of strands of semiotic approaches in this field is probably premature (an exception to this is the field of mathematics education, where the discussion of semiotics is much more advanced; e.g., Ernest (2006, 2018), and Presmeg et al. (2018)). Waszek's chapter in this handbook (▶ "Signs as a Theme in the Philosophy of Mathematical Practice") covers two important strands in the semiotics of mathematics: the use of diagrams in rigorous mathematical argumentation and the not necessarily rigorous, but creative use of signs to suggest new mathematical explorations.

It seems that most often, semiotic approaches to mathematics explore the interactions of several layers of signs – either layers of different kinds of signs, or layers within an apparently uniform regime of signs. The goal is usually to understand how such linguistic layers interact, formally or informally, coherently or ambiguously, to form new meanings.

Some prominent examples for this approach include Reviel Netz' (1999, see also his ▶ "Shaping, Revisited" in this handbook) discussion of how text and diagrams interacted to form the new discourse of classical Greek geometry, set in a cognitive history framework, as well as Vinciguerra's Foucauldian analysis of the interaction between the sayable and the visible in early modern mathematics (1999). Other attempts include O'Halloran's (2005) analysis of various semiotic modalities and their interactions across mathematical history, couched in the framework of systemic functional grammar, as well as Kvasz' chapter in this handbook (▶ "Symbolic algebra as a semiotic system") discussion of the differences between the expressive capacities of geometric and algebraic languages. Friedman (2021) opens up a general exploration of the notion of translation between mathematical languages, and Barton (2008, 7–11) presents an exciting case study of what happens to the meaning of number words when they are translated between English and the Maori language.

Looking for linguistic layers inside an apparently uniform linguistic system, we can site Rotman's discussion of the collapse of meta-language into language in mathematics (1987) and the way that different grammatical moods generate a division of labor between mathematical subject positions (2000, chs. 1–2; see also Wagner 2009, ch. 1). Gastaldi tracks down the distinction between algebraic expressions and logical propositions in Boole's work (2022), and between names and propositions in de Morgan's (forthcoming). Grosholz (2007) explores the notion of "productive ambiguity," where a single sign is interpreted with respect to two different, not necessarily coherent, systems of signification.[1]

[1] Wittgenstein's discussion of mathematical language(s) (1976, 1981) can be read as an attempt to tease layers of language that we tend to mix together around mathematics; however, Wittgenstein never considered himself, as far as I know, to be doing "semiotics."

Most semiotic approaches to mathematics point to Peirce as a theoretical source (although sometimes only superficially). Very little semiotic analysis of mathematics is done in an explicitly structuralist (or post-structuralist) framework. Brown (2001) delineates a general structuralist and post-structuralist semiotic framework for mathematics, but Herreman's (2000) Hjelmsevian approach is clearly the most developed. It breaks down mathematical languages into "planes of content" and explores how their interactions produce new mathematical ideas. Wagner (2009, 2017, chs. 3–4) explores shifts of meaning that occur when different layers of interpretation of the same signs interact, building on post-structural inspirations. Steensen's doctoral dissertation (2022) develops both approaches further, and applies her enriched theoretical framework to analyze nineteenth century algebra. Finally, Gastaldi's contribution to this handbook ("Neural Machine Learning Applications to Mathematics") points the way to a digital analysis of mathematical texts based on structuralist methods.

Here I will try to outline a semiotic approach to the analysis of mathematical text. I will first present a minimalist structuralist analytical framework, which can be extended or embedded into more elaborate ones. Next, I will apply it to a mathematical test case, that of the numeral 0. I will go on to highlight the instabilities embedded in this framework, in the vein of post-structuralist semiotic thinking. Then I will argue that the semiotics of mathematics affords a new approach to the ontology of mathematics, in a manner that fits with the interests of the philosophy of mathematical practice, rather than those of more classical ontological debates. I will conclude with some examples of such ontological descriptions.

2 Structural Semiotics

Let's start with an "origin myth" for signs, inspired by de Saussure (2011, Part I, ch. 1, part II, chs. 2–4). The pre-Saussurian origin myth of signs tells us that there are objects (such as trees), and that we can make articulate sounds (such as the word "tree"). By connecting one to the other, conventionally or by means of some hidden logic, a signifying relation is formed. De Saussure objected to this story, because it assumes that words and objects are unproblematically there in advance. But why would a tree be an objective unit, rather than the bottom half of the trunk and the surrounding patch of earth accompanied by a warm, pleasant feeling? And if words are unproblematically given, how come languages are so different, that the speaker of one language can hardly figure out where, in another language, one word ends and another begins?

To answer these questions, let me present a different origin myth, more Saussurian in nature, to explain how signs emerge. According to this myth, we are exposed to continuous, unarticulated streams of experience. These include sensory streams (like perceived sounds) and cognitive-experiential streams (like our thought-experience). These streams do not have constitutive units; their flows resemble that of water. However, such streams often correlate. We may, e.g., hear similar things while seeing similar things and undergoing similar experiences. These

conjunctions divide the streams into correlated units, which, a-posteriori, may end up being described, in the case of one such possible conjunction, as "bird-chirping sound," "the view of the sun rising," and the experiential-cognitive "concept of morning."

If we are in a linguistic community, this correlation may be further correlated with another articulation, this time an articulation of the stream of sounds of spoken language. The word "morning" may emerge from this stream and correlate with the above experiences. A sign is born: the correlate articulation of portions of two or more streams of sensory-cognitive experience. Note that the sign is neither the word (the signifier "morning") nor the experience (the signified or concept of morning), but that which binds them together as co-articulated units of the respective streams. The streams are now streams of signifiers and signifieds co-articulated into signs.

I call this an "origin myth" not just because of its idyllic setting, which connotes a biblical "let there be light" with a naïve and optimistic picture of waking up (this choice is mine, not de Saussure's). I call this an origin myth primarily because it is not at all clear how these correlations turn into a co-articulation of units and what are the metaphysical or empirical conditions for this to take place. For example, the notion "similar" in the above narrative is not well defined, and a definition risks forcing pre-fabricated units on the supposedly unarticulated experiential streams.

De Saussure is, in fact, careful enough so as not to provide this or any other origin myth. Instead, he gives us a metaphor: Just as the unarticulated flow of air and unarticulated flow of water interact to generate discrete waves, so do the flows of perceived sound and lived experience interact to generate articulated signs that bind words and concepts (de Saussure 2011, 112). De Saussure does, moreover, provide us with ways to operationalize the notion of sign articulation that he introduces. This is the test of commutation (below I will subsume all of structural semiotics under this test; this is a substantial simplification and conceptual stretch, but would facilitate the exposition).

Commutation helps identify the scope of a sign by attempting to replace a portion of one of the correlated streams and observe its effect on the other stream. For example, the phoneme "r," according to de Saussure, is not defined as such in any natural way. Different speakers of the same language (or the same speaker at different times) may pronounce the sound "r" very differently. Such differences, which are insignificant in one language, which may not even be perceived as different by speakers of a given language, may correspond to completely different phonemes in another language. Think, e.g., of the distinction between "r" and "l" in English, its collapse to a single phoneme in some Chinese accents, and its expansion into five different distinct phonemes in a language like Malayalam.

What defines the English "r" from this point of view is therefore not some physical-physiological constraints, but rather the fact that some ways of expressing "r" make a difference on the signified side, while others do not. The "r" of two different native English speakers is considered the same, because commuting one for the other does not break the bond of their different pronunciations with a common signified (e.g., the word "war" means the same, whether the "r" is rhotic or non-rhotic). However, someone will be said to have a speech impediment or a

confusing accent, if what they commute for an "r" sound may lead to bind their pronunciation of "war" with the signified normally associated with "wall." The English "r" would then be defined as all those sounds which, when substituted for Eliza Doolittle's or Arnold Schwarzenneger's "r" sound when they say "war," would still be linked to their intended signified. The phenomenon is similar on the signified side. If someone says that "this is a bush" and "that is a shrub," but I cannot figure out why I can't commute this for that and still call it a bush, then my articulation of the concept of bush is different from theirs.

A sign, in structuralist terms, is that which binds a certain part of one experiential flow with a certain part of another, and the features of those "parts" can be identified by commutation tests. A sign, therefore, is not defined positively, by its content, but negatively, by the fact that some changes in one flow (e.g., sound) make a difference in another (thought experience or concepts). Those productive differences constitute the *value* of a sign. Signs, therefore, do not have content, only values witnessed by commutations.

This is the main principle of structural semiotics: *Signs are systems of differences that are captured by commutation tests*.

Note that this principle is not restricted to the relation between spoken sounds and thought concepts. Any two streams can play the roles of signifier and signified, as long as the co-articulation of their units is captured by commutation tests. The extension of the scope of analysis from correlating speech or writing streams with concepts to correlating any two streams is precisely where structural linguistics becomes structural semiotics. This has a surprising corollary: everything is a sign. More precisely, everything is *also* a sign. Even a hammer is a sign: if I see a person holding a hammer and a person holding a pen, I tend to have different expectations about what they are going to do and who they are. I may make assumptions about their jobs and social positions. In other words, I will probably conceive them differently. This is why hammers and pens appear as meaningful signs on flags and in commercial logos.

This does not mean that commutation tests would capture everything there is to know about everything. For example, a commutation test would not capture the physical causality between smoke and fire, even if it could establish (under some constraints) that the appearance of one in the visual experience stream is correlated with the other in the heat experience stream. And one could, e.g., use a stop sign to hit someone over the head, rather than convey a commutationally-articulated meaning.[2] But structural semiotics is interested precisely in things *as* signs, that is, in what we can learn about them by means of commutation tests.

Commutation tests are in fact richer then they appear at first sight. They can be performed within a language: e.g., can I always exchange "dog" by "canine"? If so, they are perfectly equivalent; otherwise, they are not. They can also take place between languages: for instance, if commuting "I" with "you" corresponds to a

[2] Within an appropriate ontological framework, these two examples might arguably be reducible to semiotic values, but I am not interested in pursuing such a reductive trajectory here.

commutation between "je" and "tu," then the English sign relation "I : you" would be equivalent to the French "je : tu" (the presence of the French honorific "vous" complicates the picture). Such cross-linguistic commutation tests also help us understand the nuances of relations between signs and differences between languages.

There is yet another kind of commutation test. For example, if, in English, I change the subject of a sentence from "I" to "he," this often entails adding the suffix "s" somewhere else in the sentence – a change that contributes to the articulation of the grammatical notion of "verbs" and of their conjugation. Similarly, if I consider what can replace the word "dog" in the sentence "I see a dog" while maintaining grammatical correctness, I am on my way to articulate a certain class of so-called nouns. Therefore, syntactic rules are also captured by some kind of commutation tests.[3]

Note that the last two examples impose a coarser re-articulation on the already articulated stream of words (here, into verbs and nouns). This articulation is not about linking words with concepts, but about linking words with other words. The analysis focuses on the level of the signifier (words), rather than on their relation to the signified (concepts). In the development of structural semiotics, this shift of focus was indeed the trend. In fact, as structural semiotics evolved, the relation between the signifier and signified became less and less obvious. For Lévi-Strauss (1987), not every articulated signifier-word corresponds to an articulated signified-idea. The development of language is actually all about re-articulating the units of signifying matter with respect to signified experience – an adaptation that can never be perfect. For Lacan, semiotics is characterized by "the incessant sliding of the signified under the signifier" (2007, 419), and only occasionally do the two adhere to each other in a stable manner.

As a result, the structural semiotics developed with an increasing emphasis on the formation of relations between signs, rather than between signifiers and signifieds. The work of Lévi-Strauss is exemplary in this respect (Lévi-Strauss 1955 provides self-contained, accessible examples for the processes I mention below). One process of sign formation that he identifies is mediation. When an exclusive binary opposition in language is to be used in a non-binary world of experience, humans may come up with intermediary signs. For example, the opposition between life and death may be mediated by hunting, which is killing in order to live, or by ghosts.

Another process that Lévi-Strauss identifies is analogy: by relating a challenging binary opposition to a more mundane opposition, one that we are more comfortable with, we may feel that we can make sense of the former. For example, the life-death opposition may be considered analogous to sleep-wakefulness. This may help us understand the relatively rare and traumatic transition of the former in terms of an everyday occurrence. It may help us come to terms with the kind of absence that death entails, and even suggest a hope for revival.

[3] In contemporary computational settings, such binary commutation tests are usually replaced by a statistical analyses of a concrete textual corpus (see Gastaldi 2021).

Yet another process of sign formation is recombination: re-arranging the components of a sign relation in order to form new relations, which may complement them and enrich our expressive capacities. For example, if life is associated with motion and reproduction, whereas death is associated with stillness and decay, what happens when we recombine motion and decay on the one hand and stillness and permanence on the other?[4] I leave it to the reader to consider what physical, theological, or social concepts can emerge from this recombination, and how they relate to the original opposition between life and death.

This kind of sign-forming, according to Lévi-Strauss, is the universal of human thought. Even modern scientists look for phenomena at the border of life and death (between complex proteins and viruses, or among organisms that can survive a long suspension of all metabolic processes). They also use analogies, trying to come to terms with the biological life-death opposition by recasting it in chemical and physical terms, and conceptual recombinations also abound (e.g., artificial life). Of course, different regimes of knowledge scrutinize these procedures differently (a mythical analogy between life : death and sleep : wakefulness depends on a very different justification then the recasting of life : death in terms of some opposition of chemical processes), but, according to Lévi-Strauss (1966, 262–269), they share the same set of underlying semiotic moves.

3 A Mathematical Example

Let us try to explore a mathematical example for the application of semiotics. This example serves two purposes. First, it is meant to elucidate and concretize the above discussion. But it will also serve to pinpoint its weaknesses. For rhetorical reasons, I will first suppress these weaknesses, only to address them later on. The reader is asked to play along and reserve their critique until the subsequent section.

Consider the symbol 0. Let's focus on positive integer arithmetic in standard decimal place value notation. In this context, the signifier 0 is almost entirely commutable with any other digit – but only almost. We do not put zero at the leftmost decimal place of a number (i.e., the form 058 would usually be considered faulty or at least redundant). This imposes a syntactic distinction on 0, which sets it apart from other signs, even before we consider its meaning.

Does this syntactic difference make a conceptual difference? There is at least a possible difference: unlike other numerals, which represent numbers or quantities, in the above context, 0 can be conceived as a placeholder. A decimal place that is there in a number, but is unoccupied by a numerical quantity, is held by a 0. Note, however, that a place that does not belong to the range of a number, such as the place of the hundreds or thousands in the number 58, need not be "held" – it is

[4] This is a take on Lévi-Strauss's so called canonic formula (Lévi-Strauss 1955, 442). Since Lévi-Strauss himself was quite cavalier about it (Sperber 1985, 65–66), I allow myself to improvise around the original, rather than attempt to capture the original nuance.

simply not there. 0 serves as the mark of the existence of a relevant, but otherwise unmarked space.[5]

What kind of evidence can support or clarify this interpretation? One test is that of inter-linguistic commutation, namely, translation to other systems of representation. Indeed, in some closely related systems, such as the Chinese rod numerals or some Cuneiform notations (Katz 2007, 196; Schilmm and Skosnik 2011), 0 is replaced by a visible gap in the sequence of numerals. Another commutation test that can strengthen this interpretation is the presentation of unknown quantities in rule of three problems. In such contexts, 0 has a history of being used to hold the place of the unknown answer (instead of a blank space, a verbal designation, or modern algebraic letters). We can see examples of this in very diverse cultures, such as in the Indian *Bakhshali manuscript* (probably late first millennium; Hayashi 1995), in some Hebrew manuscripts of Abraham Ibn Ezra's *Book of Number* (originally twelfth century; Katz et al. 2016, 231–232) and in Simon Stevin (*La Pratique d'Arithmetique*, sixteenth century, see Coquard 2021, 467 for the extract). The numerical value of the answer has nothing to do with the modern quantitative notion of 0, so 0 is clearly a placeholder (or, in semiotic terms, commutable with empty but relevant positions), rather than a quantity.

Yet another way to explore the relationship between the syntactic distinction of 0 and its special mathematical meaning is provided by constructing closely related systems that do not have such a syntactic distinction. This would be a sort of "meta-commutation" test, comparing systems that are "almost" the same, but differ with respect to the syntactic rule we wish to analyze. This comparison would help to isolate the impact of the specific syntactic rule. Consider the place value number representation where there is no 0, and to the symbols 1,2,. . .,9 we add the new numeral X, representing 10 units. In this representation the number 100, for example, will be presented as 9X ($= 9 \times 10 + 10 \times 1$), 101 will become X1 ($= 10 \times 10 + 1 \times 1$), 110 will be XX ($10 \times 10 + 10 \times 1$), and 111 will be 111. Here, X will be syntactically commutable with any other numeral, and is clearly not a place holder (Foster 1947).[6] This lends plausibility to the relation between 0's syntactic distinction and its semantic distinction, serving as a placeholder rather than a quantitative numeral.

Let us continue our exploration of alternative representations in order to study the relation between the syntactic exception of 0 in standard decimal notation and its meaning. To do that, we will consider similar systems that do contain 0, but where it manifests no syntactic exception. Consider, for example, modern computer-oriented contexts where the number of digits is fixed in advance, and in order to maintain this

[5] Of course, this may change when this practice is considered within richer contexts, such as real numbers or temperature measurement, but a change of context often changes sign relations, as we will see below.

[6] I owe my exposure to this system to its independent development by Dirk Schlimm in his unpublished "A decimal place-value system without zero" (2012), which lists earlier publications of this recurrent idea.

number, a string of zeros is required to fill the empty decimal places on the left. Here, there is no longer a syntactic difference between 0 and the other numerals.

In this case, I claim, the entire set of semiotic relations changes, and the meaning of 0 with it. This is witnessed semiotically by the arithmetic procedures and identities applied to such strings (note that an identity, e.g., between 2 + 3 and 5, allows to commute one for the other, so it is a commutational-semiotic relation). In the fixed-length representation, some arithmetic identities must undergo some changes. For example, this representation requires handling the possibility of overflow, as in the case of 50...0 + 50...0. Moreover, the way a computer would perform these operations may be different, involving all sorts of logical operations on strings that are divorced from our handwritten decimal arithmetic algorithms, so as to adapt the code to the relevant data structure or hardware. This introduces new operations, new identities, and therefore new semiotic relations. It turns out that, in this case, commuting one materiality for another (electronic circuits for pen and paper) is correlated with differences in semiotic relations that are greater than they initially appeared.

Moreover, in the same computational context, the translations of the above fixed-length representations to the standard handwritten decimal representation (or, semiotically, their cross-linguistic commutation) is often under-determined, as in floating-point representations (where the string 0123 could mean .00123, 1.23, etc.).[7] We see that the slightly different notation, with its slight difference concerning the positions available to 0, is actually embedded in a very different notation, subject to very different operations, and therefore entering different intra and cross linguistic commutation relations.

In such a context, the gained symmetry between 0 and other numerals comes at the cost of a more formal, rather than numerical, evaluation of digits, where the arithmetical meaning of strings, numerals and even places is much less stable. This is most salient when we say things like "computers express everything by strings of 0's and 1's," considering both 0 and 1 as arbitrary and exchangeable, not necessarily numerically evaluated symbols. What appeared to be a slight syntactic difference ended up being correlated with many other differences, which change the meaning not only of 0, but of all other digits. One may even draw the conclusion that the two

[7] We have noted that the semiotic values of signs involve not only intra-linguistic commutations (e.g., the relation between 0 and other digits), but also cross-linguistic ones (e.g., the relation between different systems of number representation). This is an important aspect of mathematical signs. Historically, we can witness it in the case of negative numbers. In one context, they evolved through binomials: subtraction of two terms. Some of the earliest acknowledgments of negative numbers are in the form "0 less a number," and the rules for applying arithmetical operations to these numbers are analogous to the rules for applying operations to combinations of the form "number less number" where the result is positive (Wagner 2017, ch. 2; La Nave and Mazur 2002). However, the articulation of these new negative numbers also depended on their cross-linguistic translation to debts. Neither kind of relation determined negative numbers alone. Similarly, in the case of complex numbers, sets of rules (again, by analogy to other binomials and their roots) were usually not enough for mathematicians to endorse them as meaningful. Geometric representations also played a part, even before the emergence of the modern complex plane (Wagner 2010).

systems are not commensurable enough for the purposes of a fine-grained semiotic comparison.

The last example is actually meant as a sort of cautionary tale: semiotic comparisons that appear simple may actually depend on completely different materialities and practices, which render the comparisons possibly misleading. Can we, instead, try to isolate only the "internal" or "syntactic" difference (0 is/isn't allowed at the beginning of a number) and consider its impact alone, without introducing all the other changes involved in the computer oriented practice of the above fixed-length representation? Note that while isolating a difference in this way is tempting, it is not always practically possible. As we saw, actually attested changes in one syntactical aspect may be associated with a change in functionality and materiality (this is also attested in a remarkable manner, in the context of 0, in Herreman 2001). Trying to pinpoint a specific difference that does not occur in isolation in any "real-world" system might therefore entail uncontrollable speculations, which could lead us everywhere or nowhere. The fact that a specific semiotic difference is not actually included or excluded in isolation in "real-world" semiotic systems, without triggering other semiotic differences, *might* (but does not have to!) mean that it makes no sense to consider it separately from those other semiotic differences.

However, in our case we do have a real life close analogue that captures the relevant syntactic difference. Consider positive real number decimal representations.[8] We can easily attest the representations 0.2, 0.200, and 0.2000... in actual use. This appears to be precisely what we want to capture, only applied to the right side of the number instead of its left-hand side. What happens to 0 here? Is 0 still a place holder? The equivalence of the different decimal representations, with and without additional 0s on the right, suggests that fractional decimal places are there whether 0 holds them or not (as opposed to the standard representation, where 058 would be deviant, suggesting that the hundreds place is simply not there, and therefore should not be held by 0). The empty places to the right of the decimal point are part of the number, even if they are empty, and they do not require 0 to hold their place. If 0 is not required to hold the place, but may still be there, we may suspect that 0 is not strictly a placeholder, but has some other function – perhaps it even becomes a numerical value.

So regardless of what happens to the concept of 0 in this context, something significant has changed: all decimal places are always there, as evidenced by the potential commutations of strings with and without additional 0s on the right. Every decimal representation implies an infinity of other equivalent representations and even an implied infinite representation. As a result, there is something infinite in any real number – its infinite set of decimal places. If we allow ourselves to take the risk and speculate (in the absence of historical evidence or appropriate cognitive experiments), returning to positive integers, but now allowing arbitrary 0 signs to be added

[8] Note that I insist on positive numbers, so that the use of 0 by itself, which implies that it is a numerical value, is not available as evidence in our discussion. This is, I admit, an artificial move, as will become apparent in the next section.

on the left, the implicit infinity associated with infinite decimal representations of real numbers might end up being projected on the finite integers as well. Regardless of the meaning of 0, something might change about our notions of number. Given such a change, mathematicians may even come up with the idea of "extended natural" numbers, allowing for infinitely many digits.[9]

To clarify: I do not claim that in the original representation (standard decimal representation of positive integers) 0 is *only* a place holder, and that any attempt to tinker with its syntactic distinction implies that it is *not only* a place holder. We do not have enough evidence to claim that, and, as we will see in the next section, the question is not necessarily even well posed. The point here was to give examples of semiotic explorations of 0, building on its semiotic distinction in one system, by means of applying various kinds of commutation tests.

So let's move on. We discussed in the previous section some processes for generating new signs from old ones. What would, for example, a Lévi-Straussian "mediation" look like in a mathematical context? Consider the strict binary opposition between absence and presence of a numerical value, that is between zero and non-zero. Mathematicians have been toying with ways of bridging the gap in many different cultures and contexts well before the explosion of infinitesimals in early modern Europe (e.g., Archimedes' method for area and volume calculations, see Netz 2022, 187–193; Bar Hiyya's triangulation of the circle, see Katz et al. 2016, 306–307; Chinese volume calculations in commentaries on the *Nine Chapters*, see Katz 2007, 256–259, 261–263). But we will be interested in the example of Euler, for whom an infinitesimal was a zero ("an infinitely small quantity is simply an evanescent quantity and therefore actually equal to zero," from *Institutiones Calculi Differentialis*, quoted in Ferraro 2004, 45).

The zero-ness of infinitesimals was expressed by the fact that they were additively neutral: for Euler, a finite magnitude plus an infinitesimal strictly equals (rather than "converges to" or "is indistinguishable from") the original finite magnitude. However, without introducing a difference, the concept of infinitesimal will be strictly identical, according to the rules of commutation tests, with the old 0. So what is the difference?

The difference occurs in the contexts of division. While before infinitesimals, 0/0 would be simply meaningless – an indication that our mathematical description or calculation went wrong – in the context of infinitesimals, 0/0 (in equivalent forms such as $dx/5dx$ or ddx/dx) would have determinate values that depend on the specific infinitesimal, or, in different words, on the specific kind of zero. For Euler, quantity signs were not reducible to numerical values, not because they might lack values, but because they could be more than numerical values – their function depended on the context of their generation as well (Ferraro 2004, 42, 47–48). In this context, infinitesimals were zeros, but zeros emerging from different circumstances, and thus manifesting different relations to each other (e.g., $d(x^2)$, dx and $d \log x$ are all

[9] As my students occasionally did in the context of discussions of real number representation and naïve infinite set theory at the early stages of an introductory logic and set theory course.

zeros, but have different relations to each other). Zeros were no longer restricted to the roles of absence or place holding; as infinitesimals, they had a relative quantification (ratios to each other and to other quantities) that was different from that of finite magnitudes.

This was an instance of a Lévi-Straussian mediation. What about analogy? Euler's interpretation is not the only – nor indeed the main – interpretation of infinitesimals. There were many other approaches (Boyer 1959, chs. 4–6). One interesting approach is that which denies the existence of the infinitesimal itself, but acknowledges that there is an infinitesimal ratio. In this context, neither *dx* nor *dy* are meaningful entities, but their ratio, *dy*/*dx*, can be identified with a ratio between numbers (this was philosophically elaborated by Hegel, see Sommers-Hall (2010), but was not unique to him). In this way, we approach the question of what is an infinitesimal by analogy ("I don't know what they are exactly, but they relate to each other like . . . relates to . . .").

The story of zero is far from exhausted by these examples. Zero changes its semiotic functions (behavior in commutation tests) in as many ways as the systems in which it is embedded. When one moves from natural numbers to negative or real numbers, the notion of zero changes. Later on, when 0 is conceived as the additively neutral element in commutative groups or fields, or as the empty set in a canonical set-theoretic model of the natural numbers, it changes even further.

The bottom line is that the semiotics of mathematics studies mathematical signs and their meanings by exploring all kinds of commutation tests. We ask which signs or combinations of signs are commutable or equivalent to others in the same language, how a change of sign in one expression correlates with changes of other signs somewhere else in that expression, and how a change of sign in one system of presentation translates to changes of related signs in other systems of presentation. The ensuing characterization of signs captures their relations or values as signs, and the system of all such relations is the proper object of structural semiotics and its vehicle for discussing questions of meaning.

4 Post-Structural Semiotics

Much of what I wrote above may appear confused and sketchy. This is partly the cost of trying to condense a theoretical approach and some not-completely-trivial examples into the span of a few pages – some sketchy arguments and approximate formulations are inevitable.[10] But there are more substantial grounds to object to the exposition above. In fact, a certain kind of objection is an inherent feature of the theory.

Consider, e.g., the case of the pronunciation of "r" in English. People with different indigenous British accents may pronounce the sound "r" in "war" in

[10] At any rate, the analysis above is only meant to show how the theory works, not to make proper historical claims. The latter may be found in analyses such as Rotman (1987) and Herreman (2001).

recognizably different ways, while still maintaining the bond with the same signified. In that sense, their "r" sounds are commutable, and form the same signifier. But the difference is not meaningless. It can provide clues for where the person might be from or indicate their social position. So, if the context of signification is sensitive to such matters (e.g., "people from whatavashire actually mean 'a playful exchange' when they say 'war'," or "only if a person from the somewhere-isles threatens war, should you worry that they actually intend to deliver"), the two "r" sounds will form different signifiers belonging to different signs. This may be even be the case where the two variants sound the same to any human ear, but can be distinguished by some sensitive voice analysis instrument!

The point is that commutation tests are always context sensitive. Tests that rely on inter-linguistic translation depend on the kind of translation we are looking for and its purposes (legal? poetic?). Tests that consider intra-linguistic relations between signs are also never perfectly determined. I can claim that the word "dog" in the sentence "I see a dog" is commutable with the word "greenly," if my corpus includes what is usually referred to as non-grammatical sentences (say, in poetry, or in a recording of a language learning class, or in a corpus of examples of grammatically deviant sentences).

The same sensitivity applies to the analyses of mathematical examples, as in the case of 0 above. In fact, throughout the analysis, I pretended that I could zero in on a limited portion of mathematical language (such as positive decimal integer arithmetic). But in real life, we use mathematics in a rather fluid manner, considering at the same time various representations and uses. I may mix up notations such "504" and the spoken word "five hundred and four" (where 0 is absent); I may combine standard calculation algorithms with some ad-hoc maneuvers (using various tricks); I may apply numerological associations, and may even throw in some non-mathematical statements ("zero is like the nothingness of being"). Which manipulations and representations are and are not relevant when considering commutation tests is thus precisely a question of context.

However, the problem is actually worse. Even if one pins down a context, it is usually impossible to impose it on one's research. In a linguistics lab, there are all sorts of tricks for suppressing all sorts of semiotic contexts that one would like to exclude, but these are only ever partially successful, and there might always be some unintended context lurking in the subject's mind that the researcher neglected to suppress. In a historical setting, your sources are safe from the intervention of modern notations introduced in a later period, but you cannot always rule out practices and representations that leave little or no material evidence (e.g., fingers calculation or drawing lines in the sand), and it's terribly difficult to suppress anachronistic notations in the historian's head (or notepad). All these uncertainties can affect the intended context and outcomes of commutation tests.

In fact, this indeterminacy of context is unavoidable not only in practice, but also in principle. As Derrida observed, "by virtue of its essential iterability, a written syntagma can always be detached from the chain in which it is inserted or given without causing it to lose all possibility of functioning. . .. No context can entirely enclose it" (Derrida 1988, 9). The condition of possibility for a sign to work as a sign

is that it can be extracted from its context and copied somewhere else. Something entirely singular and immobile, like Stonehenge, is not a sign, because it cannot be extracted and commuted for other signs. However, we did say that everything is *also* a sign. This is the case to the extent that Stonehenge is copied, reproduced, photographed, painted, disseminated. The possibility of copying (a possibility that is there even before the sign is actually copied, when one only "copies" its image in one's mind) turns it into a sign that can be commuted and can attain a semiotic value; and Stonehenge is indeed used as a symbol of certain cultures. Therefore, considering something as a sign amounts to the ability to take it out of its singular context.

This entails that attempting to establish a precise context is paradoxical. When one says "consider the use of 0 only in arithmetical positive integer decimal place value notation," one assumes that one could, at least in principle, isolate this context. But the signs used *in* this context have a long history of – indeed depend on, by the fact that they are signs – being taken out of context. When using 0 in *this* context, I am using it *as something transferrable between* contexts (language learning, math schooling, a zero-shaped mirror on the wall, hearing someone being called "a big dumb zero"). The context is, therefore, not really closed, but connects with all those contexts that are involved in the fact that the sign is a sign because it can be taken out of/into them.

Even when learning a totally new sign, the context of learning is not entirely identical to the context of application, so already then more than one context is involved. Even recognizing a new sign *as a sign* assumes a certain de-contextualization for this very act of recognition ("Oh, it is a sign, like those letters I learned about last year"). To consider a sign *only* in a given context is to consider it as less than a fully functional – that is iterable – sign. The ideal sign depends on actual and potential context-crossing for its existence, so even an ideal context hosts signs that, by the fact that they are signs, echo foreign contexts, which might affect the semiotic analysis. The results of any commutation test, in any context, are therefore always somewhat open, even under idealized circumstances.

In order to try to pinpoint a specific context, one can stipulate rules of usage, and exclude any commutation test where these rules are violated. However, even in those (rare and usually artificial situations) where precise, complete rules can be stipulated, they must be stipulated in a natural language, where it is difficult to totally exclude new interpretations of the rules. Moreover, using the same signs in new or unexpected circumstances may require a new interpretation of the previously given rules – as Wittgenstein affirmed, rules are not really "rails invisibly laid to infinity" (Wittgenstein 2009, §218).

This is the principle of post-structural semiotics: *contexts are never completely determined; therefore, commutation tests are always at least somewhat open ended*.[11]

[11] Some scholars consider post-structuralism as a reaction against structuralism. I tend, like others (e.g., Maniglier 2006) to see it as a continuation and acknowledge that some of the principles most strongly identified with post-structuralism are already there in earlier structuralist thought. What changed is, I think, mostly the emphasis and goals, not the basic toolkit.

This is not a bug or a weakness of the theory. This openness is a necessary condition for our possibility to adapt our signs to a changing world. Trying to bracket, ignore or suppress this principle does not lead to a better scientific understanding of the meaning of signs, but to an essential misunderstanding. If a semiotic analysis provides a completely decisive answer, then you should know that it is wrong. A good semiotic analysis should follow the signs as they change, and study their potential for change as contexts flow and transform, rather than simply determine their meanings (for mathematical examples, see Herreman (2001) and Rotman (1987) in the analysis of 0; for other examples see Grosholz 2007; Wagner 2017, chs. 3–4). To understand 0 is not simply to decide whether, in a given context, it is a place holder, a quantitative value or a formal entity; rather it is to understand how these different roles interact across the contexts that should contain them, leading to the emergence of new meanings of 0. What may appear at first sight as a weakness or even failure of the theory, is actually its strength.

This opens up two further dimensions for discussion: materiality and power. As we said, signs can always, by the fact of being signs, be taken out of context. This means that their contexts and meanings are always somewhat open. But this does not mean that they always actually are taken out of any specific context. They may be harder or easier to carry (clay tablet vs. paper); they may survive for a longer or shorter time (clay tablet vs. lines in the sand); they may facilitate or hinder various context-transitions (pen and paper calculation facilitates moving from the context of calculation to that of verification, whereas calculating with tokens on a counting board does not).

Moreover, carrying signs between contexts is not a solipsistic, perfectly voluntary venture. Physical and metaphorical walls may be erected to prevent taking signs out of their intended contexts. Prisons may be built for people who use certain signs in unorthodox ways, or such people may form pacts of secrecy. A reality of power relations can slow or expedite the way signs move between certain contexts. A semiotic analysis is therefore not an extraction of the pure meaning or unrestricted possibilities of signs, but of the meaning and possibilities of signs in material contexts where power relations apply.

Material contexts and power relations also enable to impose some objectivity on what may seem like a theory leading to purely relativistic "anything goes." Indeed, when Wittgenstein wrote that rules were not "rails invisibly laid to infinity" (Wittgenstein 2009, §218), he meant that no amount of explanations and examples could preclude new or unorthodox interpretations of even the simplest of rules. He strongly acknowledged, however, that in some circumstances, only few explanations and examples are enough to get a large bunch of people to agree for a long while on the right way to follow a rule. This, according to him, was not due to some metaphysical conditions, but to concrete practical-cognitive circumstances (e.g., Wittgenstein 1976, 168), and, we might add, concrete power relations.

The stability or reproducibility of a semiotic analysis is, therefore, a practical issue. It is never absolute, but it can sometimes be effectively achieved. Semiotic analysis, then, even in a post-structuralist setting, can be objective, provided we understand objectivity in a practical and moderate sense. One way is to understand objectivity as the effective reproducibility of the results of an analysis among a

community of critical but well-trained experts, while acknowledging that what an objective judgment should capture changes across time and scientific contexts (Daston and Galison 2010). Alternatively, and more in line with the ethical goals of post-structuralism, we may consider objectivity as something that is achieved only in a responsible mediation of the analyses performed by a variety of relevant stakeholders – especially those who will suffer the most from the consequences of the analysis (e.g., Harraway 1988; Harding 1992; Barad 2007).

5 Semiotics as Ontology

Classically, the debates concerning the ontology of mathematics have revolved around what kind of objects serve as mathematical *referents*. This is a tricky issue, because the referents of mathematics have to be rigid enough to account for the stability and precision of mathematical knowledge and at the same time be accessible enough to account for our success in knowing and applying mathematics. If mathematical objects live in some independent realm of abstract, ideal objects, it is not clear how we know about them and why they are useful in describing the real world; if they exist in empirical reality, then they are subject to the kind of change and decay that would clash with the stability and precision of mathematical knowledge. There is a long history of attempts to find middle grounds. This middle ground could be found in logic, model theoretic structures, constructs of (pure Kantian) intuition, psycho-cognitive objects, or simply written symbols, to quote the most prominent approaches (cf. Fried's chapter in this handbook, ▶ "Ontology in the History and Philosophy of Mathematical Practice: An Introduction"). However, some philosophers completely reject the project of trying to determine object-like referents for mathematics.

A prominent instance is Wittgenstein. Wittgenstein has repeatedly insisted that talking about something in the same way as we talk about empirical objects does not always mean that it makes sense to think of them as actual objects. One example is pain (as discussed across Wittgenstein 2009). A common approach to pain is to try to locate it physically (in the body, in the brain) and come up with objective ways of observing it (by medical imaging devices). However, this is a notoriously difficult task – pain is extremely elusive. Private experiences, such as pain, cannot live up to the standard governing the discussion of inter-subjective empirical objects. It is therefore best, according to Wittgenstein, not to try to force them into the ontological template of such objects. Instead, when we are talking about pain, we should see ourselves as engaging in normative communication of demands and expectations ("he is in pain, try not to bother him"), rather than in describing or asserting the presence of some object.[12]

[12] Note, however, Wittgenstein's statement: "'But you will surely admit that there is a difference between pain behaviour with pain and pain-behaviour without pain.' – Admit it? What greater difference could there be?" (Wittgenstein 2009, §304). Wittgenstein does not deny the private experience, he only objects to its object-ification.

Wittgenstein follows a similar path in the context of mathematics. Instead of trying to figure out what kind of object "2" or a "triangle" or a "Hilbert space" is, he insists that mathematical statements impose grammar-like normative rules on descriptions without implying a reference to any real or ideal object (I will not try to justify this approach here; for a summary see Wagner 2020). My proposal is to follow Wittgenstein in denying mathematics an objective referent, but to complement his grammatical-normative approach by collapsing the sign-referent or tool-object distinction. I suggest we articulate *the ontology of mathematics as semiotic*, namely, as a collection of co-articulated mathematical signs (where, recall, everything, not just formal symbols, is *also* a sign), without an external, non-signifying referent.

Before I explain what a semiotic ontology means, let me contrast it with another proposal, which may sound similar: the formalist position, which claims that mathematics is about symbols in formal systems. According to this approach, a mathematical statement simply claims that there is a succession of symbols (a formal proof) that starts with the given axioms and hypotheses, and, following the given rules of inference, ends with the stipulated statement. So, mathematics is a body of claims about symbols. Saying, however, that mathematics is made of signs, in the semiotic sense of the term, is quite different.

First, a Saussurian sign is formed by the mutual co-articulation of symbolic material (perceived sounds or inscriptions) and thought-experience (concepts), so it is at least as cognitive as symbolic. If one prefers to discuss signs that are co-articulated against other material realities (like water and air co-articulate waves in de Saussure's metaphor) or against some ideal realm, then signs would involve the real or the ideal as well. So talking about signs does not necessarily reduce the discussion to the level of formal mathematical symbols.

Second, formalism assumes that symbols are given as such, and that, in mathematics, they are manipulated only according to the rules of a specific given context: a formal language with its axioms and rules of inference. We have already seen that this has nothing to do with the semiotic understanding of signs. Semiotically, signs are never given as such, but come into existence via the co-articulation of two or more streams, and cannot be rigidly restricted to a single context, not even in principle. It is never just a set of formal rules that determines the value of signs. The values of signs carry with them the echoes of the contexts through which these signs were and are still shaped.

Recall further that we claimed that everything is *also* a sign. The positions of planets are signs, to the extent that they enter into commutation relations with other signs (drawings, tables or astrological charts; using the naked eye or precision instruments). Food divided between workers is a sign, to the extent that the different shares can be commuted between workers or for equivalent commodities. This is precisely what happens when the positions of stars or the food allocated to workers are embedded in mathematical practice. We can therefore think about mathematics as a system of translations between various semiotic modalities (commodities, planet positions, geometric diagrams, symbolic calculations). A semiotic ontology of mathematics, then, does not reduce the scope or purport of mathematics to a limited formal subset. Instead, it covers everything that is (1) considered according to its

semiotic value and (2) is "mathematized" in the sense of being co-articulated with respect to the signs that we recognize as belonging to the core of mathematics. This core, we should emphasize, is historically and culturally contingent.

To say that the ontology of mathematics is semiotic is to say that mathematics is a collection of signs whose values are captured by the regularities in the practices of their commutation[13] – regularities that are embedded in materialities and power relations and are never completely determined. Since the regularities that define sign values are those witnessed in *practices* of commutation (rather than in some arbitrary speculation about them), a philosophy of mathematics grounded in semiotics is a *philosophy of mathematical practice*.

To say that the ontology of mathematics is semiotic also displaces mathematical concepts. From that point of view, concepts (e.g., the concept of a number as a multitude of units, as an intuitive succession, as a Fregean set, or as a symbol controlled by the axioms of Peano arithmetic) no longer dominate mathematics, but are co-articulated with practices involving the relevant mathematical signs. Instead of telling stories about how changes in mathematical concepts change mathematics, we recall that mathematical concepts have material-signifying aspects (formal or informal definitions, practices that express these concepts) and are therefore one more link in the net of co-articulated signs that is the ontology of mathematics. They are no longer *the essence* of mathematics.

The distinction between this and more traditional kinds of ontology can be highlighted by a reference to Rabouin (2017). Rabouin shows that a continuity of "style" (used to denote specific linguistic-symbolic practices, such as the classical Greek geometric style, the Cartesian style of so-called analytic geometry, the Weierstrassian style of the calculus, or the modern formal-axiomatic style) does not necessarily align with a continuity of concepts or of traditional epistemic-ontological positions. People may use the same style while making very different explicit statements on how we know mathematics and what it is about.

While a traditional ontology may aim to extract the referents of mathematics from its style, or, oppositely, to capture them by abstracting the style away, semiotics as ontology captures both the style of mathematics and its practical relations to implicit and explicit, theoretical or practical, philosophical articulations. These are all part of a connected network of correlated signs with more and less stable components. Instead of stating that mathematics is about real, ideal, pure-intuitive, logical, formal *or* other objects, we ask how mathematical signs are co-articulated with respect to reality, ideality, pure intuition, logic *and* formal systems. Instead of deciding between classical ontological proposals, we study how they relate to each other in practice via sign articulations.[14]

[13] It might sound more sensible to characterize mathematical signs in terms of operations rather than commutations, but, as we noted above, an operation is something that allows commuting the array of signs that forms the operation and the array of signs that forms the result of the operation. Moreover, this is not the only relevant kind of commutation, as we saw in the examples above.

[14] Exemplary analysis in non-European contexts, which relate the semiotic-material and conceptual aspects of mathematics include Chemla (2018, 2020) and Keller (2015).

Put this way, a semiotic ontology for mathematics allies with approaches that are already established in the context of science studies. Latour (1999, in the chapter *Circulating Reference*) describes scientific practice as forming chains of translations from one materiality to another, relating them by semiotic co-articulation, making specific manipulations (or commutations) on one side of the signifying-matter chain correspond to specific differences on the other. If science is understood entirely in terms of such co-articulations (which may be more than Latour would assert), then it can be captured by a semiotic ontology (for a mathematical case study, to which I owe this connection with Latour, see Steensen et al. forthcoming; for my elaboration of mathematical abstraction in this framework see Wagner 2019).[15]

Note that this perspective provides the term "reference" with a new meaning. In such a framework, to say that a scientific representation "refers" to some natural phenomenon is to establish rigorous enough chain of co-articulations that links one signifying materiality to another in a stable manner across the chain. In this framework, it is the stability, mobility and replicability of such chains that would render the reference "objective." Reference then circulates in a chain of signs, rather than connects signs to an ontologically distinct referent.

A related approach from a different philosophical tradition is that of Nancy Cartwright (2019, part I), who asserts that the formal "laws of nature" are never successfully universal. Rather, real contexts always require skillful tinkering with material artifacts and contextual adaptations to match real situations with laws (whereas laws that are designed to require no tinkering and no exceptions end up having an empty scope). This skillful material tinkering is something that a semiotic ontology of mathematics takes seriously – mathematics is the skillful, contingent, and context dependent fitting together of various kinds of signs, including, but not restricted to, those that belong to formal systems.[16] Our knowledge of mathematics and its applicability then derive from our involvement in crafting its formal and informal signs from the materiality of the real world (this raises the question of the stability of mathematics, which I defer to the conclusion).

The last few paragraphs show that semiotics as ontology is not necessarily unique to mathematics. However, reducing the ontology of empirical sciences to semiotics may raise objections, citing the commitment of empirical sciences to something beyond signs (or more precisely, to things not seen *only* as signs). I think that mathematics, however, can embrace the semiotic ontology proposal more readily, even without the hard work carried out in attempting to counter the former objection.[17] Even keenly empiricist views of mathematics often view mathematics as the *language*

[15] This convergence between Latour and semiotics is no accident – Latour's thought emerged, at least in part, in the context of French structuralist and post-structuralist semiotics.

[16] Isabelle Stengers (2010–2011) can be read as (but should not be reduced to) someone who incorporates Latour's and Cartwright's approaches, dwelling on the various weaknesses of scientific chains of reference without thereby dismissing them.

[17] Karen Barad (2007) goes farthest in attempting to design a full-fledged feminist post-structuralist ontology that insists on the inseparability of materiality and semiotics, and on the fact that materiality is given objectively only in semiotic co-articulations.

in which the book of nature is written. A semiotic ontology of mathematics gives both signification and materiality the respect they deserve in grounding mathematics, while focusing on the relationality that mathematics is usually considered as capturing.

6 Examples for Semiotics as Ontology

Let's move on to some mathematical examples of semiotics as ontology. The author whose work I will appropriate for providing examples of semiotic ontologies of mathematics is Reviel Netz (see his ▶ "Shaping, Revisited" in this handbook for a brief overview), even though he might have some objections to this cooptation of his work.[18] I will follow his analysis of two domains: Greek arithmetic and Greek geometry.

In *Counter Culture* (2002) Netz explains that Greek arithmetic is about counters. One of the written Greek representations of numbers is similar to the well-known Roman numeral representation, using Greek rather than Latin letters. This representation, in fact, reflects the primary representation of numbers in Greek culture: as counters on a counting board. A (Greek equivalent of a) number such as CCXXXVIIII is a description of the following situation. You have a surface divided into columns. The rightmost columns is that of units, and has four counters. The next column is the fives, and contains one counter. The next is the ten, and contains three counters. The next column, that of fifties is empty. The following column that of hundreds has two counters in it. The subsequent columns to the left (if there are any) are empty.

This notation of numbers was superseded later by a different alphabetic number representation, where the numbers one through nine, multiples of these numbers by ten, and multiples of these numbers by a hundred each had its own Greek letter. Calculation by means of counters on a counting board, however, remained the most salient means for performing non-mental calculations. Calculations (from the Latin *calculus*, or little stone – a counter!) is literally about moving counters around. Adding is grouping the counters of the added numbers together, replacing large groups by a counter in the next column. Multiplication is literally about replacing each counter by many or performing repeated addition, combined with position shifts. Subtraction and division are just as concrete. All the difficulties supposedly associated with calculations involving Roman (or Greek) numerals turn into intuitive manipulations on the counting board.

Such counter-calculations prevailed in many places in the world before and after the Greeks. The relations between counters and symbolic numeration goes at least as far back as ancient Mesopotamia (Robson 2008; Overmann 2019), and the Chinese rod numerals (Katz 2007, 194–201) are a variant of the same practice. But if we are to take semiotics as ontology seriously, we should consider the specific material

[18] In terms of Netz's paper, the scope of "semiotic" here covers both his "structural" and "material," so this is not the problem. But the commitment to a semiotic ontology for mathematics might still invoke other kinds of objections.

commutations as actualized in Greek cultural practices, rather than suggest an abstract universalization.

Where else do we find counters in Greek culture? First and foremost, Netz explains, in the newly created coin based economy, where counters (coins) are used for trade (but also in religious rituals, such as placing obols on the eyes of the deceased). Counters played a role in political and legal life as well. The identification of people, the drawing of lots for serving as jury or representatives, the votes in courts – all involved various kinds of tokens or counters. But counters were also used in games, and in playful theoretic manipulations, such as the Pythagorean geometric representation of numbers (triangular numbers, square numbers, etc.), based on arranging a given number of counters into a geometric shape.

This review is not meant to suggest a restriction of the ontology of Greek arithmetic to counters. Semiotic relations involving arithmetic operations, whether by means of counters or one of the written number representations, extended to many other contexts (architecture, engineering, various crafts). The co-articulations between the core arithmetic representations (counters, written numbers) and other signs (in economy, politics or crafts) establish cross-domain commutation relations, which all belong to the semiotic network that forms the ontology of Greek arithmetic. Indeed, if we take seriously the reciprocity of co-articulation, then anything that is co-articulated with arithmetic representations participates in the determination of the values of arithmetic signs, and is therefore part of the ontology of Greek arithmetic.

The prevalence of counters in specific social, economic and cultural domains in Greece facilitated the co-articulation between the latter and counter-calculations. This means that these domains of Greek life were more strongly "arithmetized" than they might have been otherwise. A curious hiatus, Netz emphasizes, occurs between record keeping and calculation. Since the letter representations of numbers, which dominated book keeping, are not amenable to calculation algorithms, the medium of calculations (counters on a counting board) and the medium of record keeping (letters inscribed on stone or papyrus), were different. This does not mean that record keeping was not arithmetical, but that a material barrier weakened the ability of signs to move between these two contexts, forming a weaker semiotic integration of calculation and record keeping than we would expect today, when digital or written numerals serve both purposes (for more on Greek record keeping see Cuomo 2013).

The ontology of mathematics changes dramatically, when the medium of calculation changes to place-value numerals on erasable dust-boards and later still on paper. I will not go into the details of the relevant Indian, Arabic or European systems, I only note that this change of medium weakens the relation between calculation and the actual manipulation of counters or tokens. The numeral loses its immediate relation to a collection of units ("4" is no longer primarily four tokens on the units column), and turns into an element that might participate in different kinds of combinatorial commutation relations (symbolic arithmetic). This opens up a path toward what is usually described as a more formalized kind of mathematics (once again, see Herreman 2001).

When we think about a number today, our immediate association is no longer the feeling of counters between our fingers or on a board, but a visual numerical symbol.

This transition echoes Jacob Klein's (1968; for a recent overview see Baratelli 2021) famous thesis on the difference between Greek known and unknown numbers and early modern algebraic ones. The former, according to Klein, refer to collection of units, probably imagined as counters; the latter refer to the symbolized concept of a specific or general quantity, such as three-ness, confounded with an instance of this concept, such as three things. But instead of restricting ontology to such presumed *referents*, a semiotic ontology would focus on the practices whereby sign-chains weaken or strengthen links between numerals, tokens, collections of objects and terms/concepts such as "three-ness." Indeed, both Rotman (1987) and Herreman (2001) offer such semiotic takes with interesting possible relations to Klein's thesis.

We further note that the transition to written place-value numerals places paradigmatic arithmetical signs on paper and in books, at the hands of the bookkeeper, rather than on counting boards, at the hands of the merchant. The relations between this shift and the rise of capitalism have been tentatively explored by several authors (e.g., Swetz 1987; Hadden 1994). The semiotic-ontological shift may thus be correlated with changes in social structures and the distribution of economic power.

I will briefly consider another example, that of geometry. If we consider semiotics as ontology, then, as established by Netz (1999), classical Greek geometry was organized around very strict signifying material: the geometric language and the diagrams. The language consisted of very restricted vocabulary, repeated combinations of words (which Netz calls "formulas," but are not to be confused with modern algebraic formulas) and inferential transitions. The diagrams were poorly drawn sketches, but (outside counterfactual situations) strictly differentiated straight and curved lines and were true to topological relations such as inside/outside and intersecting/non-intersecting. Letters indexed diagrammatic objects of interest, binding diagram and text. While in the philosophy of mathematics the Platonic and Aristotelian ontologies are often discussed, many Greek mathematicians (especially in the generation of Archimedes) were uninterested in philosophy – they didn't need an ontology beyond their carefully regulated diagrams and texts: "the diagram . . . acted, effectively, as a *substitute* for ontology" (Netz 1999, 54–57; for the changing attitudes of mathematicians to philosophy, see Netz 2022).

Of course, geometry was involved in various other sciences (like astronomy and optics) and practical applications (like architecture and engineering), but the strict language and specific way of using diagrams helped segregate the scholarly mathematical context from other contexts, and slowed down (but not closed off) the communication and co-articulation between the scholarly geometry and more applied contexts. This seems to have been a deliberate choice: the aristocratic creators of classical Greek geometry deliberately wanted to segregate themselves from the lower class people who made a living by means of practical geometry. In particular, in scholarly classical geometry, geometric objects were never measured by numbers (although the ratios between geometric magnitudes could equal ratios between numbers), and no counter calculations were involved (Netz 1999, ch. 6; Asper 2008 – in Euclidean-style number theory, even numbers were represented by lines, rather than tokens). The classical Greek geometers wanted to isolate an aristocratic, exceptionally stable truth, applied to their idiosyncratic realm of signs

(Netz 1999, ch. 7, Sect. 3). The zealous warding of their distinct semiotic context was an expression of power.

Other pre-modern and modern geometrical cultures, however, depended on different semiotic systems. By the eighteenth century, the classical Greek rigid linguistic structure had lost its footing and was mingled together with algebraic representations (analytic geometry). Classical diagrams were used interchangeably with new projection based graphical representations (in mapping, art, projective geometry and descriptive geometry). The latter representations could interchange straight and curved lines and distort topological relations (e.g., parallel lines intersecting at the vanishing point on the canvas or paper). Moreover, early modern and modern mathematicians, associated with a sort of intellectual or professional bourgeoisie rather than an aristocracy, were no longer as interested in segregating theory from practice, and integrated numerical measurement with geometric arguments.

The semiotic ontology of geometry changed from a co-articulation of classical language and classical diagrams that capture the properties of specific shapes to a co-articulation of numerical calculations, loosely regimented geometrical languages, algebraic representations, topologically diverse pictorial representations, and practical contexts where space itself was "sign-ified" or articulated by measurements (De Risi 2016a). A more classical view would focus on the "conceptual change" or change in the ontological referent: from shapes to space. Here, however, I would like to view the process as a change in the entire semiotic system of geometry, where referents (shapes or space) form only a part – not necessarily a dominant part – of the system of co-articulated representations that formed around geometry.

What were the implications of this change? I claim that this ontological shift was substantial enough to change the status of the parallel postulate[19] from "true but difficult (although probably not impossible) to prove" to "not necessarily true" (cf. Manders' analysis as reviewed in Waszek's chapter in this handbook, ▶ "Signs as a Theme in the Philosophy of Mathematical Practice"). To understand this claim, let's start with the classical conception of the parallel postulate. I should first clarify that classical Greek geometry was not axiomatic in the modern sense. It did, of course, have axioms (or more precisely, *common notions* and *postulates*), but there was never a stable list of axioms (De Risi 2016b), and the axioms did not play the same role as axioms in a modern formal theory. Indeed, they were never meant to control all possible inferences. Many inferences in Euclid's *Elements* derive from observing the topological properties of diagrams, and others are built into the rigid language of classical Greek geometry without an axiomatic underpinning. The axioms capture only some of the necessary principles or rules of inference. Moreover, attempts to prove axioms were quite common, and not restricted to the case of the parallel postulate.

[19] In its original form (postulate V of the Euclid's *Elements*) or in any of its modern forms, e.g.: for any straight line and any point outside it, a unique parallel to this line passes through this point.

An example of an inference that was not grounded in axioms is the ability to move a shape while preserving angles and straight lines, which is implicit in Euclid's *Elements* I.4 (the first triangle congruence proposition). Similar maneuvers came up in many of the attempted proofs of the parallel postulate (e.g., in Ibn al-Haytham's proof, see Rosenfeld 1988, 59–64). Standard historiography says that such purported proofs relied on unjustified implicit assumptions. This is true, but this is just as true for many proofs of Euclid himself! There are no unambiguous, non-anachronistic criteria for deciding whether Ibn al-Haytham's assumptions about straight-line and angle preserving motion follow or depart from those embedded into Euclid's proof of proposition I.4 (or, in other words, if one is justified in commuting one for the other within the context of the semiotic articulations of Euclidean geometry).

So, it is wrong to say that all past proofs of the parallel postulate are wrong – some of them were just as ambiguously justified as Euclid's own propositions. The persistent, unresolved disputes around this issue, which spanned over two millennia, demonstrate this fact. Instead of saying that the proofs were wrong, it would be less anachronistic to say that the semiotic articulations that specified what counts as a valid proof in classical geometry were insufficient for deciding whether such proofs should be accepted. The kind of semiotic articulations that enable a clear-cut decision on these matters (which depend on some kinds of syntactically formalized language) belongs to the nineteenth and twentieth centuries, and cannot be projected backwards. Indeed, formal axiomatized geometry depends on a very different semiotic network, where language and syntax have a dominant role, and this recent semiotic system is not the only possible historical continuation of the classical geometry that gave rise to the problem. Nevertheless, regardless of the disputes concerning *proofs* of the parallel postulate, we have no hints of a doubt as to the *truth* of the parallel postulate well into the eighteenth century. While the existence of a valid proof of the parallel postulate was a contentious issue, the truth of the postulate was evident to all – it was visually obvious.

What happened in the nineteenth century that allowed this attitude to change, even *before* formal axiomatized geometry became a dominant representation? I believe that this has to do with the semiotic-ontology shift described above. I will follow here Hodgkin's (2005, ch. 8) simple but effective summary of the main secondary literature, with some support from Rodin (2010). They both explain how Lobachevsky argued for the possibility of a non-Euclidean hyperbolic geometry, where parallels to a given line through a given point are not unique.

First, the very algebraization of geometry (stemming from Viète's and Descartes' so-called analytic geometry, capturing geometric objects and relations by algebraic ones) was a preliminary condition. Second, the new functional analysis (especially Euler's mid-eighteenth century treatment of exponentials) allowed mathematical descriptions that were crucial for the quantitative analysis of Hyperbolic geometry but were not available before. Indeed, Lobachevsky's claim that hyperbolic geometry was consistent was based on a sort of "isomorphism" between the functional equations that capture spherical trigonometry and those that capture hyperbolic trigonometry. Lobachevsky argued that since the former is consistent and

"isomorphic" to the latter, and since these equations capture the entirety of geometric relations, the latter must also be consistent.

But this was not enough for a wide acceptance of the new geometry. A crucial ingredient was the use of topologically and linearly distortive diagrammatic representations of geometry. Whereas in the classical Greek system, diagrammatic practice did not allow drawing a curved line for a straight one, the new cartographic and artistic geometric projections could commute one for the another. This meant that a straight line no longer had to *appear* straight, while a curved line could *appear* straight. Moreover, after the integration of numerical measurement practices into the semiotic network of theoretical geometry and the establishment of the nineteenth century's empirical approach to measurement (reflected paradigmatically by Gaussian geodesic science, which was re-articulated as a definition of spatiality by Riemann), it was no longer its apparent shape, unstable under a change of representation, that determined the straightness of a line. Instead, the straightness of a line was re-articulated with respect to practices of measurement. New semiotic co-articulations affected the ontology of straight lines.

For the Greeks, an arc of a great circle on a sphere could never be conceived as a straight line, simply because it was curved, and straight and curved lines were not commutable.[20] By the late nineteenth century, however, such an arc could be referred to as a straight line in spherical geometry. Indeed, the new semiotic ontology allowed a straight line to be straight even if it clearly looked curved, as long as it spanned the shortest distance between its ends according to a well-defined practice of measurement. The models of hyperbolic and elliptic geometry (e.g., Beltrami's model), which were taken as proofs of the consistency of the new geometries, depended on such curved representation of so-called straight lines.

The transition from the classical semiotic-ontology, which focused on rigid language and a specific practice of diagrams, and which made an effort to segregate itself from other semiotic contexts, made the parallel postulate obviously true, even if it was difficult to agree on its proof. The modern ontology, which included algebra, new diagrammatic representations, and empirical measurement, gave up on the rigidness of language and classical diagrammatic standards. The new representations turned the parallel postulate into a falsifiable claim. The Greeks would reject these developments because they were simply unacceptable in terms of their semiotic system. They depended on something different – not merely a different concept, but a different network of co-articulated signs: a different semiotic ontology. The co-articulation of the new geometry in terms of formal axiomatics added an extra layer that solidified this development, rather than form its ground or origin.

[20] There are other arguments for claiming that arcs of great circle on a sphere are not straight line segments – for example, the fact that two such segments may intersect in two points. But the fact is that the question was never even raised (if it had been raised, some creative tinkering might have resolved it). The above argument did not need to arise, because considering an arc as a straight line, as far as I can tell, was simply out of the question.

7 Conclusion

I hope that the above examples clarify what it means to consider semiotics as an ontology of mathematics. Mathematics is thereby conceived as the practice of co-articulating certain kinds of signs (inscriptions on paper, cultural artifacts, natural-phenomena-as-signs) with respect to each other. Given such an ontological view, the philosophical analysis would turn to the analysis of the values of signs in various contexts, their limitations, and potentials. The philosophical normative analysis would analyze how different mathematical goals are served or dis-served by various semiotic ontologies with their integrations and segregations. But the analysis would also recall that sign values are always bound with materiality and power relations. It would further assert that nothing can guarantee the purity of semiotic contexts, and therefore nothing can guarantee the perfect stability of mathematics, although various measures can be taken to strengthen or weaken it. The resulting philosophy is a philosophy of practices that value and re-evaluate signs, which stabilize or de-stabilize the semiotic systems of mathematics (those that I elsewhere referred to as constraints; see Wagner 2017, ch. 3). This philosophy analyzes and evaluates the impact of mathematical practice as a collection of semiotic, material, power-laden maneuvers.

As a philosophy of mathematics, semiotics provides a lot of flexibility for formulating solutions to philosophical challenges. Both the ontology and epistemology of mathematics become diverse and distributed, and lose their awesome mystery. The price that we pay, however, is a loss of stability and a threat to the rigor of mathematics. Indeed, how can inherently unstable semiotic systems serve as ontological grounds to something as rigorous and stable as mathematics?

My answer is that the stability of mathematics tends to be exaggerated, as witnessed by the example of the parallel postulate, where ambiguities are covered over by the anachronistic claim that all historical proofs of the parallel postulate were simply false (for a more general discussion of such ambiguities in mathematics, see Wagner 2022). Since the beginning of the twentieth century, we indeed have very stable and rigorous semiotic systems – the so-called formal systems. Earlier, we had other, relatively stable systems, like the language and diagrams of classical geometry, which were nevertheless not as stable as modern formal systems. We also had notoriously unstable systems, like early infinitesimals. Practices that stabilized the co-articulations between very stable semiotic systems and less stable mathematical semiotic systems,[21] practices that did not only consolidate, but actually changed mathematics (as argued in the latter sections of Wagner 2022), strengthened the stability of mathematics, making it a paragon consensus, at least in some of its aspects.

But mathematics is still a network of many co-articulated systems, and formal mathematics does not have an absolute hold over the entire field (Rav 2007). New

[21] This process spanned much of the twentieth century and continues, for example, in the co-articulation of computer verified proofs and contemporary mathematical practice, as discussed in Avigad and Harrison (2014).

semiotic articulations and attempted context segregations help render mathematics more stable, but cannot make it entirely so. The question whether a certain formal system is the right one for doing a certain kind of mathematics, the competition between different kinds of formal-foundational systems, and the fact that formal systems are hardly ever the tool for producing new mathematics show that such systems are just components in the semiotic ontology of mathematics. They are more or less successfully co-articulated with other semiotic systems that form mathematics, but are not, in any way, the foundation of mathematics.

Shaping, Revisited

Reviel Netz

Abstract

In this chapter, I review the argument of "The Shaping of Deduction in Greek Mathematics," explaining its elements that may be construed as "semiological," comparing them with other work I did in the semiology of mathematics, and conclude by pointing out the scope, and limits, of semiological explanation in the history of mathematics.

Keywords

Greek mathematics · Formulaic language · Diagrams · Abacus · Materialism

When asked to reflect upon *The Shaping of Deduction in Greek Mathematics* (Netz, 1999) I find myself plagued, naturally, by self-doubt. This takes a specific form. If you've read Netz (1999) you know that I do not shun the sweeping generalization but this is usually historical rather than philosophical or historiographical in character. I am out of my depth discussing methodology and usually end up with the platitude that different historiographical tools are useful for different historiographical purposes. And yet, I understand my role in this essay to be historiographical in character. The interesting question is how the example of this particular book can serve for the purposes of studying the semiology of mathematical practice in other contexts. To try and approach this question, I will present the book, discuss some of my own attempts to extend its arguments further, and – reflecting upon the limits of such extensions – conclude with some notes on the

scope, and limits, of the semiology of mathematical practice as a type of historical explanation.

And so, first of all: to *The Shaping of Deduction* itself, as an example of semiology.

It is actually not too difficult to distinguish the strictly semiological parts of the book. The first four chapters formed a description of the main formal features of Greek mathematical texts. Chapters 5 and 6 discussed consequences of those formal features for mathematical practice (chapter 5 was about "The Shaping of Necessity" – what gives rise to the sense that an argument is demonstrative, while chapter 6 was about "The Shaping of Generality" – how an argument couched in terms of a particular case is seen as valid for a general mathematical statement). Chapter 7 was my attempt to provide a historical account – in social and cultural terms – for how the formal features came to be entrenched and the Greek mathematical specific form of writing, or genre, formed. The overall structure then was to derive necessity and generality, via the formal features of texts, from a social and cultural context. This is indeed a very historical project but its central portion – and the one highlighted in the layout of the book – was the description of the formal features. Those, indeed, were not approached very historically. My descriptive strategy was to make claims concerning the Greek mathematical genre based on samples ranging across individual authors or a group of authors, but I did not try to find contrasts between authors, subgenres, or between historical eras. The underlying assumption was that there is indeed much in common between the works in the Greek mathematical genre and that we should concentrate on such generalities. As noted: I believe generalizations are valuable. Indeed, much of my work since historicized the detail of Greek mathematics further. In *Ludic Proof* (Netz, 2009) I looked for the specific motivations for mathematical writing in the Hellenistic era. In *The Transformation of Mathematics in the Early Mediterranean* (Netz, 2004) I considered the rise of commentary form in Late Antiquity (which I have since considered in a much wider historical setting in *Scale, Space and Canon in Ancient Literary Culture*, (Netz, 2020), chapter 6.5; in the same book, I consider also the specific trends of imperial era science, in chapter 6.3). A major thrust of *A New History of Greek Mathematics* (Netz, 2022) is the historical divide between the two major creative generations of Greek mathematics, the generation of Archytas and that of Archimedes. In short, Greek mathematics has a well-articulated history. Archytas' motivations differed from those of Archimedes, differing from those of Ptolemy and Pappus. Their audiences were different and their authorial values differed accordingly. What differed much less was their genre – their mode of writing – and the continuity at this level is made more, not less evident, by the consideration of the changing historical background.

The formal features surveyed in chapters 1–4 – the semiology of Greek mathematics, if you will – fell into two main parts. Chapters 1–2 described the use of diagrams (chapter 1 discussed the diagrams themselves; chapter 2 discussed the use of letters, labeling the diagram, within the main text). Chapters 3–4 described the use

of language (chapter 3 described the mathematical lexicon, chapter 4 described the use of formulaic expressions). Looking back at the reception of the book, the most surprising thing to me was the extent to which this focused on diagrams and not on language. A lot of this seems to be a bias toward the new and surprising: readers naturally focus more on what they did not expect. When considering the semiology of a text, it is obvious that one would describe its language; it was more surprising, and so more useful for readers, to learn about the place of the visual. This is especially the case because of the claim (which was made at the same time, from the philosophical point of view, by Manders (1995/2008)) that Greek mathematical diagrams are not some mere ornament, in principle eliminable, but instead serve as one of the informative vehicles of the text. This makes for a more complicated, two-lane semiology. There is more: diagrams are evidently "embodied," they subsist as graphic and ocular phenomena. To say that mathematics of a certain kind essentially relies on diagrams is to say that this mathematics is essentially embodied; this attitude, vaguely anti-Platonist, spoke to many readers (as one can see in particular in the most significant review of my book, that by Bruno Latour (2008)). The emphasis in the reception on the diagrams is thus understandable but also a source of chagrin. I did *try* to say new things about the language, as well! More seriously, and more to the point, the operation of Greek mathematics cannot be understood apart from its *two* lanes. It is precisely the combination of the visual and the verbal that makes Greek mathematics effective. The complicated semiology is not merely interesting in its added complication of a visual, put on top of the verbal: it is the interaction of the two – for which, both must be acknowledged – which matters most.

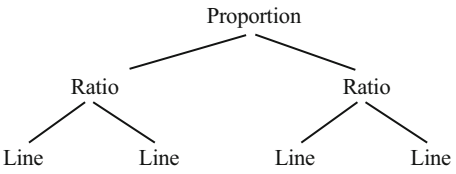
In what follows, then, I will restate my main observations; I will then proceed to discuss later additions and revisions, and then return to my tentative reflections.

To redress somewhat the balance of the reception, let me begin here with the language. The observation of chapter 3 was mostly negative (disambiguation of terms was not the only or even the central function of most introductory passages to Greek mathematical works; much of the lexicon was undefined or ambiguously defined and in general there was not a deliberate effort to regiment the actual vocabulary in use). This leads to chapter 4 where I made my more positive contribution. My argument was that the unit around which the language was organized, in use, was not the individual word but the formulaic expression. By this I refer to expressions such as ("<. . .>" mark elided words):

(1) "The (feminine article) <line> AB"
(2) "Let the <Line> AB be drawn through the <point> A parallel to <line> CD"
(3) "As the <line> AB to the <line> CD, so the <line> EF to the <line> GH".

The number of possible expressions one could compose within the Greek mathematical lexicon is astronomically bigger than the number of expressions in actual use. Typically, a Greek mathematical proposition can be broken down to a few

repeated expressions, so that even an entire treatise can be shown to use in the order of magnitude of a hundred or so. What I found most significant was the embedded tree structure of such formulaic expressions. The expression for proportion (3 above) brings together two expressions for ratio, each in turn often composed of two expressions for lines (1 above). As linguists would put this:



Now, consider a statement such as (Apollonius' *Conics* IV. 46, 72.4–8):

> Since it is: as the <square> on MΨ to the <square> on ΨI, so the <rectangle contained> by AΠB to the <rectangle contained> by ΔΠE, but as the <rectangle contained> by AΠB to the <rectangle contained> by ΔΠE, so the <square> on ΛT to the <square> on TI, therefore also: as the <square> on MΨ to the <square> on ΨI, so is the <square> on ΛT to the <square> on TI.

Such statements are the backbone of Greek mathematics: the manipulation of proportion. They appear almost impenetrable to the untrained reader, but a modern reader would immediately understand the content by being told that this is the transitivity of proportion and that the claim has the form:

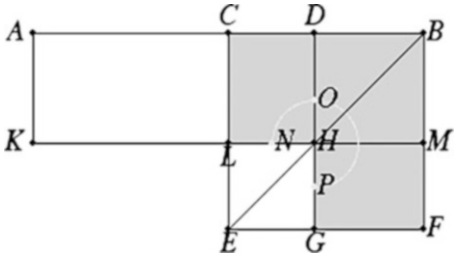
> a:b::c:d and c:d::e:f, therefore a:b::e:f

One of the key arguments of *The Shaping of Deduction in Greek Mathematics* was that (1) formulaic expressions such as those Greeks use for proportion were as transparent, to the Greek trained readers, as visual symbolic expressions are to modern trained readers, (2) that what made their manipulation so easy was the human capacity to read off the phrase structure of verbal expressions. The key operation of the Greek mathematical language was the substitution of elements within formulaic expressions. The significance of expressions such as that of proportion is that they provide, simultaneously, a substrate for substitution (the formulaic expression for proportion is composed of six lower slots – two ratios, four objects – each of which may be independently replaced) as well as a warrant for substitution (the very claim of the proportion asserts the substitutability of the two ratios).

The Shaping of a Deduction in Greek Mathematics was subtitled *A Study in Cognitive History*, not *A Study in Semiology*. In my account of the Greek mathematical language, I did provide something of a morphology of the Greek mathematical expression, a linguistic and a semiological exercise. But what interested me then was not the symbolic system itself but its interface with the human mind, making the performance of certain tasks possible.

As noted, the cognitive exercise of Greek mathematics was a two-lane process, verbal and visual. Some of the operations were supported by verbal manipulation, mediated by the phrase structure of embedded formulaic expressions. Others were supported by visual identification. Hence the role of the diagram.

The morphology of the Greek mathematical diagram is harder to provide (the semiotics of the visual – two dimensional, never a pure Piercian symbol – is always more difficult, hence the greater interest it attracts). The Greek mathematical diagram is always labeled, the combination of letters conforming with the potential combinations of geometrical objects. When lines or areas are presented in isolation, they usually are labeled with a single letter directly; otherwise labels are attached to the points at the intersections or other significant points on the lines in configuration. The purpose of the diagram is to enable readers to pick up such relations of configuration. One main function of the diagram is to support claims such as (paraphrasing Elements II.5):



[area] CH is equal to [area] FH, therefore, adding [area] DM, [area] CM is equal to [area] DF.

That is, it is through the diagram that we tell that, e.g., CH + DM = CM. This relation is not supported by any other symbolic representation. In more general terms, the diagram provides the reference for the objects mentioned by the verbal discussion and allows one to skip steps, since identities are visually preserved. For instance, in this case it is verbally asserted that the relevant lines are parallel so that we can tell that, for instance, ACLK is a parallelogram. A Greek mathematical author would not be able to tell such a property directly from the diagram (that two lines are parallel cannot be visually represented by the semiotics of Greek mathematics), but once the reference is established, one does not need to go through a separate deduction to establish that AC and KL are opposite sides, hence AC=KL. That opposite sides are equal to each other is explicitly proved, but that AC and KL are the opposite sides in the parallelogram (and not AC, AK) is *visually* established. I mention the example of parallels and the relations they engender. This is not an accidental example. In general, parallels engender, to the Greeks, similar figures. Similarity, in turn, signifies, to the Greeks, the presence of proportions. This then is the normal process of a Greek mathematical proof: embed in the visual sign the reference to parallel lines; use this to extract similarity, hence proportion; manipulate proportions via the verbal sign; this in turn may give rise to new results embedded and then manipulated via the visual sign. This

two-lane process of Greek mathematics is at the root of many creative moments in Greek mathematics. It may be that, in general, our lucky number is two. Working within a single sign system, one can do only so much that is surprising: the signs themselves suggest their horizon of applicability. Combine two sign systems together, and one no longer can tell the possible results in advance. The mathematical support for this duality, in this case, is the homology of proportion and similarity; the semiological support is the duality of language and diagram.

In the years since the publication of *The Shaping of Deduction in Greek Mathematics*, I made a few further contributions related to the semiology of Greek mathematics, which are worth mentioning before I return to sum up the relation between semiology and history.

As regard the language, two observations I made – both related more to arithmetic than to geometry – are perhaps relevant. One is in the article "Counter Culture: Toward a History of Greek Numeracy" (Netz, 2002), the other is in the article "Reasoning and Symbolism in Diophantus: Preliminary Observations" (Netz, 2012).

Both articles engage, yet again, with the theme of semiotic duality. In Netz (2002), I described the practices of calculation in the ancient Mediterranean organized around the abacus, which is simply a flat surface on which spaces are marked for specific types of numerical representations, with small tokens moved along the surfaces according to the rules of the required calculation. In the most familiar case we have the surface divided into vertical columns marked by "1," "5," "10," "50," etc. (this is most familiar as the Roman numerals). The rule is that five counters on a "1"-type column are removed and replaced by a single counter on the column immediately following; the same applies for two counters on a "5"-type column. For instance, calculate $33 + 22 = 55$ as the series of states on the abacus:

I	V	X	L	
***		***		33

I	V	X	L	
***		***		
**		**		+22

I	V	X	L	
	*		*	=55

I emphasized in Netz (2002) that such counters, moved on the surface of the abacus, form, to the Greeks, the most natural way of representing numbers. Just as,

to our mind, certain traces on paper taking shapes such as "2," "3," are the self-evident symbol for the relevant numbers, so, to the Greeks, the same numbers are self-evidently represented by the heap of counters containing the correct cardinality. The metonym of number were *psephoi* (Latin: *calculi*. To be clear: the suggestion is that the heaps of counters stood as the metonym for number – not the Greek symbolic analogues to "I," "V," "X," "L," which were more obviously mere tools for manipulating number). At the same time, the Greeks – like almost all cultures – possessed a verbal representation for numbers which, in their case, followed the base 10. (The distinction between "1" and "5" columns in the abacus is of course motivated by the limitations of the human cognitive capacity of subitization). A separate scribal convention existed to abbreviate this verbal representation. Thus, instead of writing out in full "thirty two" the Greeks could write in sequence the symbol for thirty followed by the symbol for two. The symbolism for this system – which has distinct symbols for each of the values 1, 2, . . ., 9, 10, 20, . . ., 90, 100, 200, . . . 900 – was taken from a slightly expanded alphabet. In this case, the duality of the semiotic systems – counters in the calculation of numerical values, alphabetical numbers in its record – was perhaps, if anything, counterproductive. This is because there is no two-way traffic allowing one to combine the two systems. Numbers are calculated through counters and then are entrenched in writing as alphabetical, where the process ends. The manipulation of number as a written device is the great invention of the algorithm which is, essentially, a way of turning the abacus into a written form.

Part of my interest in Netz (2012) was in the symbolism employed in the manuscripts of Diophantus' Arithmetica. (I stand by my purely semiological observations on the symbolism as such; I am much less confident of my interpretation of Diophantus offered in that article, in part because I am not longer confident that Diophantus should be considered a Late Ancient author). Diophantus explicitly develops a system of symbols based on transparent abbreviations: so, for instance, C^{u} for "cube." A special symbol is used for "number," which often is used for the number sought in the problem at hand: this then makes it functionally equivalent, in some cases, to our "x" (I will represent this as $). Remember that one may use the alphabet in a particular way, to abbreviate numerals – and, with all those abbreviations in place, many statements in Diophantus seem to be written in a quasi-algebraic format, for instance:

> [concluding a calculation] result: $A M^{o}K

This is equivalent to what we would write down as X + 20. (M^{o} stands for "monads" or the units of the number being calculated in this case. A is 1, K is 20).

My observation in Netz (2012) – which, to be honest, was not very original or controversial – was that in the manuscripts of Diophantus abbreviated and full forms are always interchangeable. In one sentence one writes down "$," in the next – "number." "K" and "twenty" may appear side by side. There seems no obvious pattern inside manuscripts, between them or across time: in all likelihood, I believe this pattern was found in Diophantus from the very beginning. The symbolic abbreviation is essentially an allograph. (This is true, to be clear, for both pairs,

"$"/"number" as well as "K"/"twenty": It should be noted that the latter allography between number abbreviation and full number word is visible everywhere in the manuscript tradition and is not specific to Diophantus). It is tempting to suggest, once again, that Diophantus was at the cusp of a semiological/cognitive breakthrough but failed to achieve it. (Because, obviously, his interests were different: he did not try to invent algebra, he tried to solve arithmetical problems). It would be only in early modern Europe that authors would start to employ abbreviated forms more consistently, creating a semiotic system in which certain observable relations between symbols may be calculated directly on the symbols as a visual system, independently of the symbols' verbal interpretation.

With both developments – the rise of visual number manipulation, the rise of algebraical symbolism – we study a similar trajectory where, ultimately, modern European mathematics would contrast with the Greek. This trajectory from geometry to algebra clearly invites a semiological account. Still, I did not pursue it much further, and only in part because of my training in ancient, and not modern mathematics. Something seems to change, I believe, in the very nature of the process, so that I no longer see how to pursue it as part of the same research program. To see why, let me add a few words on the other component of the Greek mathematics semiological system – the diagrams.

This brings us back to Greek geometry itself. The key to Greek geometry is the duality of the two semiotic systems – language and diagram, each operating based on its own cognitive lane. The two lanes, the visual and the verbal, are then most directly combined in early modern Europe by the tool of the symbolic algebraic formula, in some ways equivalent to the Greek formulaic expression but made accessible, in cognitive terms, to a more purely visual computation, bypassing the grammatical parsing of the verbal expression. In some sense, then, early modern Europe – with its Indo-Arabic numerals and its symbolic algebra – represents semiological progress.

Perhaps one reason why Greek mathematical diagrams were found, by readers of my book, more interesting than the Greek mathematical language is that there is no simple story of progress to be told and if anything there is a case to be made that the Greek mathematical use of diagrams was more subtle and sophisticated than that of contemporary geometrical pedagogy. It is often believed today that students should not rely on diagrams while making inferences, and instead rely on the discursive proof, organized in a formal manner (say, as a list of claims, each supported explicitly by axioms, previous claims, etc.). This attitude represents, at some level, a fundamental misunderstanding, as if the discursive proof is somehow semiologically innocent, as if the signs of the text and its symbolism are not a medium in and of itself. But at another level this represents a valid concern: it is essentially impossible for diagrams to convey certain types of information precisely. Roughly put, the distinction is between metrical information (the measurements of the elements of the geometrical configuration) and topological information (the contacts, containments, and intersections of the configuration itself). Greek mathematics relies on diagrams in a prudent and sophisticated way: allowing to read off the diagram the topological information but conveying all metrical information via the language.

This use of the diagram seems to be reflected in the very drawing of the diagram. In our manuscript evidence we see less metrical fidelity than one typically sees in

modern diagrams. There is absolutely no effort at any painterly effects (solid objects often appear entirely flat and indeed are often hard to interpret), and different elements, of different shapes and sizes, are often represented by the same schematic representation: the same acute isosceles triangle, whose base is parallel to the base of the page, every time a triangle needs to be represented; unequal lines often represented as equal. The only thing "correctly" represented are the relation of configuration required for the proof itself.

The transmission of ancient Greek texts is mediated, with few exceptions, through Medieval manuscripts, copies of copies of the original. Philological techniques make it possible to judge, with a great deal of certainty, how close our texts are to the authorial source. It seems clear that there is a certain amount of interpolations as well as simple mistakes contaminating our texts but that this does not disrupt our basic understanding of the language. Our semiology is safe in this regard. The matter of diagrams is more difficult. Until recently, there was not even a consistent effort to try and recover the evidence of the Medieval manuscripts concerning the diagrams (many philologers, especially in the nineteenth century, made the significant semiological choice to edit text, but to freely recreate diagrams). The observations noted above concerning the shape of Greek mathematical diagrams were made very recently, and I contributed to them in my edition of Archimedes (Netz, 2004, 2017, and see the reflections in Netz, 2012b). The best starting point is Saito and Sidoli (2012).

Since the evidence is so mediated, there is room for reasonable doubt. Carman, in articles starting in 2018, made the case that the more schematic diagrams seen in Medieval manuscripts could result from the "broken telephone" game of continuous copying. I argued against this in Netz (2020), especially from the perspective of the actual chains of transmission. But the issue should not be considered as settled.

Perhaps I can reiterate another argument made in Netz (2020), of direct relevance to semiology. If indeed we believe that schematic diagrams are authorial, how to account for this schematic character? One obvious response might be that Greek mathematicians used schematic diagrams because these are mathematically effective, for the reasons explained above. However, I find this unlikely. The argument concerning metrical properties, topology, and the logic of diagrams is complicated and was only very recently articulated by philosophers of mathematics such as Manders. (Poincaré did anticipate this argument in 1913: but few had thought as deeply on topology as he did). Even more to the point, there are no traces of any such discussions in Greek antiquity – and, had there been such discussions, how likely were they to result in a consensus? These were Greeks, after all. More likely, in my view, is that Greek geometers lucked into a semiotic device that happened to be useful for certain purposes. Indeed, this can be supported by the consideration of the scribal practices of ancient papyrus. This is, in general, a remarkably "flat" semiological practice. Formal, bookroll writing in Greek antiquity involved a single font (even nothing like our division into upper case or lower case: it was all, essentially, upper case), a single size (practically no bigger initials or titles), a single color (all the same dark brown, charcoal-based ink), no punctuation, and – most remarkable to a modern reader – no space between words. The rule can be stated simply: the scribal

code of the ancient papyrus involved zero variation because it involved zero *interpretation*. This makes sense as we consider the function of the ancient bookroll (for which see Johnson, 2000, 2010). While the ancients did read silently, they also read primarily the masterpieces of performative literature – Homer, tragedy, comedy, rhetoric, and dialogue. While reading, one always tried to project, imaginatively or even in out-loud performances, the original voice and embodied presence of the text in its full real-world power. The ability to perform a written text in this manner was the ultimate achievement of a full education: one first learned the letters themselves, the *grammata*, in a grammar school, to matriculate into a rhetorical education whose main product was the ability to declaim texts in an elegant way. Ancient education was about the ability to interpret letters. Hence interpretation, left entirely to the reader. Since the same scribes who produced texts for the general public also produced (very occasionally, never as a major part of their occupation) the texts of Greek mathematics, the unadorned, repetitive, unpainterly, and, in general, uninterepted diagrams make sense as part of the same scribal system. These suggest to us how diagrams were to be read: by a heavy interpretative investment by their readers. It is this, above all, which modern diagrams eschew.

Is this final observation at all semiological? It seems as if it should be: It is directly about the nature of a signifying system. But it is useful to note that our understanding of this practice cannot be based, in this particular case, on the symbols alone. My argument does not rely on the structural properties of Greek mathematical diagrams but instead embeds them within a cultural interpretation: I bring in a comparative structure – that of the scribal bookroll – and I interpret this, in turn, following on Johnson (2000, 2010), in terms of the ancient culture of reading as a whole but also – following especially Cribiore (2001), in terms of the practices of ancient education. Is this semiology, or history?

In general, the stories I have been retelling in this brief retrospective have three protagonists. One is the semiological system itself. This is in principle not a historical or even a specifically human system and we study it essentially in the same way we study logical or mathematical systems. The second is the cognitive apparatus with which the semiological system is engaged. This is of course human, and to some extent culturally and historically malleable (everyone can learn to parse automatically the syntactic structures of a Greek mathematical formula – to some extent, I did – but it takes a specific learning which was the hallmark of authors in a certain tradition, and not others). The third is the historical context giving rise to semiotic systems, and, as just explained, influencing the cognitive apparatus itself. I am mostly interested in the fact that people do different things in different times and places. This divides into two questions: *how* do they do that – what makes this possible? And *why* do they do that then – and not in other times and places? Often, I find situations where the *how* question has to do with the interface of semiotics and cognition – a particular semiotic system makes a certain kind of cognition possible; the *why* question has to do with the interface of both with a historical context. I thus try to build a through line from a historical context, via semiotic and (responsive) cognitive practices, to the achievement of different tasks, in this way making the history of science flow from a more fundamental historical context.

The underlying impulse for this historiography is, roughly speaking, a materialist approach to the history of culture. What is it that people actually *do* that serves to explain their more intellectual achievements?

A materialistic impulse leads one to look for conditions and presuppositions of practice that are, indeed, beyond the actors' control. I emphasized, for instance, that I doubt that Greek mathematicians simply *decided* to use schematic diagrams. I proposed an alternative account that they had such diagrams, so to speak, forced upon them given the underlying context of scribal practices as a whole, in turn driven by the underlying context of Greek writing in a world of performative literature and rhetorical education. The impulse to look for materialist accounts does not make any materialist argument correct. The question is empirical: For instance, if a lost ancient work comes to light, making the explicit case that one should rely on schematic diagrams, this would considerably reduce the likelihood of my materialist account of schematic diagrams. I tried to make the case, empirically, where possible. For instance, I argue that the set of formulaic expressions was not explicitly planned by anyone and, in this case, there are handful of historical sources of evidence we may cite: This is in part why I needed to study the Greek practice of definitions (which does not, in fact, cover the use of formulaic expressions). A particular point is that the most self-evident use of formulaic language is in the way it structures the proposition as a whole. (One of those expressions – in Latin acronym, "Q.E.D." – is so well known to have become, effectively, an English phrase!) It was therefore important for this argument to show that when the Late Ancient commentator presents an explicit schema, structuring the typical Greek mathematical proposition in terms of six parts, he does not repeat an ancient formulation but instead present what was in all likelihood the produce of later commentary (Netz, 1999b). In short, I argued in *The Shaping of Deduction* that the Greek mathematical semiotic system emerged organically, in response to a particular historical setting, and I still believe this is true. But there are of course historical examples of semiotic systems being proposed and adopted not through an organic, mostly unreflective process, but through the actors' own deliberate actions. Authors might make the case for a semiotic innovation, others might choose to follow, all based on a particular higher-order theoretical argument. I say "higher order" in the sense that such a process is no longer materialist: in such a case, what we study is the history of ideas, pure and simple. In general, we will probably find that we need to pay attention, in varying degrees, to *both* the material and to the higher order.

This is already straying beyond my field of expertise but, at any rate, it does seem that much of the history of mathematics, later than Greek mathematics itself, involves paying more attention to explicit semiotic innovations. I do not think there is a great mystery why this is the case. Greek mathematics, quite simply, presents a very clearly structured genre. It just is very evidently a semiological system. Once one wishes to reflect upon it so as to transform it, it becomes natural to propose changes that involve the rules of the genre as such, hence to propose semiotic innovations: which is obviously part of the story of the transformation of Greek mathematics in early modern Europe.

In this way, perhaps, there is something unique about the constitutive moment, as a literary genre is formed for the first time. Of course, the very semiotics of the genre are likely to emerge, in this case, more organically. Once the genre is established, however, its later evolution is described by a more complex interplay of explicit reflection and material conditions. Materialist historians may well find then that their effort is best spent on explaining aspects of the practice that are less strictly semiotic.

The point is perhaps even more basic. Why do I find materialist history compelling? Because I am, in general, interested in nonobvious explanations. There is something quite frustrating, to my mind, about arguments such that "the Copernican worldview ultimately replaced the Ptolemaic worldview because evidence gradually accumulated in support of the earlier and against the latter." The problem is not quite that this is the wrong explanation (at some level, this is obviously correct) but that this is not an explanation at all. As long as you point out such obvious, surface level observations, you do not yet explain a historical development but merely describe it. The question has to be what were the conditions that made such accumulation possible, and compelling, at a given historical moment. In other words, we are looking to explain the rise of new ideas, through some underlying conditions that are categorically distinct from the ideas themselves. This approach to intellectual and cultural history is materialist or, perhaps, structuralist.

I pursue such approaches myself but I am not keen to offer general historiographical advice, for reasons similar to those pointed out concerning the scope, and limits, of the semiotic approach in the history of mathematics. It is telling that I do not even find it important, at this point, to distinguish between materialist and structuralist accounts. Whatever works, for a given explanation, is itself an empirical question, depending on what the actors were actively considering (which varies historically) and depending on what, in the surrounding environment, was decisive (which once again changes through time).

There is nothing very controversial about a preference for materialist or structuralist explanations. From the mid-twentieth century, through several decades, such an approach became dominant (this coincided with an overall intellectual optimism associated with the expansion of public universities and a general explosion in scholarship in the humanities and social sciences). I suspect that at some point the good intuition, underlying such approaches – that explanations should be *explanations* – was marred by a bad intuition, as if there can be a single universal key, a particular type of materialist or structuralist parameter explaining all of history. Several decades ago, such universal claims began to seem – rightly – hollow. The response of scholars was to give up not only the universalist claims themselves but the very project of explanation of culture. I guess it was hard to imagine, at this point, the baby aside from its bathwater (can one imagine Marx, or Levi-Strauss, apart from their claims of universality?). Perhaps we should. One should be a materialist, or a structuralist, as the occasion demands: looking for different material or other conditions in each different case. Occasionally, then – but only occasionally – semiology, itself, may serve as historical key.

Abstract

Historians and philosophers of mathematics rely primarily on written evidence to discuss the knowledge and practices produced or put into play by actors. The point of this chapter is to offer a critical reflection on the *nature* of the written evidence on which historians and philosophers *qua* observers draw to this effect.

1 Introduction

Historians and philosophers of mathematics rely primarily on written evidence to discuss the knowledge and practices produced or put into play by actors – for sure, we should not forget that they also sometimes rely on objects, like calculating machines, but including these in the scope of the essay would lead me too far here. The point of this chapter is to offer a critical reflection on the *nature* of the written evidence on which historians and philosophers *qua* observers draw to this effect.

To follow the discussion of this issue that I offer here, some terminological distinctions will be useful. I will thus tentatively introduce indications about some terms I use, even though I am aware of the complexity of the matter, and of the preliminary character of my suggestions. In what follows, then, I will use the term "text" to designate that which we read in our written evidence (with reference to both discourse and non-discursive elements). Texts are available to us through "documents," a term I use to refer to a material object (e.g., a papyrus, a clay tablet, or bamboo slips) on which a text under consideration features. Texts have also been written by means of ephemeral "inscriptions" (using, e.g., calculating rods, tokens, or chalk), and in such cases, due to its very nature, the written evidence must be restored from clues.

This essay surveys recent work in the history of mathematics to offer a theoretical discussion of the various ways in which texts, documents, and inscriptions reflect knowledge and practices, my aim being to highlight the various dimensions of mathematical practice to which they attest. In my view, such a clarification helps us apprehend how our sources might be used to work on the activities undertaken by our actors. It can also inspire general reflections on what writing has meant – an issue to which I return in conclusion.

2 Texts Viewed as Communicating Knowledge

A common tacit assumption that historians and philosophers of mathematics make about the mathematical texts they use as sources is that these texts were written to *communicate* and more specifically to communicate pieces of knowledge – data, concepts, results, procedures, reasoning, theories, thoughts, techniques, and so on – to their intended readers. We can perceive the effect of this assumption in the way these observers engage with their sources: they seek to account for *what* is being *communicated* and formulate an evaluation of *the way* communication is *performed*

(i.e., whether the exposition is clear or ambiguous, whether it has gaps or not, and so on.)

To be sure, letters meant to convey information to an addressee and further to a wider readership when it was common practice that they be reproduced to circulate more broadly. Articles were intended for readers and, to begin with, in modern times, for referees. Books were composed with specific readerships in mind, even when they turned out to be tapped by other collectives of readers and for uses that their authors or their editors had not foreseen. However, can we assume more generally that this motivation governed the production of any text that we use as a source? Before addressing, in the next sections, the problems with this assumption, I will first analyze what recent work in the history of mathematics tells us about how we might apprehend communication.

2.1 Texts as Acts of Communication and Their Shaping

Take Euclid's *Elements* or the Chinese first-century CE *The Nine Chapters on Mathematical Procedures* (*Jiuzhang suanshu* 九章算術, hereafter *The Nine Chapters*). It seems clear that the former delivers propositions with proofs, organized according to an axiomatico-deductive order, while the latter communicates, in the form of "procedures" (*shu* 術), lists of mathematical actions to be carried out to solve problems. If we extend to written texts the classification of speech acts inaugurated by John Austin (1962), we might provisionally suggest that the former work is of the assertive type, whereas the latter seems rather of the directive type.[1]

Reviel Netz (1999) goes one step further, asking not only *what* the text of Euclid's *Elements* communicates, but *how* the act of communication was carried out. As I will argue, the "how?" question is as complex as the "what?" question. Netz's book illustrates some of the ways in which this question can be interpreted and addressed. His study of the lettering of the diagram attached to each of the propositions of Euclid's *Elements* leads to several conclusions on these issues.

First, Netz establishes that the point of theorems or problems put forward in a proposition, as well as the reasoning attached to them and the diagram on which the reasoning was based, were fully formed before the related text in Euclid's *Elements* was composed. In other words, the text did not derive from a reflection that unfolded while writing, but aimed to present propositions, after they had been acquired. This conclusion might be interpreted as supporting the claim that the intention behind the composition of Euclid's *Elements* was indeed to communicate knowledge.

Second, the diagram was drawn, and letters were added to it, following an order that combined the process of geometric construction and the flow of the argument, before the text of the argument was written up (p. 85). Paying attention to the writing practices involved in the making of Euclid's *Elements* thus enables Netz to document the writing act that produced the text.

[1] On this extension, see Chemla and Virbel (2015).

2.2 A Text Communicates at Various Scales

One could address the question of what and how the text communicates from several other angles.

For instance, a work like Euclid's *Elements* seems to communicate not only propositions but also an organization thereof, thereby conveying a meaning at a global level and hence calling for a perusal that goes, so to speak, from cover to cover. Was *The Nine Chapters*, with its 246 problems and related procedures, intended to communicate meanings of a similar nature – that is, meanings at the level of the textual organization – and therefore did the work require a global reading of this kind? This does not appear to be the case to the observers that we are. However, what did the ancient actors think about these questions? A method of addressing the issue in a historical fashion is to examine ancient readers' approach to the text. *The Nine Chapters* was handed down with a selection of ancient commentaries that were composed on the classic – that is, the one completed by Liu Hui 劉徽 in 263 as well as the one composed under Li Chunfeng's 李淳風 supervision and presented to the throne in 656. These readers do not seem to have considered that *The Nine Chapters* should be perused going simply from beginning to end. By contrast, for them as well as for us when we deal with Euclid's *Elements*, the classic required forms of global reading. In their view, at a meso-level, the chapters conveyed a mathematical meaning *qua* chapters (Chemla et al. 2018). Moreover, the set of nine chapters pointed out fundamental operations to which all mathematical procedures could be reduced: a commentator's interpretation thus aimed to establish the list of such operations using a specific reading of the procedures brought together in *The Nine Chapters* (Chemla 2008). Whatever the case might be, neither Euclid's *Elements* nor *The Nine Chapters* deal with these elements of knowledge in a discursive way. Nor do they address the kind of handling of the text required for a successful uptake. The question of how the authors or the editors of these works intended to convey meaning is thus not as straightforward as it might appear at first sight. Nor consequently is the issue of the interpretation of our written evidence.

Problems with respect to our "how?" and "what?" questions also arise at a much more local level. What did terms for operations, such as those occurring in the text of a procedure in *The Nine Chapters*, refer to? Høyrup (1990) has raised doubts about the basic answer that earlier historians had given to this issue for the case of cuneiform tablets.[2] For them, the sentences of a procedure in which these terms occur referred directly to arithmetical operations and to the operands to which they should be applied. Why, then, Høyrup asked, do we have different terms referring to what for us would be the same arithmetical operation? In contrast with earlier interpretations, Høyrup put forward the thesis that these terms referred not only to an arithmetical but also to a geometric operation: In his view, if different terms referred to the same arithmetical operation, geometrically they designated different

[2] Høyrup (2002) gives a more comprehensive treatment of this issue.

types of action. Such an interpretation of these terms entails a wholly different reading of the text of a procedure: For Høyrup, the text not only communicated the prescription of a sequence of computations but at the same time referred to a geometric configuration and its successive transformations, which made the meaning of the computations clear and thus formulated an argument for the correctness of the procedure. Contrary to interpretations that considered the text of a procedure as a simple sequence of directives giving readers the means to fulfil a task without conveying any understanding – which is how texts of procedures from the ancient world have frequently been assumed to make sense – Høyrup proposed an analysis that read proof and algorithm interwoven into a single text. This work has opened the way to a reinterpretation of whole corpora of ancient sources (Chemla 2012). One could not explain more clearly what is at stake in securing a correct apprehension of the communicative acts that mathematical sources carry out. In the same way as the questions of what and how a speech act communicates have given rise to much theorization, the same questions need to be attended to with respect to mathematical texts.

2.3 Contexts of Communication

The study of speech acts has emphasized the importance of taking into account the context of communication in order to analyze the way in which a given act was successfully performed. To investigate the nature of the communicative act carried out by given mathematical texts, taking into consideration the context in which they were produced also appears as essential. However, the nature of the contexts that are meaningful in this case raises yet another theoretical problem, which is of extreme difficulty and still awaits research in the history and philosophy of mathematics. Let me offer here some preliminary reflections on this issue.

Geoffrey Lloyd (1990) has already given the notion of context of communication pride of place. He found in this notion resources to disqualify explanations that accounted, for example, for the emergence of the axiomatico-deductive reasoning in ancient Greece, and not in China, in terms of mentality. In particular, Lloyd suggested that the latter difference could be understood as correlated with differing contexts of communication in these two parts of the ancient world, which owed to contrasting political backgrounds. In ancient Greece, unlike early imperial China, Lloyd argues, adversarial debate was common and, in specific contexts, "adjudicated by a lay audience" (p. 126). In Lloyd's view, such an environment was conducive to the development of critical analyses of argumentation and to the shaping of textual forms of reasoning such as those found in works like Euclid's *Elements*. Lloyd's argument points to a more general thesis with respect to our written evidence: it suggests how and why textual forms of communication adopted in mathematical writings may be intimately related to textual practices at play in a broader "textual culture" – in this case, argumentative practices familiar to the citizen in the context of classical Greece, owing to his or her political and social experience. However, it is interesting to note that not all Greek mathematical texts fall into this category. This

warns us against the temptation to generalize too quickly in any part of the reasoning. In particular, the identification of textual cultures appears as a potentially fruitful project, but also as a challenging one.[3]

Indeed, this is not the only case where a textual form employed in mathematical writings echoes a form common in the broader textual cultures in relation to which mathematical texts were composed. A telling case in point is that of Sanskrit mathematical "treatises" – or mathematical chapters in "treatises" on astral sciences – that are written in the form of *sūtras,* as are "treatises" in many other fields of inquiry from South Asia (Plofker 2009, Appendix A). It is beyond the scope of this chapter to discuss a definition of the *sūtra* from a textual viewpoint, assuming that such a definition that would hold for all times and places exists (Keller 2015). Suffice it to say that *sūtras* are as a rule versified and characterized by their utmost concision. Accordingly, their formulation has often led observers to emphasize their ambiguities and underline that they are "not always easy to understand" (see, e.g., Plofker 2009: 307–308, 66, respectively). The key question for us is to capture how actors came to grips with these types of text, whether the texts dealt with mathematics or with any other field of inquiry. Unfortunately, as a rule there remains no evidence that would enable us to address this question for the precise context in which *sūtras* were produced. However, "treatises" written in *sūtra* form were in general handed down with commentaries, which offer a linguistic analysis of the *sūtra* in a commentator's interpretation – making clear the meaning of the terms and the grammatical structure of the sentences. Moreover, in cases when the base text dealt with mathematics, commentaries also offered mathematical developments based on the *sūtra* as well (Keller 2006; Plofker 2009: 67). These remarks have two crucial consequences.

First, taking the *sūtras* as that which should be understood implies that one considers the "treatise" independently from the commentaries with which it was handed down. However, for the transmission of the text, actors have shaped the textual act of communication as the combination of the *sūtras* and an associated commentary. A source of this kind attests to an actor's uptake of the *sutras* – it materializes how for this actor the *sutras* communicated meanings and makes explicit the meaning he read into them. Probably, the term "treatise," commonly used in Indology to refer to a collection of *sūtras*, misleadingly creates expectations that the *sūtras* form a stand-alone text and that they carry out an act of communication different from what the actors understood (Keller 2010). Interpreting written evidence requires that we identify what for actors was the textual act.

Second, each commentary embodies a way in which actors processed a collection of *sūtras*. Observing how they drew on the text to make sense of it gives us evidence about the kind of text *sūtras* were for these actors. One example will suffice to illustrate that commentators apply ways of reading that are quite unexpected for modern readers. When the seventh-century commentator Bhāskara I reads *sūtra* 19 of chapter 2 of the *Aryabhatiya* (499), from the list of operations that composes

[3] On the problems and promises attached to various notions of cultures, see Chemla and Keller (2017).

the first part of the *sūtra*, he derives four different procedures on series through using different approaches to the wording, each of which omits a different section of the list (Keller 2006, vol. 1: xlvi). It would not make sense to consider that his reading gives the final word on the *sūtra*. However, the observation of his mode of handling the text of this *sūtra* as well as that of other commentators clearly demonstrate how misleading a modern reading of the *sūtra* would be (Keller 2015). Not all texts communicate in the same way. Applying a decontextualized approach to a text is what might lead to our perception of the text as "ambiguous" or hard to understand. By contrast, the unpredictability for us of Bhāskara I's apprehension of the text shows how essential an approach of reading from the perspective of historical anthropology is for understanding the type of text *sūtras* constituted for actors interpreting them in different given contexts. This approach is after all, here as in any other case, what can help us grasp the mathematical knowledge and practices to which a given text attests. What is more, the fact that *sūtras* deal with mathematics might give us specific resources to describe modes of reading that would then be relevant for other types of *sūtras*.

These remarks lead to a general conclusion valid far beyond the case of *sūtras*. The interpretation of mathematical writings requires that they be contextualized *qua* texts. I have suggested elsewhere that the appropriate contexts were mathematical cultures (Chemla and Keller 2017). I return to this point below. The uptake of textual acts necessitates in particular that the actual texts with which, for actors, acts were carried out be determined and that texts be approached with operations with which actors in a given context dealt with them. For the case of *sūtras*, a given commentary epitomizes a context of interpretation of this kind, which will be passed on to readers who will approach the *sūtras* within this commentary. This observation further highlights that, in addition to the context in which our written evidence was produced, the contexts in which it was appropriated and used are equally meaningful for the history and philosophy of mathematics. The last remark is meant to refer to the practices of reading and interpretation at play in the contexts of appropriation. However, in the case of mathematical writings, it extends also to actors' mathematical knowledge and practices in these contexts (Goldstein 1995; Chemla 1999; Ehrhardt 2017). Textual communication needs to be not only contextualized, but also historicized.

2.4 Approaching Texts in the Context of Mathematical Cultures and the Issue of Interpretation

Placing proofs of a Euclidean type into a wider context of communication allows Lloyd to argue for the thesis that this context might – at least partly – account for how textual forms and practices took shape in mathematics. The case of mathematical *sūtras* highlights another issue at stake in this type of contextualization: the focus here is on interpretation, an issue that is meaningful for any work written in *sūtra* form, although it might take on specific features for mathematical writings. By contrast, the works of Netz and Høyrup mentioned above highlight facets of

mathematical written evidence that are specific to "mathematical cultures," in the sense of "shared ways of doing mathematics" that can be observed in given local contexts and over given periods of time. Lettered diagrams in Greek documents and texts of procedures in cuneiform tablets are arguably facets of this kind. For Netz (1999: 60–61), lettered diagrams emerged as an artefact central to mathematical practice in some Greek contexts and became a crucial part of written documents for some (but not all) practitioners. Like Lloyd, Netz focuses on the question of the historical shaping of elements making up mathematical texts, while in Høyrup's work the emphasis is on how modern historians should interpret the lists of operations in our written evidence from Old-Babylonian Mesopotamia.

In brief, we see how mathematical texts are composed with resources taken from broader contexts as well as with resources shaped by collectives of actors practicing mathematics (Chemla and Keller 2017). In this respect, the types of text used by practitioners, as well as the operations practitioners perform with these texts, are key components of the mathematical culture in the context of which these actors carry out mathematical activity. Like other elements, textual forms are shaped and reshaped over time, illustrating the fluidity of mathematical cultures as I understand them. Texts of procedures contained in Chinese mathematical sources composed between the third century BCE and the seventh century CE provide evidence in support of these two general theses.

As with cuneiform documents, texts of "procedures (*shu* 術)" are a central component of these Chinese mathematical sources. This is notably made clear by the fact that the titles of mathematical works often refer to procedures and computation. Recent research on these texts of procedures allows us to go one step further in the description of how texts reflect the mathematical cultures in the context of which they were composed. Indeed, different Chinese mathematical sources comprise different types of text for procedures. Some of these sources contain only texts referring to operations directly, even though they do so in different ways, which can be associated with different social contexts (Zhu 2022; Zou and Chen 2022). Other sources have in addition texts of procedures prescribing operations indirectly, by stating the reason why these operations should be used: They are in this sense comparable to the cuneiform texts described by Høyrup, even though the ways in which reasons are formulated differ from those analyzed by Høyrup.

The Chinese sources that include the latter type of procedure are characterized by the fact that they also attest to another kind of texts: these texts group together in a single procedure the lists of operations necessary to process several cases to be distinguished in a given task (Chemla 2015). Accordingly, deducing from such a text the sequence of actions necessary to solve a given case requires practitioners to navigate within the text in a non-linear fashion, thus bringing into play an expert use of the list of operations. The fact that actors are interested in and shape texts with properties of this type echoes the emphasis they more broadly place on the epistemological value of generality. As a rule, the textual forms used by practitioners are not isolated facets of the mathematical culture in which they work, but present correlations with other facets of these cultures.

The two highlighted features of the text of a procedure (referring to operations indirectly and requiring a non-linear reading) signal sources communicating actions to be carried out to actors who have been acculturated in a certain way. These textual differences between texts of procedures – in other words, the different ways in which texts communicate about the actions to be performed – thus allow us to distinguish among Chinese mathematical sources different types, which reflect different mathematical cultures.

What is more, the mathematical sources in which we find texts characterized by the two features indicated above reflect transformations in the way of realizing these two features. Both the manuscript *Writings on Mathematical Procedures* (*Suanshu shu* 筭數書), written before about 186 BCE, and the classic *The Nine Chapters* (completed in the first century CE) along with its two layers of commentaries contain texts presenting these two features. However, the modes of indirect reference to operations and the nature of the navigation through texts of procedures evidenced by both documents attest to transformations that seem to illustrate actors' reshaping of the texts with which they worked on lists of operations (Chemla 2015, 2020). These observations illustrate how the elements with which actors carried out mathematical activity are shaped and reshaped in ways that are correlated with other features of the mathematical cultures in the context of which these elements were brought into play. We further see how taking this shaping and reshaping into account is essential for interpreting our written evidence.

So far, we have considered our written evidence from the viewpoint that its aim was to communicate knowledge to readers. As was emphasized above, the fact that historians and philosophers of mathematics commonly assume that this was the purpose of a text can be seen in the criticisms that these modern observers regularly formulate towards these writings. Indeed, the complaint that a text is unclear, or ambiguous, or that it has gaps, derives from the expectation that the text ought to carry out communication, and from the observation that it fails to do so adequately from an observer's viewpoint.

We have argued that not all texts communicate in the same way and that textual communication ought to be contextualized and historicized. When actors make a judgment of this kind, it gives us valuable insights to work on communication as a situated practice. However, is the assumption that the purpose of a text is to communicate legitimate for every written source? Considering this question leads us to wholly different functions of text and to the issue of the relationship between mathematical texts and practice.

3 Texts Written to Work With

Gottfried Wilhelm Leibniz's manuscripts are an excellent starting point to highlight other functions of texts for the practicing mathematician. This fact is brilliantly put forward in Knobloch's inquiry into the scholar Leibniz's "intellectual workshop."

Indeed, Knobloch (2004) explains how for Leibniz, "thinking was thinking in writing" and "text was his instrument of thinking" (p. 51). This is the second function fulfilled by texts for the actors whom we observe. Let us focus on it.

3.1 How Various Uses of the Page Highlight Different Dimensions of the Practice

Leibniz published very little in comparison with the work – notably the mathematical work – he carried out. His manuscripts attest to this fact. However, these documents do not only testify to results Leibniz had obtained without publishing them: they also shed light on his working practices. In particular, Leibniz's manuscripts contain many drafts that illustrate two main facets of his work.

First – and most importantly for us here – some of these drafts were written during the exploratory phases of his reflections on given questions. Drafts of this type attest to how Leibniz used the surface of the page – or of several pages – to work with, developing mathematical ideas and obtaining results through an interaction with the written traces of his exploration. The drafts show, for instance, how Leibniz took advantage of the space of a page to shape tables and other types of spatial layouts in order to investigate problems and look for regularities. In contrast with this "dynamic" use of tables, which exemplifies the processual use of the page (hence the subtitle of Knobloch's chapter: "text as process"), Knobloch identifies a "static" use, in which tables were for Leibniz a reference tool to "avoid repeated computations" (p. 64). The drafts also show how Leibniz drew on specific examples and how he prepared visualizations to form ideas and to think with these "paper tools" – to use Ursula Klein's (2003) apt expression.

The texts borne by these documents did not have the aim of communicating information to a reader, unless one considers the self as a reader. Perhaps in some contexts, drafts were shared with others. However, one might assume that this was not the prime objective of writings of this kind. If historians and philosophers of science were to read such drafts as giving an exposition on a given topic, we can imagine the resulting distortion in the interpretation. Instead, written evidence like this illuminates a research process in mathematics and hence notably mathematicians' practices when they are in a moment of relatively more open exploration. In particular, this type of written evidence sheds light on how in this context mathematicians use texts to think with.

Second, some of Leibniz's drafts were preliminary versions of a text intended for publication and sometimes successive versions of this text. In a sense, in contrast with the open-endedness of the previous ones, in which Leibniz appears to explore freely some mathematical issues, these drafts derive from the pursuit of a specific goal. Drafts of this kind thus shed light on the work process followed to reach this goal. They also draw attention to how the research process continues while preparing a text for communication.

The latter remark suggests that the two functions of texts that we have separated for analytical purposes interact in fact with each other. To put it differently, the different kinds of documents that we have considered in the previous section and now in this section specifically highlight different types of activity actors carry out using the space of the page. However, this contrast does not constitute a binary opposition: it simply sheds light on distinct dimensions of actors' practice that texts reflect. We return below to this issue.

3.2 The Private and the Public

Emmylou Haffner's work on Richard Dedekind's drafts highlights facets of the research process of the practicing mathematician that are strikingly similar to those brought to light by Knobloch in his study of Leibniz's drafts (Haffner 2019). She describes how Dedekind explores ideas in the context of examples, relying on the dynamic making of tables and other spatial devices that the surface of the page allows him to deploy. Haffner further shows how Dedekind shapes static tables and diagrammatic devices to perform computations and avoid repeating them. Interestingly, Leibniz and Dedekind both seek general laws and concepts, and the drafts show how they organize their search for the greatest generality possible. The parallels between these two mathematicians' working practices that their respective drafts allow us to draw suggest that Haffner's project to consider mathematical drafts in general might yield interesting results about regularities in practicing mathematicians' use of writing material in their research. This project might also help us move beyond apparent similarities to highlight personal idiosyncrasies as well as changing collective practices in the engagement with the page.

The key point for us here is that both cases show the central role played by texts that these mathematicians design at the same time as they struggle with the mathematical matter. A case in point clearly supports this conclusion. Haffner examines a case in which Dedekind identifies a symmetry in a corpus of identities and proofs that he develops (we now understand this symmetry as caused by duality). The drafts show how Dedekind shapes specific layouts and notations to observe and study this symmetry and how this work would lead him to thematize – to use Jean Cavaillès' notion – the results of his explorations with the introduction of the concept of *Dualgruppe*. In the previous section of this chapter, I had introduced the opposition between the mathematical knowledge communicated by a local, and that communicated by a global, reading of a text like Euclid's *Elements* or *The Nine Chapters*. Haffner's description of Dedekind's work on this symmetry suggests that this opposition is also valid for the texts with which mathematicians work.

However, Haffner organizes her approach to Dedekind's drafts in a way that also differs from Knobloch's, and this leads her to highlight another important issue with respect to our written evidence. Indeed, in contrast with Knobloch's global approach to Leibniz's drafts, Haffner (2019: 4–6) focuses on drafts relating to the eventual

publication of two research articles in which Dedekind introduces the notion of *Dualgruppe*. Her crucial observation is that in Dedekind's case, the mathematician's procedures in his drafts differ strikingly from the way he presents his results in his publications. Interestingly, Haffner (2021) nevertheless suggests that the same understanding of the epistemic and epistemological value of rigor can be perceived in both types of documents. A striking difference between them is that the exploratory drafts proceed by computation, while the publications put forward mainly a conceptual approach. This conclusion has important implications with respect to our written evidence, which is the focus of this chapter.

In Dedekind's case, Haffner argues, publications allow historians and philosophers of mathematics to observe only part of the mathematician's activity. The other side of Dedekind, which is mostly hidden in his drafts, somewhat invites a more nuanced understanding of his mathematical practice. From the viewpoint of the written evidence, we further see, first, that Dedekind's mathematical work brings into play two separate types of text – one of which is foreign to the purpose of communicating knowledge – and, second, that in his case the distance between the two is radical. The same phenomenon holds true more generally. This can be illustrated from another perspective with the example of Claude Chevalley's lectures to his university students, which proceeded in a highly formal way. Once, Dominique Dumont recalls, Chevalley could not remember a proof. He then moved to a corner of the blackboard and drew a diagram for himself, hiding it from the audience; indeed, a diagram of this kind did not fit the rules according to which he thought he should make a presentation. The diagram – clearly a part of his private mathematical practice – helped him recover the proof. He thus erased it and went on with the formal presentation.[4] Whether the publication of a mathematical exposition is written – as in Dedekind's articles and books – or (semi-)oral, as in Chevalley's lectures, in both cases, the private and the public practices obey different norms, and the resulting writings fall under distinct categories. Is this distance the same for all practicing mathematicians? Or, to put it differently, does the boundary between drafts and publications vary according to the authors and the collectives? Two examples suggest that this distance varies and hence that in other cases, publications reveal sometimes more of the research process than in Dedekind's case.

3.3 Intertwinement Between Exploring and Communicating Knowledge

Unsurprisingly, the first example can be found in Euler's work. I will illustrate this statement using the texts on spherical trigonometry he published between the 1750s and the 1780s (Chemla 2004). In this context, Euler, like Dedekind, encounters a symmetry between statements – and also between proofs of these statements – that we also understand today as an effect of duality.

[4] Dominique Dumont (1947–2016), ULP, Strasbourg, personal communication.

The first substantial memoire that Euler devoted to this topic, in 1753, aims to derive all the formulas of spherical trigonometry on the sole basis of the newly developed calculus of variations. What is striking is that Euler first introduces notations with which he will perform his analytical work. After pages of computations, he has obtained enough results to achieve his goal. He thus shifts to another part of the memoire, in which he will establish that any problem of spherical trigonometry can be solved using the formulas found in the first part. To this end, at the juncture between the first and the second parts – that is, in the middle of the memoire – Euler carries out a complete change of notations (Chemla 2004: CLIX). None of the previous notations is kept. However, the new notations are correlated with a textual phenomenon that affects the second part of the memoire.

In brief, these new notations highlight the symmetry between sides and angles that derives from duality. The dual formula of a given formula – as well as the dual proof – can thus be obtained by a simple and systematic translation of the text of the original formula, and of that of its proof. Accordingly, from this moment of the memoire on, Euler adopts a presentation that proceeds in a way that highlights the symmetry between dual problems, dual formulas, and dual proofs. As above, only a reading of the structure – that is, a reading of a global type – conveys the meanings expressed in this way. Interestingly, in previous articles in which Euler had dealt with spherical trigonometry, he had used other notations.

Consequently, the introduction of these new notations correlates with the fact that Euler deploys a project on spherical trigonometry as a whole: this gives him the opportunity to think about properties that are apparent at a global level. The shaping of notations and of symmetrical parts of text are resources that he creates to this effect. At the end of the eighteenth century, this very symmetry is highlighted in many works on this field, using the same type of textual resources. In other words, readers grasped the point of the new notations, and they carried out the global reading whose meaning I have just emphasized. Accordingly, Euler's notations and type of text would impose themselves in spherical trigonometry.

The fact that Euler introduces the new notations in the middle of the memoire suggests that he is struck by the symmetry, once he has obtained a collection of formulas, and that he changes notations to focus on it and work with it. This remark seems to indicate that the mathematical research presented in the memoire unfolds as Euler writes. In this case, the distance between the draft and the publication appears to be minimal. Noteworthy is the fact that Dedekind carries out a similar change of notation, in the context of his reflection about the generality of the theory he develops. However, he carries out this change in a draft, not in a publication (Haffner 2019: 14).

Euler's last contribution to spherical trigonometry, in 1781, supports the conclusion that he carried out research while writing the text to be published and that the text was a support for his research (Chemla 2004: CLXV *ff.*). The point of this 1781 article is to establish spherical trigonometry on the basis of elementary geometry and to show that all of its formulas derive from three and only three of them. We will limit ourselves to a single remark here. At the outset, Euler introduces the notations that highlight the symmetry. In the article, he tacitly draws on these notations to

derive dual formulas on the basis of dual proofs. The key remark is that, in one of these proofs, he makes a mistake, which is also to be found in the dual proof (Chemla 2004: CLXXII). This implies that Euler actually produced the dual proof and the dual formula by a step-by-step translation of the original proof and the original formula, hence relying on his knowledge of the symmetry and on his notations to produce the text of his article. In other words, Euler is concretely working with the text he writes to generate mathematical knowledge, and this is the very text that would eventually become the publication. Working with a text and communicating results are in this case intimately connected.

3.4 Another Case of Intertwinement Between Exploring and Communicating Knowledge

As shown by Anne Robadey (2006, chap. 2; 2015), exactly the same conclusions seem to hold true for at least some of Henri Poincaré's publications. Robadey obtains these conclusions on the basis – notably but not only – of her study of the way in which Poincaré proceeds to the enumeration of cases in one of his earliest writings on differential equations from 1881.

She highlights that, when Poincaré distinguishes between types of differential equations, his publication presents cases according to a decreasing level of generality. Poincaré's assessment of this degree of generality remains tacit. It can be recovered precisely from the structure of the publication and especially from how Poincaré conducts the enumeration and deals with the successive cases thereby distinguished. Robadey is thus able to make clear the mathematical knowledge that is involved in the way Poincaré proceeds. This knowledge is not the object of a discursive exposition, but the historian can grasp it using clues – which, in this context, requires notably a reading of the publication of a global type.

What is striking is that the way of enumerating illustrated by these writings recurs in other publications by Poincaré that are devoted to different topics. It thus seems to reflect a working procedure that Poincaré regularly put into play in his mathematical work, his exploration of a situation under study repeatedly proceeding from the most general cases to the "special" or "exceptional" ones. Poincaré thus works mathematically with enumerations, and he does so in a specific way. His texts keep a trace of his working process. This remark suggests that the distance between the draft and the public text is, as it was for Euler, minimal. In other words, in these cases at least, his texts were not only meant to present knowledge to readers: they also constituted a key resource with which to work. In particular, they allowed him to carry out these enumerations and deploy their different branches. This hypothesis explains why publications contain clues of the mathematician's work: this work was precisely carried out through an engagement with the text with which he develops his reflection.

Two remarks show that in these situations the structure of the text reflects something fundamental about Poincaré's mathematical work. First of all, the

cases Poincaré considers exceptional – those that are dealt with last in the enumerations – do not receive the same full treatment as the others. In other words, Poincaré first addresses the cases whose complete consideration is in his view essential for a satisfactory resolution of the question under study. In terms of mathematical practice, the type of solution he aims for is correlated with the way he proceeds with the enumerations.

Secondly, the recurring emphasis on those cases that are general enough to suffice for the treatment of a problem and thus those that require the mathematician's attention can also be correlated with mathematical innovations introduced later by Poincaré. Indeed, Robadey (2006, chap. 3; 2016) brings to light how Poincaré was able to correct his winning but erroneous submission for the prize offered in 1888 by King Oskar II of Sweden on the three-body problem, by introducing a new type of mathematical statement. Instead of claiming that his original assertion was universally true – as he incorrectly did in the submission – in his corrected version Poincaré introduced a different statement, which he maintained was true for all trajectories except a set of probability zero.

Statements asserting something to be true for "almost all" objects under consideration have become widespread in mathematics. Robadey argues that these were probably the circumstances under which they were introduced. She also describes the work on probabilities that Poincaré developed in order to put into play this new way of asserting – and also proving – the generality with which a statement holds. The type of statement and the knowledge developed to make its utterance meaningful are clearly correlated with a working procedure assessing systematically the degrees of generality of different cases that might occur: it seems that here, we witness how Poincaré's working procedure, to which the enumerations in his publications testify as early as 1881, was eventually thematized in the form of the possibility offered to the mathematician to consider new types of statements.[5]

To put it differently, the mathematician's results and in particular his conceptual innovations are intimately correlated with his working practice. Reading in texts how they reflect the mathematician's work with these texts highlights facets of the mathematical work that illuminate the production of mathematical concepts, statements, and results. In brief, unlike Dedekind, for whom only the drafts shed light on the work engaged in the observation of the symmetry permeating his object of study, Poincaré's publications reflect part of the work process, which can be recovered using clues. In the terms introduced above, his publications mirror the different dimensions of his mathematical practice.

To conclude, we thus see the diversity of documents that make up our written evidence and also the key reasons why historians and philosophers of mathematics must deploy various types of approach to this evidence. As I have emphasized above, it is not enough to read what we perceive that texts present: we must also learn to grasp clues in texts and documents and develop methods to interpret them. But there is more.

[5] Robadey (2006: 216–220) also discusses the differences between these various works.

4 Contexts and Environments

So far, we have considered actors' work with texts in the context of practitioners' explorations of new territories. However, part of our written evidence reflects other types of activity for which actors engage with textual artefacts in their mathematical work.

4.1 Learning Mathematics with Texts

Let us think, for instance, of the mathematical documents produced in the context of scribal schools from Nippur, during the Old-Babylonian period – early second millennium BCE. They exemplify the type of documents produced in all kinds of learning contexts. Christine Proust (2007) has shown how these Nippur documents – clay tablets inscribed with a stylus – attested to different moments and different facets of the learning process and how they reflected the part devoted to mathematics in the global curriculum.

Some of these documents testify to the learning of the lists of fundamental quantities, into which any given quantity could be decomposed. Proust refers to these lists as "metrological lists." The tablets in question attest to how scribes first reproduced a master's copy written to the left of the tablet and also to how, once said scribes had memorized the lists, they then wrote them on their own.

Other documents reflect the same process of textual learning with the texts to which Proust refers as "metrological tables." These tables contain in the left column lists of the type described above and in the right column the number written in a floating sexagesimal place-value notation associated with the respective quantity written to its left. Copying the master's copy and then writing the memorized table inculcated the difference between two concepts of number, respectively written in the two columns of the layout: one of them (to the left) was used in the expression of quantities, whereas the other (to the right) was used in computations – mainly those of a multiplicative type (Proust 2008). This was the first step in the acquisition of a system of computation to which tablets produced later in the learning process attest.

Particularly significant in this respect is a group of square-shaped tablets, each containing an exercise asking to determine the area of a square that the apprentice scribes had to solve (Proust 2007: 190–196). In the same way as the metrological tables oppose two types of numbers, the tablets under consideration attest to the inculcation of the separation between two kinds of moments, each linked to a type of number, in the resolution of the exercise.

The exercise gave the apprentice scribe the length of the side of the square, asking to determine its area. This length, expressed as a quantity of the type found in the left column of a metrological table for lengths, was written in the lower right corner of the tablet, together with the question and eventually the answer expressed in the same way. The numbers inscribed in the top left corner of the tablet attest to how the actual operation was carried out.

The length was transformed into a number written using the sexagesimal place-value system by means of the metrological table for lengths. The result of this conversion was inscribed twice into the top left corner of the table, and the multiplication was then performed using the numerical table for multiplication with sexagesimal place-value numbers. The result of the operation – a sexagesimal place-value number inscribed in the top left corner of the tablet – was then transformed, using a metrological table for surfaces, to find the area, expressed as a quantity (of the type occurring in a metrological list), which had then to be written in the lower right corner. In other words, a layout was shaped for apprentice scribes to work with, and this layout is correlated with the type of mathematical knowledge inculcated.

These documents highlight many general points about written evidence that are worth discussing.

First of all, clearly scribes learnt the system of computation through the inscription of tables, and then that of the solution of exercises, which they had to write using fixed layouts. The system was inculcated into them using a specific engagement with the surface of the tablet, probably under the supervision of a master. These texts were therefore in no way written with the intention of presenting knowledge to readers: some were produced for personal training, while others were presumably submitted to someone more authoritative, as proof of a successful appropriation of knowledge. These sources illustrate from a new angle the fact that practices of sharing written productions change according to context. Whoever read the document, the work to be performed with the text aimed to impart a specific body of knowledge through what we might call an "embodiment." We have encountered the use of all kinds of layout in drafts in the context of the exploration of new questions. We see again here specific layouts being used for other purposes. In both cases, these layouts give clues on actors' practices and concepts. They also shed light on the cognitive work carried out when engaging with mathematical writings and textual forms.

Secondly, as Proust (2007) emphasizes, what is at stake in the study of this written evidence is that these tablets shed light on practices that were taught to apprentice scribes: These practices were later taken for granted and hence no longer explicitly mentioned in the more advanced texts on which historians of mathematics have tended to concentrate.[6] Studying the former tablets hence gives us tools to better interpret the latter. Seen from another angle, with Dedekind's case, we had emphasized above how different contexts for mathematical activity and different types of moment are reflected by the fact that they leave different types of written different types of written evidence. The same conclusion recurs here, even though it takes on a different meaning, with the opposition between the activity of learning at school and that of producing more advanced mathematics. This remark again highlights what is at stake in the development of a historicized and contextualized approach to our mathematical documents.

[6] Ehrhardt (2008) makes use of a similar approach to situate Galois's research publications against the background of the training that he received.

4.2 How Texts Reflect Material and Social Environments

The remark applies notably to learning environments, which, in different contexts, have left us documents of different types. The scribes who learnt in the Old-Babylonian schools from Nippur and the masters who taught there do not seem to have produced lecture notes – at least not of the type that are specific to later contexts. The lecture notes surviving from other educational contexts thus seem to attest to different practices of teaching. These are only some examples of a more general phenomenon that would require that more research be devoted to it: texts and documents shed light on the social environments and more broadly the kinds of contexts in which they were produced.

To return to lecture notes, they also testify to how speakers as well as listeners engaged with the page, for the production of oral performances as well as for their assimilation of the knowledge thereby dispensed.[7] Some of these documents were meant for a quite limited circulation, others not. Actors considered some of these documents as worth keeping – for further personal use or to be passed on to future users. By contrast, others that actors employed were meant to be ephemeral, and so it is somehow miraculous that some of these ephemera survived. For drafts like Dedekind's, this is in particular related to the establishment of institutions like archives. For school documents like the Nippur texts discussed above, this is due to the fortuitous contiguity between the material used for writing and that used for construction works. When ephemera were produced with calculating rods – as in mathematical practices in ancient China[8] – in dust, as in the Arabic world,[9] or on a blackboard, they were destined by nature to disappear.[10] We return to these ephemera below.

Whatever the case might be, the various types of documents produced in related contexts and environments that we have distinguished present several forms of contiguity with each other. Our last general remark inspired by the school tablets from Nippur will bear precisely on this contiguity. It is not surprising that drafts and publications might display continuities with each other and that school documents might present correlations with mathematical writings produced outside a teaching context. However, the case of the square-shaped tablets from Nippur highlights another form of contiguity that will prove to have a certain generality. As I have explained, the solution to the exercise displayed on each of these tablets requires the bringing into play of other texts, which are not explicitly mentioned on these tablets, notably metrological tables. At the moment of their training when scribes dealt with

[7] Bruter (2008, 2012), Bustamante de la Ossa (2019).

[9] See, for instance (Saidan 1978).

[10] The introduction of the blackboard in teaching practices is dealt with in (Belhoste 2003: 322–323; d'Enfert 2014). As for the blackboard in research practices in mathematics, see Greiffenhagen (2014).

the computation of areas of this kind, these texts had been inculcated into them. Accordingly, they put these tables into play in the solution of the exercise.

Put differently, the production of a tablet involves the use of other texts – some in written form, others known by heart – which, in the case of our exercise, can be detected only through clues. This is a general phenomenon: the mathematical work in relation to which a given document is produced brings into play other texts. Some of them pre-exist to the making of said document. Others are designed while producing the document. This textual environment is reflected in the document produced. Sometimes – especially in modern times – reference to these other texts is made explicit, and even follows fixed norms, as in bibliographies and footnotes.

The type of contiguity between the document produced and the textual environment to which it adheres remains an important yet understudied research topic. However, the documents and inscriptions present in the background and put into play to produce a given text are not always the object of specific reference, as is clear from the square-shaped tablets from Nippur. Again, in such cases, historians can rely only on any clues they may find, to explore the nature and extent of the textual environment. This raises important methodological issues: which methods are available to historians and philosophers of mathematics to recover this environment and understand how actors worked with it? And also: what kind of contiguities does this environment present with the text written in relation to it? The case of mathematical texts from Early imperial China is quite illuminating on these issues. We will now focus on it, which will require that we return to ephemera of a certain type.

4.3 Ephemera

Most Chinese mathematical texts written between the third century BCE and the seventh century CE are composed of problems and of procedures solving them. The key point for us is that texts of procedures refer to inscriptions formed with calculating rods, which are in general neither explicitly described nor represented in the texts. In particular, as a rule, the procedures tacitly imply the use of calculating rods to write numbers, and sometimes they prescribe placing those numerals in specific locations, without making clear the nature of the space used for that purpose. These inscriptions were, at the time, by nature ephemeral, and yet the texts of procedures were written in contiguity with them. What can we say about this contiguity and why does it matter for historians and philosophers of mathematics? Clues that the mathematical works contain enable us to restore, at least partly, some of the features of these ephemeral inscriptions and thus to address these questions.

To begin with, at a very elementary level, procedures prescribe computations to accomplish a task illustrated by a mathematical problem. The execution of these prescriptions seems to have been carried out by means of inscriptions written with calculating rods, since the texts of procedures regularly refer to "placing" the representation of the numbers before operating on them. The complete procedure is therefore made up of the text recorded in the mathematical document and of the actual computations that put this text into play outside the written document. I will

refer to a configuration of this kind by suggesting that the text has an "aura," in which we find in particular inscriptions with calculating rods. As a result, in line with the fact that texts of procedures shed light on the inscriptions that accompany them, the restoring of inscriptions regularly enables us to interpret these texts of procedures. This would suffice to justify the importance of considering the material environment of a text, and its contiguity with the written evidence, even when this environment consists of ephemera. But there is more.

The inscriptions that the texts of procedures allow us to restore attest to facets of actors' knowledge that the works do not explicitly address. For instance, the clues that *The Nine Chapters* contains about how, at the time, calculating rods were used to represent numbers and execute operations indicate that actors employed a decimal place-value system comparable to the one we use today, when we write 123 to represent one hundred and twenty three. However, at the time, this system was only written on ephemera. We thus see the importance of recovering these inscriptions.

This is not an isolated phenomenon: Exactly the same conclusion can be drawn about the earliest extant Sanskrit and Arabic texts that deal with a decimal place-value system.[11] Incidentally, this remark illustrates a key feature of these inscriptions: they were not written in an informal way, but followed strict norms. It might be tempting to assimilate drafts and ephemera: This would be misleading and obscure our reflection on the written evidence available to us. In particular, drafts can be quite casual. This does not seem to have been the case at all for the inscriptions formed with calculating rods. In line with the use of a decimal place-value system, positions on the calculating surface were put into play for mathematical work according to strict rules. From the viewpoint of the constraints ruling over their arrangement and transformation, these inscriptions should rather be compared with the formulas on which modern mathematical practice relies.[12]

Further, restoring not only the inscriptions that are drawn in relation to a text but also how they change throughout the computations prescribed by the text of the related procedure allows us to discover and describe actors' mathematical practices with these inscriptions, on which the works cast light (Chemla 1994, 2020). The practices in turn reflect actors' mathematical work. This is all the more crucial as, in some cases, knowledge of these practices enables us to perceive historical changes and circulations that the texts alone would not make clear (Chemla 1994). This fact has a key implication. Our first remark about these inscriptions tended to suggest that, from a temporal viewpoint, the inscriptions with calculating rods were subsequent to and derived from the composition of the text: the prescription would come first, and the execution only second. However, if, as it seems, actors carried out a mathematical work with the inscriptions that is reflected in the text, presumably the write-up of the text and the inscription of the calculating rods were more intertwined. This feature also distinguishes the draft – which constitutes a pre-text – from these inscriptions.

4.4 Inscriptions as Spatial and Dynamic Entities

Finally, the case of the inscriptions with calculating rods to which Chinese mathematical documents refer is most interesting insofar as, after centuries during which these inscriptions remained purely ephemeral, from the tenth century at the latest, representations of these inscriptions were included in the pages of works (Chemla 2010). In other words, what was once contiguity between two types of textual work now took the shape of the embedding of the two practices into different zones of the same page. In fact, probably, actors continued to use calculating rods in addition to the page. However, now, writings displayed part of the work carried out on ephemera. This key shift in the nature of our written evidence enables us to perceive that the norms and practices that governed ephemera show strong continuity with those to which later mathematical writings attest. In addition, the concepts elaborated and the mathematical work carried out with ephemeral inscriptions continued to be further developed when inscriptions were included in the pages of the writings.

These remarks highlight why a long-term historical approach to mathematical activity in ancient China requires that historians and philosophers of mathematics strive to restore the ephemera used by practitioners of mathematics for their mathematical work – as can be done using clues in the mathematical writings – and even that they include these inscriptions in the corpus of written evidence. Similar conclusions can be drawn for cases in which mathematical activity is carried out only with ephemera. I argue that the mathematical explorations performed by actors in the Trobriand Islands with string figures are of this type. Eric Vandendriessche (2015) has shown why we might consider that the corpus of string figures, and of procedures to generate them, attests to an activity at least partly of a mathematical type. In this case, finger operations with strings and the resulting figures are the only material ephemera testifying to this activity, if we set aside the works of anthropologists who attempted to keep traces of these practices.

Why, one may ask, were some inscriptions that appear crucial for practitioners of mathematics apparently kept purely ephemeral for so long, and even sometimes until now? It is impossible to answer a question of this kind with certainty. However, one may note that what was inscribed on and with ephemera such as those we have described was spatial and dynamic: actors represented in this way processes – in these cases, processes of computation or of drawing. Dynamic inscriptions seem to play a specific role in mathematical activity. This is also the conclusion that Knobloch (2004) draws from the study of Leibniz's manuscripts, which he eloquently titles "text as process." Perhaps the same conclusion could be drawn to explain the persistence of the use of the blackboard among practitioners of mathematics – working mathematicians, lecturers, as well as teachers – at a time when the practitioners in other disciplines are mostly using projections of material prepared beforehand (Greiffenhagen 2014).

More generally, the Chinese writings on which the previous developments rely highlight another issue: mathematical work is carried out, more broadly, in a given material environment, which does not always consist only of documents and whose components are not always illustrated in the pieces of evidence written in this

context. For instance, Chinese works written before the eighth century refer to diagrams and blocks. Both seem to have been material objects, at least before the tenth century, and they were not represented in the texts composed before the eighth century that were handed down. However, restoring them is nevertheless essential for the interpretation of the texts written in contiguity with them. To use the expression introduced above, these material objects belong to the "aura" of the text written in relation to them. Moreover, after the tenth century, exactly as was the case of the inscriptions with calculating rods, diagrams began being included in the pages of writings, and they display striking continuities with the diagrams to which the earlier texts refer (Chemla 2010). In other words, contiguity needs not be considered only with respect to a textual environment – as I have argued above – but more broadly with a material environment.

We had evoked circulation of types of inscriptions and practices between drafts and published texts and between school texts and more advanced texts. We now see that the synchronic and diachronic circulation between different types of support needs to be considered more broadly to understand, in an appropriate textual and material context, the production of the texts that form our written evidence. How the elements of the textual and material environments are put to work to produce another document is a complex question, which would require a historical study of the reading of mathematical documents and inscriptions. We will leave it here.

5 Conclusion

Clearly, to treat the written evidence available to historians and philosophers of science as solely having the aim of communicating concepts, ideas, and results makes us run the risk of a rather narrow approach to these texts, even for published works. Indeed, texts like documents contain clues about the mathematical work carried out in producing them as well as about the environment in which this work was undertaken. In other words, seen from this perspective, our written evidence gives us insights into actors' mathematical practice in context. However, it does so according to modalities that depend in part on the context and the practices of the actor observed. Indeed, as we have seen, publications by Euler, Dedekind, and Poincaré do not reflect the work from which they derive in the same way. What is more, documents produced in different contexts and at different moments of mathematical work yield clues of different kinds. Whatever the case might be, I suggest that, in order to deploy a full approach to mathematical practices, historians and philosophers of mathematics might benefit from a reflection about the nature of the written evidence on which they rely.

In this chapter, I have foregrounded a key type of mathematical practice: actors' engagement with texts and documents. These reflections lead me to a more general remark about how writing is often discussed. In *The Domestication of the Savage Mind* (whose purpose seems to be better rendered using the title of the 1979 French translation, *La raison graphique*), Jack Goody (1977) put forward an argument that has had a tremendous impact. He argued that societies in which writing was

available were able to shape and work with new cognitive technologies, like lists and tables, in such a way that their members were able to develop bodies of knowledge more elaborate than those in other societies. In this proposition, writing referred to the writing down of speech, the existence of which, in Goody's view, brought about a major shift for the societies in which this technology was developed and adopted.

However, what we have seen above suggests an inflection of this argument. Indeed, if we take the example of the ephemera to which ancient Chinese mathematical texts refer, we see that their inscription was independent from the writing of the Chinese language and that mathematical bodies of knowledge were developed with inscriptions of this kind – notably a decimal place-value notation.[13] More generally, tables and other types of layout that abound in drafts do not all seem to depend on the writing of utterances. The study of the written evidence that attests to mathematical activity thus invites us to rethink how we approach writing. In particular, it questions the assumption that the writing of speech would be the basis for all the other uses of writing. The latter assumption might well be another way of asserting that communication was the primary function of writing in general. However, I have argued how limited this view is.

By contrast, a reflection about the written evidence available to historians and philosophers of mathematics cogently suggests that the writing of utterances is only one of many writing practices and that other writing practices have been essential to the development of mathematics. Writing may have played a central role in mathematics primarily insofar as practitioners shaped the types of text with which they could work for the issues they were addressing. Such an assumption would easily account for a patent phenomenon: mathematical texts have changed constantly in the course of history, and they have done so much more substantially than the technologies of writing speech might explain.

Abstract

The history of mathematics can be read in two ways. On the one hand, unlike the history of physics, it does not proceed by conjectures and refutations. New theories rarely refute old theories, but give them new foundations, generalize them, and reinterpret them through new concepts. This reading is unifying, highlighting the unity of the history of mathematics from its origins, through the permanence of its truths. On the other hand, many contemporary historians of mathematics have insisted on the diversity of methods, objects, and practices throughout history. They have shown that the objects of the past mathematics are not the same as those of today. That second reading shatters the illusion of unity. It disjoins what the first reading unifies.

Rather than deciding between these two readings, this chapter examines what makes them both possible and legitimate, based on an analysis of the acts of reading that we have to perform when confronted with the pages of a mathematical text, its signs, diagrams and images, and the different language modalities it employs. Starting with a discussion of Husserl's theses in The Origin of Geometry on the role of writing in the history of mathematics, and using a number of

historical examples, the chapter shows that any reading of a mathematical text involves at least three divisions, three delimitations made by the reader's gaze: divisions between the true and the false, between language and image, and between what is inside mathematics and what is outside. For the same text, these divisions are traced by the gaze in different ways throughout history.

The chapter develops an example in greater detail, concerning the status of the equation in Descartes' Geometry. It discusses the contrasting recent readings of the equation by two historians of science, Henk Bos and Enrico Giusti. It shows the concepts of The Geometry and the ideas the philosopher develops on reading and the nature of the sign. It shows how these ideas can be used to reconstruct how Descartes might have read a mathematical text, and it explains how successive readings of The Geometry can at the same time insert it into the mathematics of later centuries.

Husserl · Peletier du Mans · Descartes · Pascal · Bachelard · Quine · Davidson · Mathematical sign · Henk Bos · Enrico Giusti

1 Introduction

Mathematics has undergone some upheavals and overhauls. It no longer conceives its rationality as Euclid's contemporaries did. It has never ceased discussing and reconstructing its foundations and what defines the nature and the rationality of its objects; but neither has it ever experienced the great collapses endured by physics: indeed, while Galilean physics might have owed some of its concepts and problems to medieval science, it simply wiped out the earlier scientific concepts of cosmos and motion; after Einstein, Newton's physics can only be described as having, at best, approximate validity. The history of experimental science is replete with rectifications, refutations, and renunciations, the analysis of which is at the heart of the philosophy of physical and biological sciences. How can a theory be held true for centuries, defended by arguments to which all contemporaries give their unreserved assent, confirmed by numerous experiments – and then simply discarded, and refuted? By contrast, much of ancient mathematics still holds true for us. We still teach Pythagoras' and Thales's theorems as part and parcel of our own knowledge. In other words, mathematical theories endure. To read a mathematical text from the past means, first and foremost, to experience permanence: its theories are still entitled to a place in our knowledge. Mathematics is reread, reinterpreted, and extended, new foundations are discovered – but its theories are not forsaken.

Of course, locally, sequences of past knowledge have been shown to be erroneous or meaningless. Mathematicians' papers often contain mistakes, corrected through posterior research. Poorly justified methods or principles sometimes lead to system-forming errors: thus, in the mid-eighteenth century, Leonhard Euler wrongly asserted that a principle he thought to be fundamental, the "law of generality of algebra"

(discarded some decades later), would lead us to admit, against all evidence, that $-1 = 1 + 2 + 4 + 8 + 16 + \ldots$[1] However, such errors exist only against a background of truths, truths that were born someday and have remained valid for the most part until now. Mathematical theories last, and they last until us.

In *The Origin of Geometry*, written in his later life, the philosopher Edmund Husserl marvels at such a permanence:

> Our interest shall be the inquiry back into the most original sense in which geometry once arose, was present as a tradition of millennia, is still present for us, and is still being worked on in a lively forward development.[2]

The mythical act of the first geometer who, out of mere land surveying, invented the ideality of the figure, endures to this day in geometry; and geometry still has it embedded within its body of knowledge.

And yet, such permanence contradicts the science historian's experience in her concrete practice of reading texts – an experience of strangeness and difference. When reading ancient texts, the historian almost inevitably finds out that, even if they still hold some truth today, their objects are not identical to those we manipulate, taking this idea in its most immediate and naive sense. Even if the discussions since the beginning of the twentieth century on the foundations of mathematics may lead us to think that mathematics is not really a discourse about objects, it may nonetheless be said that Euclid's *Elements* is about points, straight lines, triangles, and magnitudes, or that Euler's *introductio in analisin infinitorum* speaks of functions, series, logarithms, and roots of equations: both texts use terms referring to such objects, and assert their existence. The historian may well find contemporary truths in ancient texts – but the objects will not be identical. While most statements of the ancient theory of magnitudes may still be considered true, the very notion of magnitude was abandoned with the arithmetization of Analysis in the nineteenth century; similarly, although much of the Italian scholar Bonaventura Cavalieri's geometry of indivisibles could be retained as part of integral calculus, the geometric concept of indivisible is no longer relevant in today's mathematics. The theorems of Thales and Pythagoras have lost their generality in contemporary geometry, and retain only a limited value in particular axiomatics. The straight lines and triangles involved in both theorems no longer have the "thickness" and intuitive evidence they had in ancient science.

[1] Leonhard Euler (1751) On the controversy between Messrs. Leibniz and Bernoulli concerning the logarithms of negative and imaginary numbers. Berlin Acad Sci 5:139–179, 1749. The text is reproduced in the *Opera omnia*, XVII, series 1, pp 195–232. Euler obtained this result by giving x the value -2 in the series $\frac{1}{1+x} = 1 - x + x^2 - x^3 + x^4 - x^5 + \ldots$ Whose validity, formally demonstrated, is for him necessarily universal (Euler 1996).

[2] Jacques Derrida, *Edmund Husserl*'s *Origin of Geometry: An Introduction*, translated with a preface and afterword by John P. Leavey, University of Nebraska Press, Lincoln/London (Derrida 1962, p. 158).

Let us take one last example, on which we will dwell a little later. The historian who examines Descartes' *Geometry* will discover familiar equations, such as, in Book II, the equation of the hyperbola, the first analyzed by Descartes: $yy = cy - (cx/b)y + ay - ac$. For us, such an expression represents a curve only insofar as the variables and constants represent real numbers; we establish a correspondence between ordered pairs of real numbers and points on the coordinate plane. However, in the Cartesian text, the letters of constants and variables do not refer to numbers, but to lines of finite length. Even operations such as addition and multiplication are based on lines, not on numbers. So again, his equation is not ours, and does not refer to the same objects.

All the above-mentioned examples point to one conclusion: the historicity of mathematics seems markedly different from that of experimental sciences. When attentive to the details of texts and arguments, the historian of mathematics will not stumble upon a field of ruins made of discarded theories and misconceptions, so typical for the historian of experimental sciences: She discovers familiar propositions, which he can identify with those she learned in her own classes of mathematics. But these rediscovered truths are not based on genuine identities. The objects are no longer the same and we erroneously posit an identity between what are, in fact, non-identical objects. Such a discrepancy, while here mentioned in the context of the present reading of past texts, may, however, also be found within the history of mathematics itself: the protagonists in the history of science do not refer to the same objects as the very predecessors they are commenting – or sometimes, even their quasi-contemporaries. Bernoulli and Leibniz might debate about logarithm, and even agree on the essentials – yet is it really the same object? And is it the same as that of Descartes, who constructs the curve of a logarithm without naming it, all the while not even considering it as a genuine mathematical object?[3]

How is this possible? How can the history of mathematics present us both with a science that maintains the truth of past statements as it expands and transforms, and, at the very same time, a body of knowledge in which these very same statements continually refer to different objects and concepts? How can there be a durability of truths, in the sense that we continue to assent to the statements of past texts, while their terms have change meaning?

2 The Reading Process

To try to understand this, we should return to what is first given to the historian. In truth, past mathematical knowledge is not handed to us in the form of concepts, truths, and theories from the outset. We read texts, and it is only through the signs and traces marked on their pages, which somehow act upon us, that we have access to the truths and errors of the past. The mediation between us and past texts is therefore an act of reading, and this act allows us to enter the world of a particular

[3] In his letter to Florimond de Beaune dated 20 February 1639 (AT, III, 409).

theory. What is the nature of this singular reading-act that it allows for both identity and difference? What property of its gaze enables us to recapture both the Pythagorean Theorem and the difference that separates us from what it was at the time of its discovery? What is the relationship between our own reading of past texts and the reading that past scholars made of each other's works?

Husserl, in the above-mentioned text from *The Origin of Geometry*, precisely addresses this act of reading. According to him, geometry's permanence from its origins to the present day, the fact that its truth has been maintained until now, may be clarified by interrogating the meaning of the act of reading and the status of written signs. The knowledge of first geometers was recorded in written signs, and this is what allows us to revive it today and acknowledge it as our own. A modern reader of Euclid's *Elements* can find truths in it – but only because reading a mathematical text differs from the mere reception of a message, as happens in ordinary reading and its process of passive elucidation:

> Consider, for example, the way in which we understand when superficially reading the newspaper, and simply receive the "news"; here there is a passive taking-over of ontic validity such that what is read straightway becomes our opinion.[4]

Reading as a way to convey information consists merely in the reception of a meaning received passively by the reader. It presupposes knowledge of the language, but does not guarantee the truth of what is meant, nor does it rely on such a truth. On the contrary, according to Husserl, reading a mathematical text involves a requirement that of its own substantiation as a mathematical text by demonstration:

> In accord with the essence of science, then, its functionaries maintain the constant claim, the personal certainty, that everything they put into scientific assertions has been said 'once and for all,' that it 'stands fast,' forever identically repeatable, usable in evidence and for further theoretical or practical ends-as indubitably able to be reactivated with the identity of its genuine sense.[5]

To identify a text as mathematical when reading it is to conceive of it as written in the past as a sequence of universally valid deductions. Thus, for Husserl, we inevitably insert this text into our currently accepted science, which may be seen both as the text's historical aftermath (with the successive extensions, amplifications and justifications which make up the history of mathematics) and as its clarification and elucidation. If we accept Husserl's position, then twentieth century geometry, with its new foundations, would actually be the appropriate way to tackle the authentic content of an ancient theorem like that of Thales, and grasp the grounds for its truth and demonstrative force. For the German philosopher, the relationship between past and present mathematics is thus rational in two ways: the past is the reason for the present, in the sense that the latter is the consequence of the former,

[4] Husserl, *op. cit.*, p. 165.

[5] Ibid., pp. 169–170.

because the history of mathematics consists of a series of rationally solved problems; and the present is the reason for the past, in the sense that our contemporary mathematics, with its founding principles and rules, clarify the true meaning and nature of ancient objects and theorems. Zermelo-Frankel's axiomatics, for example, can thus shed light on what a number is and always has been, as well as on what founds its properties.

There is therefore a kind of reciprocal entanglement of the present in the past and of the past in the present, which for Husserl is at the heart of the mechanism of reading the signs written on the pages of ancient texts, and which guarantees the permanence of geometric truths.

Husserl's interpretation may undoubtedly seem naive to a historian of mathematics. It assumes that our contemporary but retrospective readings of ancient texts are based on a core of identity and permanence whereas, as we have seen, what is experienced is rather the dispersion and heterogeneity of objects in the texts. Historians of science have long denounced the illusion of retrospective readings that attempt to clarify the past by simply projecting ideas of our present onto it. They insist that mathematics should be considered as a practice rather than as knowledge, and have emphasized the diversity of practices and ways of doing things throughout history. Hilbertian axiomatics used games and their rules as template to think about the nature of mathematics. They turned this metaphor against the axiomatic conception and, following Wittgenstein, thought of mathematics as a plurality of language games with diverse and changing rules, identifiable by a "family resemblance" rather than by lists of strict rules. Just like Husserl, they emphasized writing, the role of signs and their different uses; but they refused to think of the sign merely as a means for placing and registering a meaning, and to examine it solely from a semantic point of view. They proposed looking at the signs of mathematical texts in relation to the images, tables, and graphs also present on the page, in a semiotics for which they sought to create tools.[6] This fertile new approach has revealed a diversity and variety in the history of mathematics that had been erased by a retrospective reading of past texts.

And yet, Husserl's reflections emphasize that such a retrospective reading is not only possible, but is also at the heart of what makes a text mathematical; and that this needs to be explained: mathematics is the practice and the science in which the present can find its own truths in the past, and thus embed the past as a part of itself. Husserl believed that it was possible because of permanence and identity, and on this

[6] In his *Mathematics as Sign* (Stanford University Press, 2000), Brian Rotman proposes just such a semiotic, drawing in part on Peirce's theory, and expressly criticizing Husserl's theory in *The Origin of Geometry* (cf. p. 47). Brian Rotman is undoubtedly unfair to Husserl in considering that the latter merely grants the sign the role of recording an ideality born originally in the solitary consciousness of a mathematician. Actually, the German philosopher defends the idea that the object or the mathematical truth only becomes truly objective, and thus mathematical, properly speaking, through the mediation of writing, its "linguistic flesh." The sign thus has a constitutive role for him. Nevertheless, Brian Rotman is right to point out that a reflection on the signs' nature and form, and on how they influence and transform the nature and form of mathematical objects, is utterly foreign to Husserl's thinking.

issue, he was wrong. But when historians saw mathematical texts as a locus of multiple rules and sign-games, and invented tools to describe the diversity of functions these signs held, they also lost the possibility to explain such a retrospective view. In *Mathematics as Sign*, Brian Rotman points out that when we assimilate Euclid's proposition "given any prime number, it is possible to find a larger one" to the modern proposition of the existence of an infinite number of primes, we do not discover a timeless truth, but we produce a "historically imposed continuity."[7] But nowhere does he explain how imposing such a continuity in mathematics is possible.

Actually, such an "imposed continuity" is linked to the mathematician's own view of her history. When the mathematician is interested in the past texts, she needs to find in them the questions that she himself asks. His gaze reads his own truths in the ancient texts when she seeks in them the original form of the questions she asks and, sometimes, the means to retrieve the answers he gives. In contradistinction, the historian views history as a kind of divergence and disagreement. There are thus two poles in any reading of a mathematical text which, to simplify matters, we will call the historian's pole and the mathematician's pole. But what matters here is not to take sides, but to understand the nature of both a mathematical text and our gaze on it for such an equivocality to be possible. How can the very same text disclose ever-differing objects yet mirror today's knowledge and objects?

Perhaps we should conceive of the text as a divisible space, the partitioning of which would be done by reading and looking. Reading is not about deciphering signs, or looking at diagrams, graphs, and figures. A mathematical text should not be understood as a collection of signs with their semiotic, diagrams with their specific classification, and images of mathematical objects like figures that could be analyzed with the tools available to the historian of science. Instead, we should think of reading as the act of drawing lines of division in the text, an act of the gaze that is the result of an interaction between the reader and the text. And among all these divisions, we note that which separates signs, diagrams, and figures, which, as we have seen, do not exist as such in the text, but only as the effect of said interaction. To study the different forms that the present reading of the past may take, therefore means to first and foremost analyze the various ways of drawing these dividing lines.

The mathematician's backward glance rediscovers her own knowledge because she draws lines of division in the text – lines which are not the historian's. We may thus in turn distinguish at least three major partitions possible, which are the conditions for reading a mathematical text:

3 The Partition of Truth and Falsehood

The French tradition of history of science from the 1930s to the 1970s has taught us that no reading of a scientific text can happen without an act of judgment and a value position: in other words, without an act of division between truth and falsehood. In

[7] *Op. cit.,* p. 40.

the tradition of philosophers of science such as Gaston Bachelard in physics, Georges Canguilhem in biology, and Jean Cavaillès in mathematics, highlighting the meaning and problems of a scientific text first requires us to distinguish what Bachelard called the "sanctioned past," which has received the seal of approval of the present and is still accepted as true, and the "outdated past," abandoned to the world of error and scientific nomadism.[8] This division is useful to understand the difficulties faced by past mathematicians when establishing and constructing knowledge, the epistemological obstacles unknowingly encountered, and the detours and side roads taken – often indispensable errors in order to reach a truth. As Jean Cavaillès said, "the after explains the before":[9] for instance, Galois' group theory explains the difficulties encountered by earlier mathematicians in their attempts to find a solution in radicals of a quintic equation. The historian of mathematics must therefore rely on present knowledge in order to shed light on the progression of past knowledge; but the difficulty is to maintain this requirement while avoiding the pitfall of a reading that would only project today's knowledge onto the past, and thereby lose the past's own rationality: in other words, the challenge is to avoid the naive view of the historian looking for "discoveries" and "first times."

Thus understood, the French tradition has put great emphasis on the retrospective point of view, which places it at the opposing end of sociology of science, or of a conception that would make science an anthropological practice of the same type as other cultural artifacts. If science is not merely a cultural phenomenon, and if it is not to be considered only as such by the historian, it is thanks to this division, which it continuously draws in its past, and which the historian must take into account. The historian's view of the text is based on this division, and can therefore never completely disregard what her present holds to be true; however, she must be aware that such a division does not exist *as such* in the text from the past, but is merely the inevitable outcome of the past and the present's encounter. It is the effect of an interaction. Thus, the history of science tags along today's science, and will also need to be rewritten, at least in parts, with each transformation of science. Such a process allows for all sorts of reversals. In the eighteenth century, the Marquis de l'Hôpital believed he had discovered a new world of numbers, the world of the infinitely small, in differential calculus. He asserted the existence, in addition to ordinary quantities, of infinitesimally small quantities. In the nineteenth century, Cauchy and Weierstrass brutally erased this delusional belief, by rigorously constructing the concept of convergence of a function. The derivatives of functions do not imply the existence of infinitesimal numbers. They are defined as limits of ratios, without assuming the existence of vanishing quantities: the Marquis de l'Hôpital's statements then appeared as mere errors and naiveties. But in the mid-twentieth century, following work on Tarski's model theory, Abraham Robinson invented a new discipline, non-standard analysis, which restored the possibility of

[8] Gaston Bachelard (1965) *L'activité rationaliste dans la physique contemporaine*. PUF, p. 25.

[9] Jean Cavaillès (1962) *Remarques sur la formation de la théorie abstraite des ensembles. Philosophie Mathématique*, éd Hermann, p. 27.

infinitesimal numbers.[10] This in turn led the historians to modify the division line between truth and falsehood in eighteenth century texts. It goes without saying that it would be naive to try to find non-standard numbers in the Marquis de l'Hôpital's text: the recurrence of the mathematical gaze is never simply the discovery of present objects in a past text, nor was its author a mere forerunner – we all know the weakness of such a concept. But Robinson's invention forces us to re-read the past and to analyze differently the obstacles to, and the conditions of the emergence of truth.

Now this new division of truth and falsity should not be understood as the reattribution of a truth value to statements whose meaning would remain unchanged. By redistributing these values, the historian also transforms the meanings she uncovers in the texts. The philosophy of language of the second half of the twentieth century, and that of Quine and Davidson in particular, has taught us that it is impossible to separate the question of belief from that of meaning in discourse. We assign a meaning to an interlocutor's words and sentences that is always determined by what we hold to be true in her discourse. In a sentence, we have the choice of deciding that it is true and refers to a given object, or that it is false and refers to another one. There is thus an irreducible indeterminacy, which will be made manifest in the experience of radical translation, but which we encounter in fact in the most mundane conversations. In radical translation, I am faced with a discourse in a language of which I know nothing. In order to interpret it, I have to decide what is to be held true, in order to correlate the words to the surrounding context. But such a decision is not unequivocal. I have to make choices, from which the meanings I attribute to those words will derive. Imagine two explorers-translators separately trying to understand the language of an isolated tribe: they may come up with two manuals with radically different meanings to the words of the tribal language, without it ever being possible to decide which one is correct.[11]

Such an indeterminacy, here illustrated by the fiction of the radical translation of an absolutely unknown language, is at the heart of our own language. When someone speaks, we too have to decide whether the words uttered are true about one thing or false about another:

> Let someone say (and now discourse is direct), "There is a hippopotamus in the refrigerator"; am I necessarily right in reporting him as having said there is a hippopotamus in the refrigerator? Perhaps; but under questioning he goes on: "It's roundish, has a wrinkled skin, does not mind being touched. It has a pleasant taste, at least the juice, and it costs a dime. I squeeze two or three for breakfast". After some finite amounts of such talk, we slip over the lines where it is plausible or even possible to say correctly that there was a hippopotamus in the refrigerator, for it becomes clear he means something else by at least some of his word than I do. The simplest hypothesis so far is that my word 'hippopotamus' no longer translates his word 'hippopotamus': My word 'orange' would do better.[12]

[10] On this question, see Jean-Michel Salanskis, *Le Constructivisme non standard*, Septentrion, 1999, which presents Robinson's conceptions in "Robinson" while discussing the question of historical recurrence in the introduction (Salanskis 1999).

[11] On this issue, see Quine (1999). *Word and object*. MIT Press.

[12] Donald Davidson (1984) *Inquiries into truth and interpretation*. Oxford University Press, "On saying that," pp. 100–1.

And thus, adds Davidson, "beyond a point, there is no deciding, even in principle, between the view that the Other has used words as we do, but has more or less weird beliefs, and the view that we have translated him wrong."[13]

This experience of the orange-hippopotamus is at the heart of our reading of past science. The historian's gaze on a past text leads her to constantly make choices. If such and such term, such and such expression, means this particular concept, then we must accept that this particular sentence in the text is false, whereas that other one is true. But if it means another concept, then truth and falsehood are reversed. These choices are not arbitrary. If I want to understand this past text, I have to hold it largely as true. According to the Davidsonian formulation, I must maximize agreement.[14] But there are many ways to do this. Hence the equivocality of the ancient text, depending on whether I maximize its truths in relation to those of today's science, conveying the partition between truth and falsehood in some way, and thereby disclosing certain meanings rather than others; or whether I choose to correlate its sentences to those of its contemporaries, or to other sentences by its author. In the latter case, I interpret the words I read, as a historian does, on the basis of what I know of what the author and his contemporaries held to be true. And this single assumption of truth reorients and reorganizes the meanings of the text. There is nothing here but the normal game in which all the meanings of language are given. In one case, I discover the unity of science by separating it from its surrounding culture, and, thereby decipher my own meanings in the text; in the other, I choose to see its dispersion and heterogeneity throughout history. These are two ways of conveying the division of truth and falsehood.

4 The Partition of Language and Image

But the act of reading past texts cannot be understood merely as an operation of interpretation, which concerns both oral and written discourse, and is not specific to scientific discourse. The written nature of mathematical knowledge introduces new uncertainties. When facing the text, the eye does not merely have before it a set of signs given as positive objects it could simply record. As mentioned above, we must draw the division (and this is the second division) between language and image, between sign and fragment of a sign, between a significant difference in a sign and a negligible variation, between what we see and what we read. But here again, all sorts of indeterminacies remain. Let us, e.g., take a look at Pascal's short 1654 treatise on the arithmetic triangle.[15] He describes the construction of a set of lines intersecting at right angles, delimiting squares called cells. In each cell, there is a number.

[13] Ibid., p. 101. In "Radical interpretation," Davidson discusses "the trade-off between the beliefs we attribute to a speaker and the interpretations we give his words" (Ibid., p. 207).

[14] On the relation between these general analyses of beliefs and meanings and some problems in history of science, see "On the Very Idea of a Conceptual Schema," Ibid., pp. 183–98.

[15] Blaise Pascal (1970) *Œuvres complètes*, eds Jean Ménard, Desclée de Brouwer, pp. 1176–1332. On this treatise, see Lucien Vinciguerra (1999) *Langage, visibilité, différence. Histoire du discours mathématique de l'âge classique au XIXe siècle*. Vrin, Chapter 1.

What kind of object is here open to our reading? On the one hand, we see the construction of a figure, which is the object studied by the mathematician. Pascal describes it to us as Euclid would, in the form of a progressive construction. The numbers in the cells, identified by Pascal in his text to the cells themselves,[16] thus appear as parts of the object triangle. Such a geometrical reading is unquestionable, and is buttressed in the second print of the pamphlet by a reinforced use of a geometrical vocabulary. But on the other hand, one may also see in it a multiplicity of statements summarized by their graphic representation, since each line of the triangle may be read as an arithmetical statement. The figure is merely a way of synoptically formulating a list of arithmetical propositions concerning binomial coefficients. Now if we turn to the discursive organization of Pascal's discourse, we find good reason to favor the first hypothesis. Pascal first describes the triangle as a genuine figure, whose construction he goes on to produce in a separate treatise; further treatises then make suggestions as to how to use this arithmetic-geometric construction. But what are we to do with such an object if we want to situate it in the history of mathematics, and make some sense of it in today's mathematics, where it appears as a nothing but a chimera? Our decisions as readers will embed Pascal's treatises either in the history of mathematics, or in the works of the philosopher.

Let us consider another example in the history of algebraic notations. Jerome Cardan's *Ars Magna*, published in 1543,[17] developed problem-solving procedures without using symbolic notations. In the French publications that followed his work, at the time of the Renaissance and the early classical age, we witness an increasing use of symbols. Jacques Peletier du Mans, in 1554, introduces the letter *R* to designate the unknown, the *res* of the *Ars Magna*, but all the other quantities in a geometric or arithmetic problem were still named discursively.[18] Shortly after, François Viète, in the *Isagoge*, used different letters to designate the unknowns and the data in problems, and arrived at true symbolic equations, but at the cost of massive preparatory work made necessary by the difficulty he faced in conceiving the multiplication of quantities. Descartes used similar symbolism for unknowns to what we use today, and simplified the notations. But for Jacques Peletier, was the letter R really designating an object? He writes:

> So for the unknown number, I put R, that is to say I put R to be equal to the unknown number. Then I reason as follows: The third part of R is 1/3R, and the fourth part of R is 1/4R; these parts substracted from R leave 5/12R. But since R is equal to the entire unknown number, 1/3R is equal to 1/3 of it, and 1/4R to 1/4. Thus, after substracting 1/3R and 1/4R from R, and similarly 1/3 and 1/4 from the number to be found, as the question requires, the two that remain are equal. Now 1/4R and 1/3R substracted from R leave 5/12R, and 1/4 and

[16] For example, we read: "In any arithmetic triangle, the sum of the cells of each base is the double those of the preceding base" (Pascal, *op. cit*., p. 1292).

[17] Gerolamo Cardano (1974) *The great art of the rules of algebra*, trad: Richard Witmer T. MIT Press.

[18] Jacques Peletier (1554) *L'Algèbre. . . departie en deus livres*. J. de Tournes, Lion.

> 1/3 substracted from the number I am looking for leave 10. So 10 must be equal to 5/12R. Here is our equation.[19]

The calculation is oddly duplicated. Although Peletier uses R, each statement involving this R is then repeated in another statement about the unknown number, called "the number to be found" or "the number I am looking for." If you think about it, R is not a term for Jacques Peletier, or else his duplication would not make sense. When he writes: "For the unknown number, I put R," he perhaps means that R replaces the unknown number in his calculation: R is thus another object, substituted for the unknown object in order to have something more familiar to compute. Peletier's algebra would thus maintain an essential proximity to the old geometry, which requires its object to stand before the reader, and cannot make sense of a calculation on an absent and unreachable object. There is no doubt that the decision to make R a letter, a term of a language to be interpreted, re-embeds Peletier's work in the universal history of algebra. But to make it an object in the stead of another, something closer to a figure than to a word, opens up a very different story.

5 The Partition of the Mathematical and the Non-mathematical

A third division remains. A mathematical text is never mathematical through and through. The reader must know how to draw what, in the text, is truly mathematical knowledge and theory, apart from what is external, and has to be rejected. Text and theory are always in reciprocal excess. A theory is never wholly contained in a given text; it always extends toward other real or possible texts, toward statements that may be deduced from the text before my eyes, toward constructions that may be added to those represented in it, toward objects other than those in the text. Conversely, a text is never purely theoretical through and through. Alongside the process of the proof, the concepts and objects that define what one would might call the theoretical content, the text presents us with remarks to accompany the reader: preliminaries, digressions, possibly historical or biographical annotations. But above all, there are statements, terms, and objects that may not evidently be elements of the theory constructed in the text.

Let us take another example from Cartesian mathematics. Descartes' *Geometry* may be read as a theory of equations, a new way of solving problems of planar or solid geometry. It mentions curves and lines. Depending on how we look at it, we can emphasize its place either in the history of algebra or in the geometric tradition. But there are several instances in the book where one also discovers the description of mechanisms used by the philosopher to build geometrical curves, such as, in Book II, small set squares sliding or pivoting in relation to each other.[20]

[19] Ibid., p. 24.

[20] This instrument generalizes another one, sometimes called "mesolabum," known before Descartes. It is used by Descartes for the first time in the *Cogitationes privates* of 1619.

The curves AH, AF, AD, are described by the points H, F, D as the compass XYZ is progressively opened. But what is the use of such a mechanism in geometry? Are these set squares also mathematical objects in his discourse, and do they belong to Cartesian theory? Are they necessary to understand the status of curved lines of geometry, by defining the "regular motion" that allows them to be "received in geometry?"[21] Are they themselves theoretical objects? Or are they merely auxiliary procedures and practical illustrations which may be erased? Today's science no longer grants them any importance, and, reasonably enough, is led to neglect them. But is this legitimate, and if so, in what sense?

This leads us to a third division to be made: we must, in the text, distinguish between an interior and an exterior of the text, a theoretical core and an impure husk. In a way, mathematics has never ceased to separate the pure and the impure throughout its history, sever what is truly mathematical from what is not. But such a division is not fixed, and mathematicians constantly trace its line in various ways and places in past texts. Descartes excluded the so-called mechanical curves from geometry, those produced by movements incommensurable with each other, such as logarithmic curves or spirals. According to him, what defines a curve as mathematical is the possibility of generating it from a finite sequence of ratios of proportions; the device of set squares gives us an image of this finite constructability of truly geometrical curves. The mechanism with set squares, which, for us, is deeply non-mathematical, is on the contrary for him what establishes the mathematicality of a curve. It plays more or less the same role as set theory or axiomatic rules in the foundation of twentieth century mathematics: a hitherto foreign element one day introduced into mathematics, of which it is claimed that it contains the very essence of mathematics. Thus, what defines mathematical purity for Descartes is no longer, as in the Platonic conception of geometry, the figure as object of contemplation, an ideal figure separate from the concrete and impure figures in the sand or on the page, but a finite succession of mind-acts establishing clear chains of relations. His geometry thus establishes a new division between what, in it, is mathematical and what is not.

This partition of the mathematical and the non-mathematical in mathematical texts runs through the history of mathematics. In ancient Platonism, it took the form of a rejection, outside the ambit of mathematics, of the concretely drawn figures. In *Geometry*, Descartes places the line of division differently – not only in his own text, but, just as much, in all the ancient texts he reads. And it can be said that, by rejecting the idea of mathematics as a discourse about objects, i.e., by refusing the very notion of mathematical objects, Hilbert's axiomatics once again drew a boundary between the texts' interior and exterior. According to Hilbert, there are no mathematical objects, but only mathematical structures that can be applied to any class of objects, as long as these verify the structure's axioms. This means in turn that, in the mass of historical mathematical texts, all the terms which are used to refer to these objects no

[21] Descartes (1954) *The Geometry*, trad: Smith DE, Latham M. Dover Publications, p. 47 (AT, VI, 442).

longer designate anything determined; they are no longer part of the truth of mathematical knowledge. Instead of discussing points, lines, and planes, we might as well be talking about chairs, tables, and beer mugs, the Göttingen mathematician once joked. The purity of mathematics is in the axioms, not in the definitions.[22] What the sentences in mathematical literature refer to must therefore be excluded from mathematics. While constantly reactivating its own past, mathematics continually re-draws this third line of partition.

These three dividing lines, which do not exclude others,[23] are not independent of each other. To move one of them in a text is necessarily to move all the others. We should not therefore think of them as elements of a combinatorial system with several entries leading to a classification. They are really the result of a historical shift of the gaze. The mathematician who reads the past texts is in reality in front of a moving landscape, implying zones of indeterminacy. In fact, he has a choice. He can choose to read the arithmetic triangle as a figure or as an abbreviated set of arithmetic statements. He can choose to read a triangle geometry proposition as dealing with an ideal object, or as a set of symbols subject to rules. He can choose to admit the Euler's law of generality of algebra, or to reject it. Some choices made in the course of history have allowed us to overcome obstacles that appeared insurmountable to the old mathematicians. They thus give an impression of necessity, and the new mathematics seems to emerge inexorably from the problems that were posed to those that preceded it. But this necessity is probably illusory. It is the effect of our difficulty, once these limits have been moved all together, to conceive another set of divisions.

6 The Case of the Equation in Descartes' *Geometry*

We have on several occasions drawn on Cartesian geometry, and while we have discovered an easy familiarity with it, we have also found objects we are not familiar with, another way of applying arithmetic operations to geometry, as well as another way of providing a foundation for mathematics. Let us take a look again at the 1637 text of *The Geometry*. It contains equations. What does it means? What happens when we read an equation?

[22] "Mathematics goes towards its purity as much and more than it comes from it," Michel Serres writes in "La querelle des anciens et des modernes," *Critique*, 1963, reprinted in *La communication*. Seuil, 1969, p. 73 (translation ours). Suzanne Bachelard comments: "Mathematics never stops moving toward purity. The principle of purity remains a regulating principle. The principle of purity is a principle native to mathematics. Recognizing it does not prevent us from recognizing that impure conceptions, when they are born with the great mathematicians, can be catalysts" (*La Représentation géométrique des quantités imaginaires au début du XIXe siècle*, Palais de la Découverte, D 113, translation ours) (Bachelard 1966).

[23] In a recent book, I tried to describe what we can call a fourth limit, the limit between the subjective position of the mathematician in the text and the space of its objects. On this question, see Lucien Vinciguerra, *Celui qui parle. Science et roman* (Hermann 2019).

Since the end of the nineteenth century, an algebraic equation with two unknowns x and y is an expression, a set of symbols combined according to given rules, and whose two unknowns will take their values in the set of real numbers. Depending on the values of x and y, the expression will be true or false. It can thus be considered as the representation of the calculation procedure for a function, whose starting set is $R \times R$ (set of ordered pairs of real numbers) and the ending set is the pair {true, false}. Solving the equation then means finding the elements of the starting set that are mapped to "true." An equation may in turn be represented as a curve by associating each couple of numbers verifying the equation with a point, whose coordinates would be that very couple, in a coordinate plane. The equation $x^2 + y^2 = a^2$ is verified by the couples of numbers (x,y) such that M(x,y) is on the circle whose center is O and radius a. It is thus the equation of this circle.

In this conception, the equation is fundamentally related to the set concept of function, and to the construction of real numbers as developed in the nineteenth century. The equation is like a sentence, but about numbers, to which it refers by the number names it contains, and the letters a, b, c, etc., which are parameters. But it is an incomplete sentence, with some empty spaces (x and y); it is this incomplete or, in Frege's vocabulary,[24] unsaturated character that makes the sentence the expression of a function.

Now, if we conceive of the equation in this way, the mathematician's view of it is in fact twofold, as the purpose of the calculation is its resolution (i.e., finding the objects that make it true). As an incomplete sentence, it has a meaning, and gives me the stage of a calculation: an expression like $2x = y$, for instance, tells us that "y is double x"; it has the same linguistic status as the latter sentence in quotation marks. When I read it, I access a certain content. But the equation is also an object, the object of a discourse which is in a position of a metalanguage vis-à-vis it; such discourse argues and questions the equation's truth, by linking it to a pre-existing set of numbers that must be constructed and posed independently of it: e.g., it would allow me to state "$(2x = y)$ is true for (1,2) and false for (5,7)." This is why the algebraic equation presupposes the prior construction of its world of objects (the set of couples of real numbers), and a gaze that, in the text of the equation's resolution, must go back and forth from the expression as object to the world of objects that make it true or false. The equation thus does not have the same mode of existence as the language of the mathematical text that surrounds it, refers to it, and tells us how to transform it; a language which, with respect to the equation, is in a position of metalanguage.

Now, let us open Descartes' *Geometry.* The issue of the nature and the place of equations in Descartes' book has, in recent decades, given rise to a lively debate among science historians. Enrico Giusti emphasizes the importance of the relationship between equation and geometric curve in the treatise. *The Geometry* was originally conceived as a general theory of curves as geometric knowledge, for

[24] See Gottlob Frege (1960) Function and concept. In: Geach P, Black M (eds). *Translations from the philosophical writings of Gottlob Frege*. Basil Blackwell.

which the theory of equations would act simultaneously as criterion of identity, of admissibility, and of classification.[25]

The thesis that curves are the objects of geometry was quite radical in the seventeenth century, as it departed from the idea that geometry's true objects were figures – entities, originally introduced together with boundaries in Book I of Euclid's *Elements*,[26] which the mathematician has to imagine and contemplate, and which he can divide as he wishes by drawing new lines. Now, stating that there was a correlation between equations and curves also amounted to demote an operation which, until now, had been at the heart of geometry: the typical "geometric construction" (whereby successive acts of drawing lines are undertaken on given figures in order to reach the points solutions of a problem) ceased to be the fundamental mode of access to a geometric object and to a proper resolution of a problem. Two instruments – the ruler and the compass – had been considered by Greek geometers as the privileged means of geometric construction; when faced with their limits, mathematicians had then attempted to invent new ones, which would enable the resolution of problems unsolvable with the mere use of compass and ruler. The above-mentioned *Mesolabum* played in the seventeenth century a role in keeping with just such an instrumental and constructivist tradition. Nonetheless, these methods (which we do find in *The Geometry*) merely led to disparate techniques. As Giusti notes, Descartes' universal method in science could not be founded on them:

> There is no universal compass. Any new machine would merely generate a new curve, without affecting the overall situation. And to such an array of instruments, there can be no corresponding array of methods and research approaches.[27]

The theory of equations unifies what, in construction methods, remains scattered, and thus makes Cartesian science coherent with the principles of its own method. The degree of the equation offers a universal criterion to classify all geometric curves. In the eyes of a long tradition of science historians, of which Giusti is one of the most rigorous representatives, *The Geometry* therefore undoubtedly represented a theory of equations.

But other readings of *The Geometry* are possible. If we look more closely at the internal structure of the book, which until now seemed to lack coherence,[28] if we take into account its position in the slow development of Cartesian science starting from his first works in 1619, as well as its situation in mathematical debates in the

early seventeenth century, then a whole new project emerges, as shown by Henk Bos.[29] According to Bos, *The Geometry* is not a theory of curves, nor even a theory of figures. Its goal was rather the attempt to uncover a general method of resolution of geometric problems. It aimed at classifying and solving problems, and the starting point to understand the meaning of his work should precisely be this notion of problem. If that is the case, the formulaic rendering of an equation could not offer a satisfactory resolution of problems; indeed, finding the solution to an equation does not necessarily allow us to construct its solution geometrically. This is why, according to Bos, Descartes insists on retaining construction devices. The *Mesolabum*'s concatenated set squares thus remained, in his eyes, the device *par excellence* to highlight a problem's complexity. The number of necessary set squares, i.e., the number of basic moves to complete in order to reach a solution (moves ordered by the progressive opening of the compass), represented the consecutive stages of a deduction which could then be grasped in one single intuition, as per the *Rules for the Direction of the Mind*.[30] The set square device thus plays a major role in the implementation of Descartes' method (although, as Bos notes, this is probably truer of the method exposed in the *Rules* than that in the 1637 *Discourse*). Contrary to the first uses of the *Mesolabum* in his works dating from 1619, Descartes could now relate his instrument to the theory of equations. This new relation led him to progressively opt for the uniformity and the universality of algebra over geometry's instrumental processes.

> Descartes finally adopted algebraic criteria, abandoning earlier attempts to classify according to methods of tracing. The process may be described as an infiltration of algebraic thinking into the interpretation of geometrical exactness. It is indeed a natural process.[31]

[29] Henk JM Bos (2001) *redefining geometrical exactness. Descartes' transformation of the early modern concept of construction*. Springer.

[30] See rule 7: "Si igitur, ex.gr., per diversas operationes cognoverim primo, qualis sit habitudo inter magnitudines A and B, deinde inter B and C, tum inter C and D: non idcirco video qualis sit inter A and E, nec possum intelligere praecise ex jam cognitis nisi omnium recorder. Quamobrem illas continuo quodam imaginationis motu singula intuentis simul and ad allia transeuntis aliquoties percurram, donec a prima ad ultimam tam celeriter transire didicerim, ut fere nullas memoriae partes relinquendo, rem totam simul videar intueri" (AT, X, 388). "If, for example, by way of separate operations, I have come to know first what the relation between the magnitudes A and B is, and then between B and C, and between C and D, and finally between D and E, that does not entail my seeing what the relation is between A and E; and I cannot grasp what the relation is just from those I already know, unless I recall all of them. So I shall run through them several times in a continuous movement of the imagination, simultaneously intuiting one relation and passing on to the next, until I have learnt to pass from the first to the last so swiftly that memory is left with practically no role to play, and I seem to intuit the whole thing at once" (*Philosophical writings*, vol. 1, p. 42). On the relationship between the compass device and the *Rules*, see Vuillemin J (1960) *Mathématiques et métaphysique chez Descartes*. PUF and Serfati M (1993) Les compas cartésiens. *Arch Philos* 56: 197–230.

[31] Henk JM Bos, *op. cit.*, p. 361.

Let's now take a sidestep, and look at the position of *The Geometry*'s reader, and at the body of knowledge accessible to Descartes about the act of reading and the type of gaze it enables. *The Geometry* can certainly be understood from the standpoint of all these mathematical "objects" bequeathed by his predecessors, and debated by his contemporaries: curves, figures, equations, constructions, techniques, and instruments. But it also involves the act of reading, the mode of existence of signs on a written page, as well as the action of light rays travelling from the page to the geometrician's eye – all elements which intertwine Descartes' optics, mathematics and philosophy in a most profound way.

Let us examine the first pages of *The Geometry.* How does the text begin*?* Not with the definition of objects, numbers, lines, curves or figures, nor with the construction of a new language, nor with axioms or principles; it opens with the definition of operations on straight lines: addition, subtraction, multiplication and root, geometric and non-arithmetical operations, named using the traditional symbols of corresponding arithmetic operations. Once these operations are constructed, Descartes names the lines using letters, whether the lines are given and known, or still unknown; he reserves the last letters of the alphabet for the latter:

> If, then, we wish to solve any problem, we first suppose the solution already affected, and give names to all the lines that seem needful for its construction, to those that are unknown as well as to thoses that are known.[32]

From there onward, the equation never appears in Cartesian discourse as a language-object, whose truth conditions must be found. Its resolution is not the search for a world of objects under a set of written signs and numbers, itself another object. It is conceived as an operation of ordering, the ordering of a set of relations between lines. These relations are expressed in the equation, but in an initially confused form, which will need to be disentangled and ordered:

> Then, making no distinction between known and unknown lines, we must unravel the difficulty according to the order which shows most naturally of all in what way they mutually depend on each other, until we find it possible to express a single quantity in two ways. This will constitute an equation.[33]

A bit further down, Descartes characterizes a division operation as "démêlant ces équations" ("disentangling these equations").[34]

If we take all this vocabulary of confusion and entanglement seriously, we discover that the Cartesian equation does not exist on the page of *The Geometry* as it does in our algebra textbooks. According to Descartes, the operation of resolution

[32] Descartes (1954), *The Geometry*, op.cit., p. 8 (AT, VI, 372).

[33] Ibid. (translation modified).

[34] Ibid., 374. This metaphor is not translated in the English version. And at the next paragraph, "lorsque la dernière équation aura été entièrement demêlée" is translated by "when the last equation shall have been entierely solved" (*op. cit.*, p. 13).

is not to be understood as the mapping of an expression (a linguistic object) onto another type of object, which would be, for example, numbers. The equation is fully a discourse. The letters, a, b, c, x, y, are the names of lines or line segments, and the calculation symbols refer to operations on these lines. When I write $z^2 = -az + bb$, I am stating the relation between a line z to two other known lines a and b. The line is either in whole or in part determined by these relations. And by ordering these relations between lines, I find the line z, and I know it distinctly: I can now determine it by distinguishing it from the others, in accordance with the Cartesian theory of the distinct idea, "so precise and different from all the others that it includes in itself only what appears manifestly to the one who considers it as it was meant to be."[35] To solve then, does not mean finding the objects that make an expression true: it, very simply, means to order. Such an ordering process does not refer to the signs of the equation conceived as material objects. The equation is a discourse on the pages of *The Geometry* at exact par with the other surrounding sentences, which explain how to draw lines, join points, etc.: a discourse about the world of geometric objects, without any attention ever being paid to the materiality of its signs. The only peculiarity of the equation is to refer to these objects with letters and symbols rather than words. Thus, in the text of *The Geometry*, we do not witness the double modality of discourse, which would see one language-object on the one hand, and a metalanguage, on the other. In the Cartesian text, the equation is nothing but discourse: it is never an *object* for a discourse. And its resolution is the ordering of this initially confused set of relations between known and unknown things.

When we pay attention to the detail of the Cartesian text without immediately dividing it into language and object, we may find the traces of a specific mode of existence of what is, for him and for us, an equation. Certes, this equation is not the same for Descartes as it is for our gaze today; but we might still be able to reconstitute the Cartesian gaze to a certain extent. Descartes was not only a mathematician: he was also a philosopher, who reflected on the nature of language, of writing and signs, of looking and seeing. Unlike many other mathematical texts for which the act of reading can only be inferred from the organization and structure of the text, Descartes conducted analyses in various non-mathematical writings that shed light on this issue.

In a famous passage in the beginning of the *The World*, the dissimilarity between the linguistic sign and the object it signifies appears to be the template of that between the sensation – or the idea received in the mind – and the object that causes it:

> For although everyone is commonly convinced that the ideas we have in our mind are wholly similar to the objects from which they proceed, nevertheless I cannot see any reason which assures us that this is so. On the contrary, I note many observations which should make us doubt it [4]. Words, as you well know, bear no resemblance to the things they signify, and yet they make us think of these things, frequently even without your paying attention to the sound of the words or to their syllables. Thus it may happen that we hear an utterance whose

[35] Descartes, *Principles*, I, 45.

> meaning we understand perfectly well, but afterwards we cannot say in what language it was spoken. Now if words, which signify nothing except by human convention, suffice to make us think of things to which they bear no resemblance, then why could nature not also have established some sign which would make us have the sensation of light, even if the sign contained nothing in itself which is similar to this sensation?[36]

Ideas of sensations are not similar to the material things that gave rise to them. The content of a sensation such as light does not resemble the material sign that caused the sensation; the experience of hearing someone speak is a better template of their relation than the resemblance of images. In the text, Descartes uses an analogy the order of which must not be reversed: what the material sign that causes sensation is to the idea or sensation, speech is to the thing it signifies, that is, to the meaning of that speech. But for Descartes, this experience of listening is, surprisingly enough, the event of a discourse whose audible materiality has disappeared for the person at the receiving end: the word is not heard as an object, a sound which would simultaneously be associated to a meaning; rather, it opens up a meaning at the exact moment it is erased as such from my representation, so that I do not even know in what language they were uttered. There is no doubt that Descartes' mastery of foreign languages led him to experience such a situation on numerous occasions: linguistic communication is an exchange in which one's mind's thought can be conveyed to another through the medium of discourse, itself a material object which does not require to become an object of representation and thought in order to perform its function. I hear the meaning without thinking about words or language, and this is valid for both oral or written speech. Years later, in a letter to Clerselier dated April 23, 1649, Descartes writes:

> Forgive me for having interlarded this letter with Latin; the brief time I have had to write it has not allowed me to think of words.[37]

To pay attention not to ideas but to words requires a special effort of the mind. If we are distracted, preoccupied, or tired, we become oblivious to them, and yet, we still speak, and understand what is said. We may therefore conclude that it is not because we perceive the sound of words that we grasp their meaning: the two processes are autonomous.

In the fourth part of the *Principles*, Descartes again refers to this experience; it concerns writing too, and he is again seeking a model of the action of the body on the mind:

> For we see that spoken or written words excite all sorts of thoughts and emotions in our minds. With the same paper, pen and ink, if the tip of the pen is pushed across the paper in a certain way it will form letters which excite in the mind of the reader thoughts of battles, storms and violence, and emotions of indignation and sorrow; but if the movements of the

[36] Descartes (2009), *The Philosophical Writings*, vol. 1, p. 107 (AT, XI, 4).

[37] Descartes (1991), *The Philosophical Writings*, p. 378 (AT, V, 357).

> pen are just slightly different they will produce quite different thoughts of tranquillity, peace and pleasure, and quite opposite emotions of love and joy.[38]

The linguistic sign is a material thing. When we think of its effects, we are in the field of causality and action: the sign "excites," "produces," "occasions acts." What the sign-thing affects is the mind, which, modified by this action, then has a thought. At that moment, the mind gets a representation: it imagines battles or peace, it feels the passions of sadness or love, and imagines or perceives the objects of these passions. Writing is thought of within the framework of the union of soul and body, of which it is also the template.[39] Writing is not intelligible without that union. But this in turn means that the sign is not an object of interpretation or decryption: this would imply that it becomes, at some stage, an object of representation, to which the mind would associate another object – another thought. The relation of the sign to what it represents is not an association in the mind of one representation with another. The meaning is entirely clarified by the action of a body on a mind.

How and why can the sign operate in such a way? Actually, the sign belongs to the bodies explored by Descartes in his physiology and his optics, of which he says they act on the soul because they belong to the mechanical process that makes us perceive. This process must be conceived as a material movement: the traces and impressions in the brain, the nerve fibers, the image on the retina, the vibrations of light. A sign is all these things for Descartes. Now, such signs cause the soul to perceive and to have a representation, as per the institution of nature, only insofar as they are not seen.[40] The cerebral impression and the physical substratum of light lead to a perception only for those who do not see them. These signs are invisible for those who perceive, and visible only to a third party, such as a physicist depicting light in the form of straight lines in an optical treatise, or an anatomist describing someone else's eye and brain. If we were to see them, as Malebranche noted, it would then be impossible to see the representation they excite.

The linguistic sign, though a human institution, draws its efficacy from a similar process. Descartes conceives the linguistic sign on the general model of the sign as unperceived trace; this is why, when he analyzes language, he refers to the experience of a discourse whose meaning we grasp without perceiving its material reality.

But is there truly nothing in common between the sign and the representation it generates? Let us dwell on the above-mentioned text in the fourth part of the *Principles.* It refers to a quill that moves in different ways. And the differences in its movement arouse "quite different thoughts." Similarly, in the following article,

---

[38] Descartes, *Principes*, IV, 197, in *The Philosophical Writings*, vol. 1, p. 329 (AT, IX, 316).

[39] On this issue, we may of course also refer to the fourth discourse of *Dioptrics*, op. cit., p. 202 (AT, VI, 112).

[40] In the fourth discourse of *Dioptrics,* it is indeed what is sent "inside our brain," such as the vibration of the nerve fiber or the image on the back of the eye, which receives the qualification of sign likely to excite thoughts in the soul, "as for example signs and words, which do not resemble in any way the things they signify" (Ibid.).

Descartes evokes "les divers mouvements de quelques corps [qui] suffisent pour lui faire avoir tous les divers sentiments qu'elle a."[41] There is no resemblance between the sign and what it means for the soul, but there is a corresponding difference. In the same French edition of the *Principles* dated 1647, article 71, Part I, Descartes mentions the relation between color and its signs, the bodily movements which he describes as the "sentiments tels que sont ceux qu'on nomme goût, odeur, son, chaleur, froid, lumière, couleur et autres semblables, qui véritablement ne nous représentent rien qui existe hors de notre pensée, mais qui sont divers selon les diversités qui se rencontrent dans les mouvements qui passent de tous les endroits de notre corps jusqu'à l'endroit du cerveau auquel elle est étroitement jointe et unie."[42] And in his *Dioptrics*, Descartes, in a new attempt to explain both the dissimilarity between sensations and their material causes and the possibility for one to represent the other, brings in the character of a blind man touching different things with a stick. He writes:

> They certainly do not transmit anything to him except in so far as they cause his stick to move in different ways according to the different qualities in them, thus likewise setting in motion the nerves in his hand, and then the regions of his brain where the nerves originate. This is what occasion his soul to have sensory perception of just as many different qualities in these bodies as there are differences in the movements caused by them in his brain.[43]

The bodies' relations to each other are similar to those of the stick's movements, and to those of the qualities experienced by the soul. Yet again, the same differences and the same relationships between the bodily sign and its content may be found. While there is no resemblance between the sign and its content, something does remain from one to the other insofar as one is erased to make the other visible: the same differences and the same movement.

We can now return to the Cartesian theory of the equation in *The Geometry*, and to the historians' debate concerning the respective place of equations and geometric problems within it. In a way, Giusti's and Bos' interpretations of Descartes' work reflect different views of its position in the history of mathematics. Giusti, a mathematician first and foremost, legitimately reads it from the starting point of what happened later. Bos, on the other hand, emphasizes the concepts common to Descartes and his contemporaries. However, both agree that *The Geometry* contains something like a theory of equations, these peculiar objects progressively and collectively constructed by algebraists in the sixteenth and seventeenth centuries; they further agree that other shared objects exist, such as curves, as do geometric problems. But what is the relation between these two classes of objects?

[41] Descartes, *Principes*, IV, 198 (French translation of Claude Picot revised by Descartes).

[42] AT, IX, 58. In this two passages, the french text dated 1647 is very different from the latin text dated 1644. It was probably modified by Descartes himself.

[43] *Dioptric,* discourse four, in Descartes (2009), *The Philosophical Writings*, vol. 1, p. 202 (AT, VI, 114).

Descartes could not have made his equation the true object of the reader's gaze. Its signs must disappear under the gaze of the geometer reading the treatise on *Geometry*, as must all the traces that made it visible.[44] Descartes notes in his definition of an equation that what is given to the reader consists indeed of relations – readily known relations, between known and unknown lines, but which require some ordering in order for the reader to know what exactly they relate. It is immediately clear that, in Cartesian science, it is impossible to interpret the algebraic expression as a set of material signs on a page, which we would have to associate to a field of objects. Strictly speaking, there is no set of objects to be associated with the equation. The equation is not a function with values in a set, be it a set of numbers or of anything else. It presents me with a diversity, which, if the solution is not readily apparent, may be ill-ordered and confused. The resolution of the geometric equation is therefore first and foremost the act of a gaze which orders and re-arranges things. It is this very reading device, which is intimately linked to Descartes' philosophy, which allows us to find the objects of his *Geometry.*

The relationship between the geometric curve, the problem, and the construction that will generate its solution must thus be conceived in light of the Cartesian dualism of body and mind. For the philosopher, a problem is a mental entity (which it was not for the Greeks who, like Menaechmus, conceived of geometry as a theory of problems). As such, its reality is that of a meaning, something I have "in mind," endowed with both clarity and confusion, disclosing some of its objects and obfuscating others. The equation is nothing but a problem, when my gaze pierces through the material symbols on the page and reaches the entangled relations that require ordering. Ancient geometricians conceived the resolution through a construction, a process whose starting point were specific objects, from which one would then amble to reach new objects, through the drawing of lines and determination of properties; this whole process was thought of as wholly undertaken in the world of mathematical objects. Descartes, on the other hand, conceptualizes a process which arises in the mind to reach the world of geometric objects that stems from a question in the geometer's mind to reach an answer whose job is first and foremost to order that which, in the question, had remained muddled, thus eventually uncovering its objects clearly and distinctly. This, in turn, also alters the very notion of construction. Insofar as it now pertains to analysis and no longer necessarily to synthesis, a geometric construction may now be conceived as a

[44] It might be argued that *The Geometry* never presents the problem in this light, and that it never evokes the theory of the sign of *The World* or of the *Dioptrics*. However, it should be remembered that *The Geometry* is the third essay of a series of works which began with the *Discourse of Method*, *Meteors* and the *Dioptrics*; and that Descartes prefaces his table of contents at the end of the work with the following warning, which remains relevant to this day: "Those who visit the tables of books only in order to choose the subjects they wish to see, and to exempt themselves from the trouble of reading the rest, will derive no satisfaction from this table: for the explanation of the questions mentioned therein almost always depends so expressly on what precedes them, and often also on what follows them, that it cannot be understood perfectly unless the whole book is read with attention" (AT, VI, 486; this passage is not translated in the English version).

succession of operations whereby the mind grasps the object it seeks thanks to the analysis of given relations in the question it itself had asked.[45]

A geometric construction is a set of acts – the act of drawing lines. To draw circles or lines, whether straight or not, means to initiate a movement. We know, though, how much the ancient and the modern conceptions of movement differ. For the Ancients, movement is a whole, defined by its starting point and its end. The successive acts undertaken in the construction of a figure is thus a succession of indivisible steps. When a point is constructed as the intersection of two semi-circles, the outline of the two semi-circles is not envisaged as the succession of points passed through by the compass's mobile tip, but rather, as the encounter of two singular acts, which each find their fulfilment in that one remarkable point of intersection. In Descartes' thinking, on the contrary, the outline is the path delineated by the succession of indifferent points on lines and circles, a succession that may be measured by the y-intercept along a line of reference.[46] Descartes thus opposes the curves in which only a few remarkable points may be traced to the "good" geometric curves, in which any point whatsoever may be reached. He correlates this possibility (intrinsic to the form of the equation) to the notion of regular and continuous movement.

> On the other hand, there is no point on these curves which supplies a solution for the proposed problem that cannot be determined by the method I have given. But the fact that this method of tracing a curve by determining a number of its points taken at random applies only to curves that can be generated by a regular and continuous motion does not justify its exclusion from geometry.[47]

Descartes emphasizes the idea that the delineation of a curve necessarily implies a device which allows for a regular movement passing by every single point of the curve; this explains why, in the opening lines of *The Geometry*'s Book II, he expresses reservations about the term "mechanical," in reference to the Ancient geometers' opposition between geometric and mechanical curves (an opposition which he incidentally retains):

> Nor do I see why they called the latter mechanical, rather than geometrical. If we say that they are called mechanical because some sort of instruments has to be used to describe them, then we must, to be consistent, reject circles and straight lines, since these cannot be described on paper without the use of compasses and a ruler, which may also be termed instruments.[48]

[45] This idea is at the heart of the fifth and sixth *Rules for the direction of the mind.*

[46] Descartes evokes "the fact that all points of those curves which we may call 'geometric', that is those which admit of precise and exact mesurement, must bear a definite relation to all points of a straight line, and that this relation must be expressed by means of a single equation, *The Geometry, op. cit.*, p. 48, livre second (AT VI, 392)."

[47] Ibid., p. 91 (AT VI, 411).

[48] Ibid., p. 43 (AT VI, 389).

Let's take a new glance at Descartes' set square device. As the compass is progressively opened, the points D, F, and H move away from point A. When the compass is fully closed (an impossible position, practically, but theoretically and mathematically rigorous), all these points merge into one. All along their path, ratios are preserved throughout the continuous and ordered movement undertaken: YA/YC = YC/YD = YD/YE = YE/YF = YF/YG. They remain identical, but progressively more explicit as they progress, and it is always possible to stop the compass on any given point of the curves' trajectory to find random proportional averages. We may thus see this ratio-preserving movement in light of another movement: that which, in the theory of perception and of reading, correlates meaning, sign, and thing: from start to end, the differences remain identical. The mathematician who reads an equation in Descartes has a muddled meaning in mind; in a way, she is akin to the closed compass where all the ratios are present, but reduced to one single point, with no extension, all jumbled. In order to solve the problem, she needs to open the compass: the same ratios will emerge, but ordered thanks to the movement of the device. The construction's movement is similar to that of the mind progressing methodically until it finds the solution of the problem, from the unextended thing to the extended thing.[49]

There is a deep solidarity between the opening pages of *The Geometry,* in which Descartes defines the equation on the basis of ratios between lines, as expressed by arithmetic operations on the one hand, and the mechanisms whereby Descartes represents these very ratios, linked together so as to disclose the very object they purport to be the ratio of, on the other. What we may derive thereof is that the issue is not to reconcile, in Descartes' work, a theory of equations and a search for geometric constructions, as much as it is to understand how the partitions drawn by Descartes' make the equations and figures objects which, while embedded in a tradition, are related to his philosophy, and thus differ from his predecessors' notions.

7 Conclusion

Tracing back the mechanism of reading at play in Cartesian thought, we may now be able to read *The Geometry* in a manner closer to how Descartes himself read the very mathematical text he was writing, and probably the other texts he read. The case of Descartes is naturally special: as a philosopher, he was able to explicitly examine the nature of the sign and of reading. And yet, it reveals a more general reality, present in all texts in the history of mathematics. The way in which we make objects and meanings appear in them depends intimately and irreducibly on the form of the reading that we choose to implement. Such an interaction in reading always consists

[49] Michel Fichant, in "La géométrisation du regard. Réflexion sur la *Dioptrique* de Descartes" (re-edited in *Science et métaphysique dans Descartes et Leibniz*, PUF, 1998), has emphasized the role of movement in the Cartesian analysis of vision: "It is the ordered set of all these movements (and not the more or less resembling traces they leave in their wake) which signifies to the soul what it interprets as a thought of seeing" (p. 48; translation ours) (Fichant 1998).

in linking the current text to other texts, which will help us delineate the above-mentioned divisions between truth and falsehood, between the visual and the linguistic, between the interior and the exterior of mathematics, in our current reading. Thanks to these divisions, objects, concepts, and identities are disclosed. By linking *The Geometry* to other texts written by Descartes that do not belong to mathematics, we make these objects appear, and discover that they are not the same as ours; we also find out that Descartes' text followed a reasoning foreign to us. Does it allow us to conclude that we have found the "true" objects and the "true" principles of *The Geometry*? Would it mean that science is not universal in any way, but consists only in a multiplicity of private knowledge systems, each with its own objects? In which case, how can there be a scientific community? In truth, by linking the text of *The Geometry* to the texts of *The World* and the *Dioptrics*, by trying to identify a properly Cartesian way of reading, we have gained something: it becomes clearer how the problems and questions presented themselves to the mathematician himself. But this is essentially only another partition line, and, with it, we lose an essential element: we are no longer able to explain how *The Geometry* exists as a milestone in the history of mathematics. We have wrested Cartesian science from its future by linking sentences in *The Geometry* to other contemporary texts, which we can no longer say belong to mathematics. As such, this reading is no more true than a retrospective reading, which is just as indispensable. At every step of the historical process of science, it is indeed this backward glance that restores the unity of science. Such a possibility was and remains crucial.

Abstract

The invention of symbolic algebra in the sixteenth and seventeenth centuries fundamentally changed the way we do mathematics. If we want to understand this change and appreciate its importance, we must analyze it on two levels. One concerns the *compositional function* of algebraic symbols as tools for representing complexity; the other concerns the *referential function* of algebraic symbols, which enables their use as tools for describing objects (such as

polynomials), properties (such as irreducibility), relations (such as divisibility), and operations (such as factorization). The reconstruction of both the compositional function and the referential function of algebraic symbols requires the use of different analytic tools and the taking of different temporal perspectives. In this chapter, we offer both: a reconstruction of the compositional function of algebraic symbols, and a reconstruction of their referential function.

Keywords

Logical power · Expressive power · Integrative power · Pictorial form · Epistemic subject · Symbolic algebra

1 Introduction

There is no lack of literature on the various aspects of the language of mathematics.[1] The different approaches describe important aspects of the language of mathematics, but they usually do not provide an overall picture. The purpose of this chapter is to *propose an analytic framework* based on the insights of Frege and the early Wittgenstein *for the study of mathematical language* in its complexity, and illustrate this framework through the specific case of the symbolic language of algebra.

To achieve this goal, we propose a specific understanding of the symbolic language of algebra. On the one hand, we suggest understanding it in an inclusive sense, thereby including *all symbolic tools* used in books, papers, and manuscripts devoted to algebra from the fifteenth century onwards, when the use of algebraic symbolism became sufficiently complex.[2] Thus, we include the language of polynomial, linear, and multilinear algebra just like that of group theory, ring theory, or lattice theory – so practically everything that algebraists use to communicate their ideas and results.[3] However, on the other hand, we propose to understand the language of algebra in a purist sense and exclude all symbols imported into algebra from differential and integral calculus (e.g., the functional notation), predicate calculus, and set theory. More radically, we exclude all commentaries in ordinary

[1] See (Rotman 2000, Lakoff and Núñez 2000, O'Halloran 2005, Barton 2008, Avigad 2015).

[2] To a historian, the choice of the fifteenth century as a starting point may appear arbitrary, as all the symbolic tools of fifteenth-century European algebra had already been available in Latin, Arabic, Sanskrit, and other cultures. Nevertheless, as our aim is not a historical analysis of the birth of algebra but an *epistemological* reconstruction of the functioning of its language, we prefer taking the fifteenth century as the starting point because the language of algebra at that particular time was already sufficiently complex for epistemological reconstruction.

[3] We do not differentiate between the use of words, letters, and special symbols – they are all included in the symbolic language. The key distinctive feature is whether a particular symbol obeys some rules specific for algebra, such as substitution, raising to a power, extracting roots, and permutation. Thus, if in a text a word appears by which the mathematician enacts such an operation, it belongs to the language of algebra. If not, then not.

language.[4] Thus, in short, we will be interested in changes of the language of algebra over long periods of time while excluding all external influences.[5]

We shall use material from the history of mathematics because taking a historical perspective allows us to see the different aspects of the language of algebra in the process of change, thereby making it possible to discriminate these aspects more easily. Nevertheless, we have no intention of offering any contribution to the discipline of the history of mathematics. As far as is possible, we will stick to the standard interpretation of the historical material and simply use it for making epistemological claims. Thus, in order to understand the way symbols are used in algebra, the language of algebra will be approached from a diachronic point of view.

The following pages focus on two developmental processes taking place simultaneously, but on *two different time scales*. This will help to discriminate *two semiotic components* of the language of mathematics, the compositional and the referential. The compositional component of the language of algebra concerns how individual signs are put together to form composite expressions, such as those used for representing polynomials, matrices, and tensors. This component is closely connected to the syntax of algebraic language. However, syntax is a well-defined notion in logic, and it automatically uses functional notation, so we prefer using the expression *compositional component*, to which we can attach our own meaning and strip the symbols of any functional connotations. Similarly, the *referential component* concerns how the composite expressions represent aspects of reality and how they acquire meaning from this representation. Just as in the previous case, the referential component is closely connected to the semantics of the algebraic language. However, semantics is a well-defined notion, and we prefer speaking about the referential component in order not to give the symbols unnecessary logical connotations.

Having distinguished the compositional and referential components, we will leave the history of mathematics and shall examine the individual semiotic

[4] These commentaries in ordinary language, of course, are part of the *practice of algebra*, yet we suggest *not* counting them as part of *algebraic language proper*. It is as if algebraic symbols – and these symbols can have the surface form of words, for what turns them into symbols are the rules, which are applied to them – were read in English and the commentary, say, in Hungarian. This difference is even more radical in the case of geometry, where the iconic language of geometry belongs only to that which occurs on paper due to the rules of construction and letters, as (Netz 1999) convincingly showed. All commentaries in ordinary language are excluded. We all are, of course, bilingual; we understand both English and Hungarian, but if we wish to reconstruct the functioning of the language of algebra in this restricted sense, we must pretend that we cannot speak Hungarian. We can do whatever the instructions in Hungarian require, but they are not part of the English language. By a *rational reconstruction* of the symbolic language of algebra (or the iconic language of geometry), we mean the reconstruction of the rules that govern this English part of our common (bilingual) linguistic practice.

[5] This second move is, of course, a methodological decision. If we sufficiently well understand both the dynamics of the development of the language of algebra and the dynamics of the development of the language of differential and integral calculus, it will be possible to analyze their mutual influences.

components separately. We understand semiotics in the most neutral and uncontroversial way as a theory that describes how signs acquire meaning and reference. Applied to the language of algebra, the role of semiotics is to elucidate how particular signs, such as the sign for the cube root, are used, what their meaning is and to what, if anything, they refer, how they join other signs to form more complex expressions, etc.[6] These semiotic components of the language of mathematics have already been studied, first by Frege when he developed his system of logical notation (Frege 1879) and then by Wittgenstein in his picture theory of meaning (Wittgenstein 1921). In a sense, the following pages are an attempt to apply Frege's and Wittgenstein's theories to the understanding of the epistemological structure of the language of algebra.[7]

In the first part of this discussion, algebraic symbolism is distinguished from other similar systems, such as arithmetical symbolism, the symbolism of the differential and integral calculus, and the symbolism of the predicate calculus; and epistemological characteristics such as the logical, expressive, methodological, integrative, and explanatory power of algebraic symbolism are characterized. In the second part, the picture theory of meaning is introduced, first as a tool for analyzing the development of the iconic language of geometry; then it is transferred to algebra to be used in the reconstruction of the referential component of algebraic language.

2 The Compositional Component of the Language of Mathematics

Frege called his variant of logical calculus *Begriffsschrift* – concept-script (Frege 1879). In the subtitle he characterized it as "*eine der aritmetischen nachgebildete Formelsprache des reinen Denkens*" (a formula language of pure thought created according to the model of the formula language of arithmetic). Later, in *Funktion und Begriff*, Frege outlined the *history of mathematics* as a sequence of such formula languages (Frege 1891, p. 30; English translation p. 40):

> If we look back from here over the development of arithmetic, we discern an advance from level to level. At first people did calculations with individual numbers, 1, 3, etc.

[6] Signs are human artifact, and so they are rooted in social practices of communication, problem-solving, knowledge preservation, and the like. This chapter will not deal with these questions, which are well described in the literature by scholars such as Karine Chemla, Albrecht Heeffer, Jens Hoyrup, Raviel Netz, Vincenzo de Risi, and Roy Wagner in the works listed in the references.

[7] The reader may argue that we also apply general theories to the language of mathematics. However, compared with the approaches mentioned in footnote 1, the difference is that both Frege's concept-script and Wittgenstein's picture theory of meaning are theories that generalize some principles of the language of mathematics. In Frege's case, this is clear from the subtitle of his book. In contrast to the books mentioned in footnote 1, which apply notions from cognitive psychology, general semiotics, or linguistics to the language of mathematics, here concepts that were created on the basis of the analysis of the language of mathematics itself shall be used.

$$2 + 3 = 5 \qquad 2.3 = 6$$

are theorems of this sort. *Then they went on* to more general laws that hold good for all numbers. What corresponds to this in symbolism is the transition to the literal notation. A theorem of this sort is

$$(\mathrm{a} + \mathrm{b}).\mathrm{c} = \mathrm{a.c} + \mathrm{b.c}.$$

At this stage they had got to the point of dealing with individual functions; but were not yet using the word, in its mathematical sense, and had not yet formed the conception of what it now stands for. *The next higher level* was the recognition of general laws about functions, accompanied by the coinage of the technical term "function." What corresponds to this in symbolism is the introduction of letters like f, F, to indicate functions indefinitely. A theorem of this sort is

$$\frac{dF(x).f(x)}{dx} = F(x).\frac{df(x)}{dx} + f(x).\frac{dF(x)}{dx}.$$

Now at this point people had particular second-level functions, but lacked the conception of what we have called second-level functions. By forming that, we make *the next step forward*.

In this passage, Frege distinguishes four stages in the development of mathematics.[8] Importantly, he distinguishes these stages based on the way they use symbols to express *generality* and, in particular, he characterized algebra on the basis of its use of *letters* to express generality. We now turn to the language of algebra, i.e., the second stage in the development of mathematical symbolism, and thereby complement Frege's description of it as a system of "*laws that hold good for all numbers*" with more detail in order to obtain a more comprehensive set of semiotic characteristics.

The point of introducing the long quote from Frege is that Frege found *a level of abstraction* (and the corresponding temporal scale) at which the development of mathematics may be analyzed if we wish to understand the main innovations that shape the language of mathematics. Of course, generality is not the only aspect that is changed in this development. By supplementing generality with other aspects,[9] which might be called the *potentialities of the language of mathematics*, we can offer a comprehensive view of the first component of the semiotic system of mathematics:

[8] We start our analysis of the compositional component of the language of algebra with Frege. Rotman criticized Frege's views: "*Frege gives no idea, explanation, or even hint as to what this 'something' might be which allows the subjective, temporally located bearer* [of thought] *to 'aim' at an objective, changeless thought*" (Rotman 2000, p. 33). Below we shall answer Rotman's criticism by complementing Frege's analysis with the analysis of the pictorial form of the language of mathematics.

[9] These aspects are *analogous to generality* in the sense that they change on the same scale as generality and characterize the language of mathematics at the same level of abstraction as the quote from Frege. Potentialities 1, 2, 4, and 5 are presented in more detail in Kvasz (2008, pp. 11–84) while 3 and 6 are in Kvasz (2012).

1. *The logical power*, which shows how general formulas can be proven in the language
2. *The expressive power*, which shows what new facts and relations, which in the previous stages defied expression, can now be expressed in the language
3. *The methodological power*, which shows what new methods can be introduced into the language where at previous stages there was only a tangle of unrelated tricks
4. *The integrative power*, which shows how language discloses unity and order where, in the previous stages, only unrelated cases were seen
5. *The explanatory power*, which shows how the new language makes it possible to explain the failures of language that were incomprehensible at the previous stage
6. *The constitutive power*, which shows how language helps us to transcend the limits of the previous language and to establish radically new kinds of objects

When it comes to mathematical symbolism, linguists are usually attracted by its effectiveness, accuracy, and brevity, and interpret it as a tool for the effective coding of meaning that already existed before it had been coded (e.g., O'Halloran 2005, pp. 110 and 126). However, symbolism can do more. Accuracy, brevity, and efficiency can appear in some contexts as secondary to the logical, expressive, and methodological power of the language. Thanks to these potentialities, mathematical symbolism is able to radically change the scope, reach, and depth of our thinking. Symbolism can give our thinking new qualities, such as generality.

The main feature of the symbolic language of algebra used during the fifteenth and sixteenth centuries was the introduction of a symbol representing the unknown quantity (see, e.g., Scholz 1990, Alten et al. 2014, and Hoyrup 2019). We all learned a version of this symbolic language in high school. Let us consider its potentialities.

2.1 The Logical Power of the Language of Algebra

The language of algebra contains a fundamental innovation – the symbol for the unknown. In this context, Frege spoke about counting with letters and the ability of the language to express generality in an explicit way. The introduction of letters for the unknown has two sides. The symbol x stands for *an arbitrary object* to which the language can refer and for something with which algebraic operations can be done, i.e., it stands for *an arbitrary argument*. It seems that the unknown originally represented not an arbitrary object but an arbitrary argument, something that could be manipulated. Algebra was born as a language for general operations – as a language for *al-jabr* (if on one side of the equation there are terms that need to be subtracted, then the corresponding value is added to both sides), *al-mukabala* (if the same powers appear on both sides, subtract the smaller term on one side from the larger one on the other), and *al-rad* (if the coefficient of the highest power of the unknown is different from one, then it divides the entire equation), and one of its earliest documents is (Al-Chorezmi, 850).

A letter, for instance x, represents an arbitrary number, generality thereby becoming a fully explicit aspect of the formula language.[10] Nevertheless, the symbolic language of algebra contained a further aspect that the language of synthetic geometry lacked: functionality. Let us take the formula expressing the solution of the equation $ax^2 + bx + c = 0$:

$$x_{1,2} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}. \tag{1}$$

The parameters a, b, and c give this formula generality. However, the formula expresses in a symbolic way not only the solution of *any quadratic equation*, but it also expresses the *steps* of its calculation.

A diagram of synthetic geometry contains all the elements of a particular construction. Each line or point used during the construction process remains as part of the resulting diagram. What is lost, however, is the sequence of steps. Therefore, in geometry textbooks, the diagram is supplemented by a commentary in ordinary language which indicates the order of steps of the construction.[11] The symbolic language of algebra does not need such a commentary because it expresses the order of the steps of the calculation to a sufficient degree.[12] The formula (1) contains a set

[10] Of course, if we were to ask from whence comes this generality, the answer would be, from ordinary language. In ordinary language, we have words such as every, all, any, etc. which allow us to express generality. However, this is not the point. In a sense, all aspects of the formula languages of mathematics are derived from the corresponding aspects of ordinary language. The difference is, however, that a formula language is governed by explicit rules, and so we can build and manipulate complex representations which would cause comprehension problems in ordinary language. The quantifiers, as used in ordinary language, allow us to go rather far in developing calculus. If we use a notion with three quantifiers, like that of convergence, it is not easy to maintain control of its use, as Cauchy discovered, when he believed he had proven the false theorem that the sum of a convergent series of continuous functions is continuous. The theorem is valid if the convergence is uniform, but the difference between the pointwise and the uniform convergence is the order of quantifiers, which is difficult to handle in ordinary language. Even more delicate is the case of four quantifiers, like in the notion of Hausdorff dimension. The same thing applies to generality, where algebra is the symbolic tool that allows us to build and manipulate complex representations of general properties and relations in the form of polynomials of higher degrees. Linear and quadratic equations can be handled in ordinary language, as the Babylonian texts sufficiently manifest. However, to solve a cubic equation, to understand this solution, and first of all to be able to explain this solution to others, requires at least a rudimentary formal language, that is, a language in which you can handle substitutions, raise composite terms to powers, transform equations, and the like.

[11] This does not influence the rigor of proofs, as shown in (Netz 1999 or Manders 2008a, b). However, from the point of view of our reconstruction, these commentaries are not part of the language of synthetic geometry.

[12] To express the order of steps in full detail, some conventions concerning the priority of arithmetic operations and the scope of the root must be met. However, the letter labels in geometry, as shown by Netz, can tell us a lot about the order of operations, although it is still true that an algebraic formula indicates to a sufficient degree the order of steps of its execution, while in a geometric diagram this is mostly lacking. If we take, for instance, formula (1), it is true that it uses some conventions, as for instance the priority of multiplication over addition. In our view, this means only that the formula is not indicating the steps of the calculation unequivocally, thus we could produce

of dependencies (we must first evaluate the difference of b^2 and $4ac$, before we can take the square root of it; but before we can evaluate the difference, the two terms, the b^2 and $4ac$ must be themselves evaluated), which introduce some order into the steps of the calculation of its value.

An algebraic formula thus denotes not only *the quantities* that appear as the result of say, a geometric construction, but it also indicates *the order* of the steps. Thanks to this, it is possible to represent the *process* of a geometric construction (a sequence of steps) as an algebraic *object* (an algebraic formula, the different elements of which correspond to the steps of the construction). It turns out that in a geometric construction, only quantities expressible by the four operations and a sequence of quadratic root extractions can occur. Thus, it is possible to describe the system of all constructible quantities as a number field, that is, the union of all possible sequences of quadratic extension. To prove the non-constructability of a particular geometrical object, it is sufficient to prove that it contains a line segment, the length of which does not belong to that field (see, e.g., Stewart 1989).[13]

The language of algebra can prove theorems of this kind because the process of solution can be represented in the symbolic language. The question of solvability thus becomes a question of whether a certain linguistic expression belongs or does not belong to a certain set of expressions. In the iconic language of synthetic geometry, we cannot *represent* the set of all constructible objects in the form of a mathematical object (such as, for instance, a number field), because this iconic language cannot represent a procedure (the process of construction) but represents only its outcome (the constructed object). In contrast to this, the language of algebra can express a procedure (in the form of an algebraic formula). Thus, in algebra, it is possible to reconstruct the steps of a geometric construction. As the construction goes on and on, the diagram becomes more and more complex, and the accompa-

two or three alternative readings, the choice made being based on conventions. The point is that in a geometrical figure, we have no alternative readings of the process of construction, as we have no reading of the order of steps at all. It is not that the determination of the order of the steps of construction in a diagram is not perfect, there is simply none. (We have, of course, to keep in mind footnote 4 and the distinction of the "Hungarian" and "English" part of the text. When I say that in a geometrical diagram there is no indication of the order of steps of construction, I mean of course the "English," that is, the iconic part of the diagram. I admit that in "Hungarian" everything is present, but we are reconstructing the "grammar" of "English," that is, of the compositional component of the language of mathematics).

[13] It is important to realize that in geometry, we can perform a construction, but we cannot turn it into an object. Only the outcome of a construction, but not the process itself, is iconically represented, i.e., represented as a geometrical object. Algebra changes this situation as it represents the steps by means of operations, and thus a formula indicates not only the result but also how it was obtained. So, the question of the constructability of an object is, from the algebraic point of view, identical with the question about whether the features of the object can be expressed by algebraic means that correspond to the different construction steps.

nying formulas will become more and more involute. Nevertheless, thanks to the functionality of the algebraic language, the order of steps is represented.[14]

At the end, we thus have a set of algebraic formulas (and the corresponding set of quantities) that represent the process of construction. The point is that we can characterize by algebraic means the sets of quantities that correspond to geometric constructions. They belong to a finite sequence of quadratic extensions of the field of rational numbers. So, it is possible to form the union of all such finite sequences, which is the set K of all constructible quantities. This set has several algebraic properties. To prove that a quantity, such as the length of the side of a regular heptagon inscribed into the unit circle, *cannot be constructed* by ruler and compass, it is sufficient to show that it *does not belong* to the set K. So, the nonexistence of a construction was turned into the relation between a set and an element, details of which can be found in Courant and Robbins (1941). The proofs of insolvability are thus an illustration of the logical power of the language of algebra.

2.2 The Expressive Power of the Language of Algebra

The expressive power of the language of algebra is based on the operation of exponentiation, i.e., the creation of an indefinite sequence of powers of the variable: $x, x^2, x^3, x^4, x^5, x^6, x^7, x^8, \ldots$. The first three members of this sequence, x, x^2, and x^3, are anchored in geometry: x is length, x^2 is area, and x^3 is volume.

Nevertheless, algebraists have overcome the limitations of three-dimensional space by means of a syntactic operation that could be iterated indefinitely. It is this ability to transgress the boundary of space that establishes the expressive power of the language of algebra. In geometry, an unknown quantity is expressed by a line segment of indefinite length, the square of the unknown by a square constructed above this line segment, and the cube of the unknown by the corresponding cube above the line segment.[15] The language of algebra is able to create powers of any degree. Italian mathematicians of the sixteenth century, such as Girolamo Cardano,

[14] Symbols of algebraic operations are *functional symbols*. In expressions like $\sqrt{5+4}$, 5 and 4 are arguments of the (binary) *function* of addition, while 9 is its value. This value is the argument of the (unary) *function* of square root, and the number 3 is its value. So, in this formula, the addition must be executed prior to taking the square root. If we have a more complex *formula*, composed of, say, 250 elementary symbols, it is possible to form a tree indicating the dependence of different steps. In the case of a geometric diagram that consists of 250 points and lines, something of this sort is not indicated by the diagram itself, but only by a commentary attached to it. This commentary is in ordinary language, and so is not part of the language of geometry.

[15] Many Greek and Arab mathematicians discussed sequences of proportional lines, which allowed them to speak about quantities, which algebra would represent as monomials and polynomials of high degrees. Nevertheless, these discussions occurred in ordinary language, and thus, due to the rule expressed in footnote 4, they cannot be counted as belonging to the language of geometry, understood as a representational tool. This only shows that linguistic practice is always much richer than the rules explicitly allow.

called the unknown *res* and symbolized it as *r*, the square of the unknown *zensus* and symbolized it as *z*, so they wrote the fourth power as *zz* (*zenso de zensu*), the fifth as *rzz*, the sixth as *zzz*, etc. In this way, the language of algebra surpassed the boundaries placed on the language of geometry by three-dimensional space.

In *Ars Magna Sive de Regulis Algebraicis* (Cardano 1545), Cardano formulated the equation of the third degree as "*De cubo & rebus aequalibus numero*" and stated its solution in the form of a rule. "*Cube one third of the number of things; add to it the square of one-half of the number; and take the square root of the whole. You will duplicate this and to one of the two you add one-half the number you have already squared and from the other you subtract one-half of the same. You will then have a binomium and its apotome. Then subtracting the cube root of the apotome from the cube root of the binomium, the remainder [or] that which is left is the thing*" (Cardano 1545, p. 98).[16] To understand what Cardano is doing, we can write the equation in modern notation as $x^3 + bx = c$ and its solution as:

$$x = \sqrt[3]{\frac{c}{2} + \sqrt{\left(\frac{c}{2}\right)^2 + \left(\frac{b}{3}\right)^3}} - \sqrt[3]{-\frac{c}{2} + \sqrt{\left(\frac{c}{2}\right)^2 + \left(\frac{b}{3}\right)^3}}. \qquad (2)$$

Cardano never wrote such a formula. In his time, algebra was a set of verbal rules.[17] The language of algebra contained names for powers and roots as well as the terms *binomium* and *apotome*. Cardano called $\frac{c}{2} + \sqrt{\left(\frac{c}{2}\right)^2 + \left(\frac{b}{3}\right)^3}$ a *binomium* and $-\frac{c}{2} + \sqrt{\left(\frac{c}{2}\right)^2 + \left(\frac{b}{3}\right)^3}$ an *apotome.* These seem to be some of the first technical notions denoting *terms*.[18] The solution of the cubic equation thus illustrates the expressive power of the language of algebra.

[16] Cardano expressed the rule for the solution of the *general* cubic equation of the form as $x^3 = bx + c$ only in words, as he did not have *symbolic means* for expressing coefficients of the general case. Nevertheless, his language contained *technical terms* representing the coefficients of the equation, and it described the steps of the construction of the solution in a precise technical way.

[17] It seems that Cardano's book has so impressed some philosophers and linguists that they have claimed that mathematical expressions are rules and not descriptions (see, e.g., Barton 2008, p. 127). What they claim is partly true. The case of Cardano shows that there was a time when algebra was a set of rules (*regula della cosa*). However, to interpret all of mathematics on the basis of this limited fragment of algebra is difficult to justify.

[18] These terms are, of course from geometry, from Book X of Euclid. However, in the iconic language of geometry, they are present only as line segments, i.e., without an indication of the steps of their construction; such steps in Euclid are given in ordinary language, and so in our account (expressed in footnote 4), they do not belong to the language of geometry proper. Algebra turned these quantities into terms. Thus, despite the fact that Cardano's proof of the "formula" was geometric – a long time passed before mathematicians realized that algebra also needs axiomatic foundations – the formula itself is expressed in the language of algebra, and thus it illustrates the expressive power of the language of algebra. Ancient geometers were not able to solve cubic equations – the expressive power of the language of geometry did not allow this.

2.3 The Methodological Power of the Language of Algebra

Euclidean geometry is a set of construction tricks.[19] Each problem is solved in a special way that needs to be remembered. Algebra replaced these tricks with the analytic method presented by François Viète in *In Artem Analyticam Isagoge* (Viète 1591).[20] Before Viète, algebraists used different letters (*r*, *z*, *c*, *zz*, *rzz*, etc.) to denote *different* powers of the *same* unknown, so normally they used equations with only one unknown. This does not mean that mathematicians could not introduce more than one unknown. Nevertheless, their handling required special attention and was not done automatically by the syntax of the symbolic language. Viète marked different powers of the same unknown with the *same letter*, with its power indicated by a word. He wrote the first three powers of the unknown *A* as *A-latus*, *A-quadratum*, and *A-cubus*. The capital letter *A* thus indicated the identity of the unknown, and the word indicated its power. This made it possible to work simultaneously with several unknowns.

Another important linguistic innovation introduced by Viète was to mark the coefficients of the equation with letters and thus to introduce a distinction between a parameter and an unknown. Viète's analytic art, as he called his method, was based on *expressing* all aspects of a problem, the known as well as the unknowns, by symbols, "*lifting*" the problem in its generality into the symbolic language, *turning* the problem into an equation. This gives rise to the analytic method which is *a general procedure for solving problems of a certain kind, which is explicitly expressed in language*.

The methodological power of the language of algebra is thus based on a linguistic innovation – the introduction of a *conventional distinction* between the symbols for the unknowns, Viète using the vowels *A*, *E*, *I*, etc., Descartes the letters from the end of the alphabet *x*, *y*, *z*, etc., and the symbols for the parameters, Viète using consonants *B*, *C*, *D*, Descartes the letters from the beginning of the alphabet *a*, *b*, *c*, etc. Nevertheless, it is a strange distinction – it exists only in the language and does not correspond to any real difference in the world described by the language. It corresponds to the difference in the degree of our knowledge: the unknown is unknown to us, while the values of the parameters are known to us. Thanks to this distinction, a problem can be expressed in its generality, using

[19] This view of geometry is due to Descartes. Later, Poncelet and Chasles were able to change the practice of geometry, and under the heading of projective geometry, they also introduced into geometry aspects of the methodological power of the language of algebra. However, even if one accepts that projective geometry has some esthetic appeal, Klein's *Erlanger Program* shows the methodological superiority of algebraic methods also in this area.

[20] Pappus described the analytic method temporarily: one should imagine the problem already solved and work backwards in time along the possible steps of its construction or proof until one comes to a contradiction or to something familiar. Thus, Pappus' analysis operated outside the iconic language of geometry proper. Viète's main achievement was that he incorporated analysis into the language of mathematics.

equations. The distinction between the unknowns and the parameters forms the basis of the analytic method and thus establishes the methodological power of the language of algebra.

2.4 The Integrative Power of the Language of Algebra

Cardano considered the equations $x^3 + bx = c$; $x^3 + c = bx$; and $x^3 = bx + c$ to be different and dealt with each of them separately. It was natural to deal with these types of equations separately, because European mathematicians of his time usually accepted only positive numbers both for the coefficients and for the solutions. Michael Stifel found a way to simplify this situation. In *Arithmetica integra* (Stifel 1544), he introduced rules for counting with negative numbers. He also started to use negative numbers as the coefficients of equations. Thus, it became possible to unite the three kinds of equations of the third degree into one form, which was an important step on the way to the notion of a polynomial. Polynomials, just like matrices, are formal objects. By their means, algebra achieved a deeper understanding of the unity of algebraic expressions. Where Cardano saw three different problems, namely, $x^3 + bx = c$; $x^3 + c = bx$; and $x^3 = bx + c$, Descartes presented only one, the general equation of the third degree. This unity illustrates the integrative power of the language of algebra.

By iterating an operation with the variables beyond any boundary, and combining the thus created expressions into *terms* and forms, the language of algebra has acquired a wealth of expressive possibilities. The language of algebra makes it possible to represent a situation by means of several syntactically different but semantically equivalent expressions. The process of solving an equation is based upon passing from one such representation to other semantically equivalent ones. If we take Cardano's equation: "*Cubus et rebus equalibus numero*," i.e., $x^3 + bx = c$, (in our symbolism), there are four different but semantically equivalent ways of writing it:

$$x^3 + bx = c, \quad x^3 = -bx + c, \quad x^3 - c = -bx, \quad x^3 + bx - c = 0.$$

The equation "*Cubus equalis res et numero*," i.e., $x^3 = bx + c$ can be similarly written as:

$$x^3 = bx + c, \quad x^3 - bx = c, \quad x^3 - c = bx, \quad x^3 - bx - c = 0.$$

And the last type, "*Cubus et numero equalibus rem*," i.e., $x^3 + c = bx$ can also be written in four forms:

$$x^3 + c = bx, \quad x^3 - bx = -c, \quad x^3 = bx - c, \quad x^3 - bx + c = 0.$$

Descartes unified the equations $x^3 + bx - c = 0$, $x^3 - bx - c = 0$ and $x^3 - bx + c = 0$ into a single form from which the notion of a polynomial could be created.[21] Thus, the notion of a polynomial was formed by uniting *formally similar* representations of *semantically different* situations.[22]

The four equations in each line are *semantically equivalent*. They are syntactically distinct representations of semantically identical content. However, Descartes did not use the semantic affinity of the expressions in a particular line, but *united syntactically similar but semantically unrelated expressions*.[23] He did not unite the expressions which say something similar, but he united those that are syntactically alike, even though each of them says something completely different. The unity he introduced into the language is not semantic, but formal. What unites these expressions is the common process of solution. The integrative power of the language of algebra consists in its ability to introduce a unity for which there is no support in reality that is represented by the language. Polynomials are new objects created "inside" the language. They were introduced formally, and *this* allows the language of algebra to find connections between situations where there is no relation at the semantic level. The aspect that establishes the integrative power of language is thus the *union of terms into polynomial forms*.

2.5 The Explanatory Power of the Language of Algebra

The language of algebra makes it possible to understand why some geometric problems, such as the trisection of an angle or the construction of a regular heptagon, are insolvable with ruler and compass. In problems that can be solved with ruler and compass, there occur only line segments whose lengths can be expressed using the four arithmetical operations and square roots. The reason for the insolvability of the two aforementioned problems is that their solution requires the construction of line segments, the lengths of which are solutions of irreducible cubic polynomials. Such

[21] Descartes came up with the idea of moving all terms to the left-hand side. The concept of a polynomial was thus created in two steps. The first was the unification of different types of equations into a single form by accepting both the positive and negative values of coefficients. This step was made by several mathematicians in the second half of the sixteenth century, among others by Stifel. The second step consisted in a specific choice of this form by moving all members to the left-hand side and putting zero to the right.

[22] A polynomial is an objectification of the equation, replacing the equation (which is a relation) with an object. A polynomial arises when the left-hand side of the equation is extracted from the equation and manipulated separately from the equation. Nevertheless, first all terms of the equation should be put on the left-hand side, otherwise the polynomial would not correspond to the equation, would not represent it.

[23] The unification is, of course, due to suspending the positive/negative difference. Nevertheless, the unification as such, that is as a change in the writing of expressions (the introduction of a new practice of writing one and the same expression where formerly one would write three different ones), is a change of the language of algebra.

lengths cannot be expressed using only square roots (see Courant and Robbins 1941, pp. 134–139).

Algebra can explain the failure of geometry to construct a regular heptagon using ruler and compass because the polynomial forms that establish its integrative power enable us to introduce the predicate "*to be the root of an irreducible third-degree polynomial*." This predicate is a tool for explaining why the side of a regular heptagon is unconstructible. No line whose length is the root of a third-degree irreducible polynomial is constructible, and the side of a regular heptagon inscribed in the unit circle is just that. In this explanation, we classify quantities that describe real phenomena on the basis of which polynomial they suit. We thus characterize a geometric object by means of whether it suits a certain artificially created linguistic expression. A polynomial (at least at the first sight) has nothing to do with geometry. Geometric lines seem to have nothing to do with polynomials. Surprisingly, if we project polynomials onto the world of geometry, they make it possible to understand the difference that is crucial for their construction. The boundary that separates problems that can be solved with ruler and compass from those that are not solvable in this way is determined by the predicate "to be the root of an irreducible third-degree polynomial." We can understand insolvability with ruler and compass because the language of algebra allows us to make certain distinctions. The explanation of the insolvability of the above problems illustrates the explanatory power of the language of algebra.

2.6 The Constitutive Power of the Language of Algebra

In addition to the equation $x^3 + bx = c$, the solution of which was presented in Sect. 2.2, Cardano also found a rule for the equation $x^3 = bx + c$, which can be written as:

$$x = \sqrt[3]{\frac{c}{2} + \sqrt{\left(\frac{c}{2}\right)^2 - \left(\frac{b}{3}\right)^3}} + \sqrt[3]{-\frac{c}{2} + \sqrt{\left(\frac{c}{2}\right)^2 - \left(\frac{b}{3}\right)^3}}.$$

When he tried to solve the equation $x^3 = 7x + 6$, he obtained a solution, which we would write as:

$$x = \sqrt[3]{3 + \sqrt{-\frac{100}{27}}} + \sqrt[3]{3 - \sqrt{-\frac{100}{27}}}.$$

A negative number appeared below the square root sign, $\sqrt{-\frac{100}{27}}$ which does not make sense.

When we liberate algebraic expressions from their close connection to reality and start to consider them as separate objects, the square roots of negative numbers can

be seen as a special kind of number. Even if we do not know what they represent, we can calculate with them, as Euler put it:

> However, notwithstanding this, these numbers present themselves to the mind; they exist in our imagination, and we still have a sufficient idea of them; since we know that by $\sqrt{-4}$ is meant a number which, multiplied by itself, produces -4; for this reason also nothing prevents us from making use of these imaginary numbers and employing them in calculations. (Euler 1770, § 145)

The introduction of complex numbers illustrates the constitutive power of the language of algebra.[24]

The constitutive power of the language of algebra is based on the introduction of new objects by means of definite descriptions. An example of a definite description is "the only x for which $p(x) = 0$."[25] For predicates which establish the explanatory power of the language, usually there exist objects that satisfy them. These objects are the ground upon which the corresponding explanation is based. However, there are predicates, such as $P(x)$: $x^2 + 1 = 0$, for which we cannot find any object that satisfies them. There is no real number whose square root is equal to minus one. When mathematicians postulate complex numbers, *they seem to adjust reality to fit language*.

In most languages, operations occur in pairs. In arithmetic, we have addition and subtraction, in algebra, raising to power and root extraction, in mathematical analysis, derivation, and integration. It is these inverse operations, i.e., subtraction, root extraction, and integration, that force us to expand the field of objects so that the inverse operation can always be executed. Thus, the operation of subtraction forces the introduction of negative numbers, root extraction yields complex numbers, and integration forces us to introduce transcendental functions.

Therefore, definite descriptions make it possible to define new objects even in situations where these objects cannot be expressed by means of inverse operations (for example, in the case of fifth-degree polynomials). Thus, the development of the formula language of algebra is completed only when mathematicians realize the limitations of the inverse operation.

[24] There are, of course, several ways the complex numbers might be introduced, some algebraic, some geometrical. The positing of the square root of -1 as an imaginary unit is just one among them. However, to fully appreciate this problem, one must understand why the first complex number was discovered in connection with the cubic equation $x^3 = 7x + 6$ and not much earlier in connection with some quadratic equation, which also has complex roots. The reason is that if a quadratic equation with real coefficients has a complex root, it has no real roots, so it is possible to claim that if the discriminant is negative, no root exists. In the case of the cubic equation, Cardano knew that it had a real root, and so there was a chance (which turned out to be the case) that the strange expression with square roots of negative numbers represents the real root $x = 3$. So, we have a context in which the introduction of complex numbers is not only possible, but also meaningful.

[25] When x is understood as a number, it is not unique because a polynomial of n-th degree has n roots. However, this is a small complication – we can talk about field extensions, and these are, up to isomorphism, unique.

2.7 Summary

For the language of algebra, we obtained a list of potentialities, the growth of which characterizes the development of the language of mathematics at the level of abstraction adopted by Frege. The language of mathematics is a human creation and so the increase in its logical, expressive, methodological, integrative, explanatory, and constitutive power lies in specific semiotic innovations. Introducing objects using definite descriptions is an operation that closes the circle of the construction of a new formula language. In the first step of this construction, a new kind of variable was introduced to enable general reference to *objects* of the traditional kinds (numbers or geometrical quantities). In the sixth and final step, by means of definite descriptions, new objects are introduced. These new objects belong to the domain of the same variable whose introduction started the whole process.[26] The circle of construction of the new formula language ends, returning to individuals. However, while at the beginning these were individuals represented by means of ordinary language (as well as arithmetic and synthetic geometry), and the new language was used only as a *means for their more efficient description* (as many linguists understand the role of the language of mathematics to be), in this last step language becomes a *tool for the introduction of new objects*. The complex numbers could not be coherently thematized before the algebraic operations underwent a series of semiotic innovations.

The process of constructing a new symbolic language has been shown to consist in six steps: *first* – the introduction of a *new kind of symbol*; *second* – the introduction of a *new operation* with these symbols that can be iterated indefinitely; *third* – the introduction of an *epistemological distinction* between symbols; *fourth* – the unification of various expressions representing semantically different situations into a *new form* on the basis of their syntactic similarity; *fifth* – the introduction of *new predicates* using the forms; and *sixth* – the postulating of *new objects*. We see that for each of the six *potentialities* of the language of algebra, a corresponding *syntactic aspect* could be found.

3 The Referential Component of the Language of Mathematics

The most suitable tool for the analysis of the *second, referential component of the semiotic system of the language of algebra* seems to be Wittgenstein's picture theory of meaning. We will start by showing how the picture theory of meaning can be used to analyze texts on synthetic geometry. In Sect. 3, we will transfer the picture theory of meaning into algebra, and finally, in Sect. 4, we will take the example of one

[26] In algebra, complex *numbers* have been introduced, and the construction of the language of algebra started with the introduction of letters referring to arbitrary *numbers*.

specific algebraic symbol and seek to elucidate how the *referential component of the semiotic system of the language of algebra* could be established.

In analyzing the development of the referential aspect of the language of geometry in the present section, the basic idea is to apply the picture theory of meaning to pictures contained in mathematical texts. It seems that it is possible to base the analysis of the development of the referential aspect of the language of geometry upon the picture theory of meaning. We borrow some ideas from Wittgenstein's theory but, from the very beginning, we reject the idea of the existence of a single, universal, unchanging pictorial form common to all languages. Instead, the assumption that the language of geometry passes through developmental stages, which differ from each other in their pictorial form, makes it possible to use Wittgenstein's picture theory of meaning and, above all, the notion of the pictorial form in the identification of stages in the history of geometry. The pictorial form allows a conceptual grasp of the unity of a stage in the development of geometry as a set of propositions together with their representative and argumentative practices, all of which share a common pictorial form.

Nevertheless, Wittgenstein's notion of pictorial form is complex and comprises several core ideas, only some of which are useful for the reconstruction of the referential aspect of algebraic symbolism. We can discriminate six core ideas.

1. The idea that *there exists a form that is shared* by both, i.e., the language and the reality that this language represents. This idea allows Wittgenstein to explain how it is possible that language represents reality.
2. The idea that this shared *form is compositional* so that the parts of language into which the form decomposes a proposition, and the parts into which it decomposes the reality represented by the proposition, correspond to each other. Thus, these parts can be projected onto each other because the corresponding parts are in the same relations to each other on both sides.
3. The idea that this *form is logical* in the sense that it represents the logical relations between propositions and the corresponding states of affairs, which make these propositions true or false.
4. The idea that any linguistic representation comprises *an implicit form* that cannot be expressed by the language but is displayed by it.
5. The idea that the implicit form *is identical* with the compositional form of the language.
6. The idea that this implicit, logical, compositional form of the language is the *one, unique, universal form* common to all languages.

Wittgenstein gave this unique, implicit, logical, compositional form of the language the name *pictorial form* and made it the basis of his picture theory of meaning. Although Wittgenstein later abandoned his picture theory of meaning, it seems that it is still possible to use it for the restricted task of elucidating the referential aspect of geometric pictures or of algebraic symbolism. However, to turn the picture theory of meaning into a working interpretative tool, from the above six core ideas, we will *retain* three (points 1, 2, and 4) and modify the rest (points 3, 5, and 6).

First (contra point 3), it seems that the compositional form of any language must be identical with the (full) logical form. At the time Wittgenstein wrote his *Tractatus*, Frege's logic was the latest tool of symbolic representation that mathematics had developed, and so it was rather natural to identify the compositional form by its means. However, after Gödel, Turing, Post, Church, and others developed the new representational tool in the form of the *theory of algorithms* (or recursive functions, Turing machines, or some other equivalent form) and, on this basis, the theory of generative grammar was introduced, it was natural to drop the identification of the compositional form with logic. Instead of taking one particular tool and identifying the compositional form of language with it, it seems more natural to leave this question open and decide how the compositional form actually works in each particular case. That is why in Sect. 2, we tried to reconstruct the actual logical, expressive, integrative, etc. power of the language of algebra and did not substitute for them the logical, expressive, integrative, etc. power of predicate logic (as Wittgenstein did in the *Tractatus*).

Second (contra point 5), it seems unnecessary to identify the compositional form of a language with its implicit component. The reason is that, even if the compositional structure remains the same, the border between the implicit and the explicit part of the language can move and, as it will appear in this section, it actually did move in history. We will shortly describe three different kinds of implicit form – the perspectivist, the projective, and the coordinative, all three of which have the same compositional structure, thus project the same parts on reality. This indicates that the form of what is implicit has a much finer structure than the compositional form. We must fix the compositional form to be able to study the (changes in) the implicit one.

Third (contra point 6), it seems that there exists a plurality of forms – both compositional (which were described in Sect. 2) and implicit. The development of mathematics can be interpreted as the development of the compositional and the implicit form of its language.

Yet despite these differences, if we *narrow down Wittgenstein's notion of pictorial form* (i.e., retain points 1, 2, and 4) while allowing a plurality of pictorial forms (instead of point 6) and distinguish the pictorial form from the compositional (instead of identifying them), it seems that we can obtain an important tool that allows us to understand the referential aspect of such languages as symbolic algebra and classical mechanics. Because the compositional form of formal languages was already well represented by Frege's notion of a formula language, and Frege understood the compositional form as evolving (as the quote from *Funktion und Begriff* testifies), we suggest retaining Wittgenstein's term "pictorial form" in this narrower sense for the implicit aspect of language which Wittgenstein introduced into the philosophical discourse. This text is thus not an exercise in Wittgenstein exegesis, but rather an attempt to mobilize the insights from the Tractatus to understand the referential aspect of formal languages such as symbolic algebra.

3.1 Pictorial Form as a Tool of Epistemological Reconstruction

As mentioned above, Wittgenstein's picture theory of meaning, understood as a tool for the epistemological analysis of the development of the language of geometry, is based on three theses.

The first thesis is the thesis of the *existence of the pictorial form*. It can be formulated as the belief that, in addition to grammatical structure, language has a further, independent structure, which Wittgenstein called the "pictorial form" TLP 2.2:[27] "*A picture has logico-pictorial form in common with what it depicts*." An important feature of this form is that it cannot be expressed in language. TLP 2.172: "*A picture cannot, however, depict its pictorial form: it displays it*." Wittgenstein also described two elements of this form. The first is the limits of language. TLP 5.6: "*The limits of my language mean the limits of my world*." These limits are, in the light of TLP 2.172, inexpressible in the language. It is not difficult to transfer the notion of the limits of language into the context of geometric representation. For example, in a Renaissance painting, these limits are present as the horizon. However, if we went into the landscape depicted in the painting to the place where, according to the painting, the horizon was located, we would not find anything special. The horizon that appears in the painting is an element to which nothing corresponds in reality. It was not created by strokes of the brush. It only appeared when the painting was nearing completion. The horizon is an illustration of Wittgenstein's distinction between what the picture "depicts" and what it only "displays." Although the horizon is present in the painting and we see it clearly, it is not there because it represents some element of reality. The horizon does not belong to the subject matter but to the form.[28] According to Wittgenstein, the second aspect of the pictorial form is the subject of language. TLP 5.632: "*The subject does not belong to the world*." This means that it is an element of the pictorial form. TLP 5.641: "*The philosophical self is not the human being, not the human body, or the human soul, with which psychology deals, but rather the metaphysical subject, the limit of the world – not a part of it*." Like the horizon, the subject is present in every representation. Each representation is constructed from a particular point of view, but this point of view is not depicted.

The early Wittgenstein believed that the pictorial form is unique, and thus, if a particular representational system claims to be a language, it must have the same pictorial form as the one described in the *Tractatus*. Later, Wittgenstein abandoned the idea of the existence of a single pictorial form common to all languages. He

[27] The sentences of Wittgenstein's *Tractatus Logico-Philosophicus* (TLP) are numbered by a system of decimal classification, whereby sentence TLP 2.2 comments on sentence TPL 2, just as sentence TLP 2.172 comments on sentence TLP 2.17. Therefore, it is customary to refer to the sentences of the *Tractatus* by their number.

[28] The horizon (i.e., the point at infinity) has played a crucial role throughout the entire history of geometry. The systems of Euclidean, projective, and non-Euclidean geometry differ in the nature of the horizon. This indicates that by analyzing the changes of the pictorial form of the language of geometry, we can really characterize from an epistemological point of view the development of this language.

introduced the concept of a language game to capture the diversity and richness of the possible roles of language. He had reasons for abandoning the position of the *Tractatus*, which we shall not question. Nevertheless, the description of the pictorial form contains valuable insights into the functioning of the second component of the semiotic system of mathematics. Therefore, instead of abandoning the picture theory of meaning for the sake of pluralism, we can try to introduce plurality into the picture theory itself. As already mentioned, the aim is not to interpret the views of the historical Wittgenstein, but to use his picture theory of meaning as a tool in a study of the development of geometry. It turns out that many aspects in the development of geometry can be understood if we interpret the development of geometry as a sequence of pictorial forms.

The second thesis is the thesis of the plurality of pictorial forms. This thesis can be formulated as the belief that there are several different pictorial forms and several different ways in which language can be related to the world. The turning points in the development of geometry, such as the discovery of non-Euclidean geometries, are closely tied to a transition from one pictorial form to another. In order not to cause confusion, a few adjectives can be added to the term "pictorial form." We will thus talk about the *perspectivistic form of the language of geometry.* The word *geometry* refers to the discipline whose language we are analyzing and indicates the compositional structure of language, in the framework of which the pictorial form operates. We assume that the pictorial form of the language of algebra will consist of different elements from those that form the pictorial form of the language of geometry. The word *perspectivistic* refers to a specific period in the development of this discipline (i.e., geometry) during which linguistic representations were understood to be pictures of reality, constructed from a fixed point of view. In other developmental periods of the discipline, the pictorial form had a different nature.[29]

The third thesis is the thesis of the *evolutionary nature of pictorial form*. As mentioned above, Wittgenstein identified the pictorial form with a particular compositional structure of language, namely, its logical form. As a consequence of his rejection of the metalanguage in logic, Wittgenstein was committed to rejecting any kind of external position concerning the pictorial form. As soon as we abandon the identification of the compositional and the logical form, we can accept the existence of an evolutionary process by means of which the pictorial form can evolve. It is the process of *incorporating the pictorial form of language into the language* itself. This does not contradict our first thesis because in this way a new language with a new pictorial form emerges, whose pictorial form is again only implicit. The history of mathematics exhibits several examples of such a process.

[29] The phrase *perspectivistic form of the language of geometry* can be abbreviated by omitting some of the words that are obvious from the context. Thus, use will be made of abbreviated terms such as the *perspectivistic form* (to emphasize the particular period), the *form of the language* (to emphasize its conventional character), and the *pictorial form of the language of geometry* (to emphasize the particular discipline). However, all abbreviated forms should be understood as abbreviations of the full name: *perspectivistic form of the language of geometry.*

To sum up, the notion of pictorial form as a tool of the epistemological reconstruction of the development of mathematical disciplines such as geometry or algebra is based on three theses:

The thesis of the existence of pictorial form as a linguistic structure that includes everything that cannot be explicitly represented in the language but is only displayed. The elements of the pictorial form are not accidental defects of language manifesting its failure to represent but form a system establishing the relationship between language and reality.

The thesis of the plurality of pictorial forms, according to which the language of a particular discipline is at each moment in history based on a single pictorial form, but this form can change over time. Changes in the pictorial form are tied to the turning points in the development of the discipline.

The thesis of the development of pictorial form. The pictorial form of the language J_1, which cannot be expressed in J_1 but is only displayed, can be incorporated into the language. For example, in projective geometry, the point of view of the previous pictorial form is represented as the center of projection. This incorporation creates a new language, J_2, with a new pictorial form that cannot be expressed in J_2. However, J_2 will contain the means to express the pictorial form of J_1.[30]

3.2 Aspects of the Pictorial Form of the Language of Geometry

As a result of the above three theses, an epistemological reconstruction of the development of geometry has become a well-defined problem – to find elements of the pictorial form of the geometric language, for its developmental stages as normally distinguished by historians of geometry. To cut to the chase:[31]

1. *The point of view* is the point from which the correspondence between the picture and the world is constructed. The use of a single stationary point in the construction of perspective was invented by Brunelleschi. This point belongs to the pictorial form because it is not depicted in the picture, but is only displayed by it. The position of the viewpoint affects the perception of the picture, and its position can often be determined.

[30] The mechanism of incorporating the pictorial form into the language is an optimal tool for describing the development of a theory. The conceptual structure, present only implicitly, i.e., only displayed but unable to be depicted by the language, will become explicit. This will enrich the conceptual systems of the theory with new concepts, but without any contradiction between the conceptual system of the old and new theories.

[31] The possibility of expressing the pictorial form of language J_1 in language J_2 opens the possibility of the emergence of a *sequence of interconnected languages*. In this sequence, the stage J_n contains the pictorial form of the language of the previous stage J_{n-1} and its own pictorial form becomes expressed in the next stage, J_{n+1}.

2. *The horizon,* which, as already explained, is an aspect of the pictorial form (i.e., nothing corresponds to it in the world, nor does it represent any real object), displays the altitude of the viewer's eyes, and so indicates the position of the point of view. The horizon represents the limits of the world depicted by the picture.[32]
3. *The relation of identity*, i.e., the rules allowing us to identify different representations as representations of the same object, can be interpreted as a further aspect of the pictorial form. Painters discovered these rules when studying the changes in the size of the simplest object – a square – forming part of a regular square grid, called *pavimento*. To represent more complex situations, it is necessary to know the exact construction of the *pavimento*, which helps to properly place the individual figures and elements of architecture. The exact construction of the *pavimento* comes from Leon Battista Alberti. The rules of the reduction in the sizes of tiles forming such a *pavimento* are an aspect of the pictorial form. Nothing corresponds to these rules in reality: the tiles do not get smaller with increasing distance. The reduction of the sizes of the tiles displays the *relation of identity*. If we ask an observer about the tiles, she must answer that they are the same, despite the fact that she is looking at quadrilaterals on the picture that are of different sizes.
4. *The relation of synonymy* is defined as the relation holding between expressions that are in principle different but within the given pictorial form are represented by the same individuals. This means that in the universe of discourse, we are unable to illustrate their differences. Synonymy understood in this way is an aspect of the pictorial form, because when the pictorial form changes, the individuals that became newly expressible by the language may illustrate the difference. Expressions that were synonymous within one pictorial form can cease to be synonymous after the transition to a new form. For example, the expressions "equidistant lines" and "parallel lines" are synonymous within Euclidean geometry: equidistant lines are parallel, and parallel lines are equidistant. However, in non-Euclidean geometry, which is built upon the basis of a new pictorial form, they lose synonymy. In non-Euclidean geometry, equidistants to a straight line are curves, while parallels to a straight line are not equidistant.

   By moving to more complex pictorial forms, *the relation of identity expands* – the language becomes able to represent wider classes of things, which we formerly perceived as different objects, as only different positions of the same object. On the other hand, by moving to more complex pictorial forms, *the*

[32] One could object to our including the horizon among the aspects of the pictorial form. The objection might go as follows: "The objective of a perspectivist representation is to represent a landscape (for example) as one would see it from a certain point of view. However, a landscape seen from a certain point has a horizon, which is an intrinsic property of this view, and not just of the painting. The horizon is part of what I see and therefore also of what must be represented in the painting. I cannot go to this point because it is at infinity. The objective of the painting is to represent the landscape as I see it. And I see the horizon when I am in front of the landscape." This objection is interesting. To answer it requires more technical tools, so we postpone the answer to the next section.

relationship of synonymy narrows down – properties that the language was unable to distinguish, because it lacked suitable objects, become distinguishable.

5. *The background* against which we recognize the identity of objects in geometry is the space. A geometrical object retains its identity when we move it through space. Space is an aspect of the pictorial form because it cannot be depicted in the picture: it is only displayed. If, on a picture, two lines converging toward the horizon are drawn, adopting the perspectivistic form of language means acquiring the ability to see in them two parallels running into the depth of space. To the question "What do you see in the picture?" we must answer not according to what we are looking at (convergent lines), but according to what, strictly speaking, is not present in the picture (parallels).
6. *Ideal elements* are the last aspects of the pictorial form. An example of ideal elements in geometry are points at infinity. The purpose of their introduction is to unify the schemes, so that, for instance, any two straight lines in the plane intersect, which simplifies geometric constructions.

The viewpoint, the horizon, the relation of identity, the relation of synonymy, the background, and *ideal elements* compose the pictorial form of the language of geometry. These aspects are not factual; nothing corresponds to them in reality. Wittgenstein's words are thus given a precise technical content. The pictorial form includes everything that the language displays but cannot depict.

3.3 The Development of the Pictorial Form of the Language of Geometry

We can apply Wittgenstein's notion of the pictorial form to analyze pictures contained in classical texts from the history of geometry and try to identify in these pictures the various elements of the picture theory of meaning. The development of geometry will become a sequence of pictorial forms so that each stage contains the pictorial form of the previous stage incorporated into the language. The pictorial forms differ from each other in the way they relate representation to reality. We shall start with the perspectivist form of geometry but will make a short detour into painting because the concepts of space and of projective transformations were not introduced by mathematicians but by painters. In this way, the history of Renaissance painting, at least indirectly, is part of the history of geometry.

In the *perspectivist form*, a representation is understood as a picture of a real situation. The paintings of Masaccio, van Eyck, and Leonardo, as well as those of many other Renaissance painters, can be characterized by means of the above aspects of the pictorial form, which means that these aspects were introduced as they are present in the perspectivist form. They depict the world from one fixed point chosen as the point of view. The landscape leads in a regular way to the horizon, to which the parallels smoothly converge, letting the objects in a systematic way diminish with distance. The previous section sufficiently explained why we should interpret perspective as a pictorial form in this sense, that is, as a system of conventions regarding how to "see" what is displayed by a painting. It seems that

the Renaissance can be characterized as that period in the history of art which was based upon *perspective as a pictorial form*. Let us turn to the ensuing period, Mannerism.

In the *projective form* that is typical for projective geometry, a representation of representation is created, and so the concept of a geometric transformation becomes explicitly expressible in the language. The projective form was introduced in Mannerism, but we can introduce it by a short detour into astronomy. It is well known that in 1543, Nicolaus Copernicus (1473–1543) published *De Revolutionibus Orbium Coelestium*, in which he proposed a heliocentric astronomy. With this work, he brought a radical shift in pictorial form, that is, in the way of organizing a pictorial representation. Copernicus does not depict the universe from the fixed point from which we observe it. Naturally, from our terrestrial point of view, the Sun and the stars appear to move while the Earth stands still. Nevertheless, Copernicus insisted that the motions of the Sun and stars are only apparent. To be able to say this, he must have been imagining himself, and any other observer of the skies, from an external point of view far apart from the Earth. In his mind's eye, he abandoned his geocentric perspective and, from somewhere "up there," observed some astronomer seated on a rotating, orbiting globe. From this external position, he could see the motionless Sun and understand that the motion of the Sun, which the terrestrial observer perceives, is only an apparent motion.

We can take the viewpoint of the external observer as the point of view (that is, as an aspect of a new pictorial form) and put it on a par with normal perspective, which was the pictorial form of the Renaissance period. To derive a theoretical analysis of the projective form, we can turn to an etching by Albrecht Dürer. Just like Copernicus, who was born only 2 years after him, Dürer observes somebody at work. In his imagination, Copernicus was observing an astronomer observing the skies, whereas Dürer was observing a painter constructing a perspectivist painting. In a sense, the representation in Fig. 1 has two viewpoints. One is external: it is the point from which the space of the room is constructed. The other is internal, the eye of the painter, or more precisely, the point where the rope with the tube is fastened to the

Fig. 1 Albrecht Dürer (1471–1528), *Underweysung der messung mit dem zirckel und richtscheyt* (1525)

wall. This split (or duplicated) viewpoint is one aspect of the projective pictorial form.

If we realize that Copernicus observed an astronomer (and he himself was an astronomer), just like Dürer was observing a painter (and he was a painter), we see that they are incorporating into representation a reflection of the self. We can term this pictorial form *projective form*, because what Dürer depicted is the projection itself; he is representing the process of representation.[33]

The next pictorial form, that is the *coordinative form*, can be introduced with a similar detour to that of the projective form, but this time not into astronomy but cartography. If we take the map of Africa constructed by the Portuguese cartographers in the fourteenth century, it is a representation that is radically different from perspectivist paintings in the sense that before the astronauts flew above Africa, no one could perceive the shape of Africa. Nevertheless, we know that what the cartographers constructed is a sufficiently accurate picture of Africa. However, it was constructed not as perspectivist pictures are, by someone looking at an external object from a fixed viewpoint; neither was it constructed as projective representations used to be, by someone looking from an external viewpoint at how someone else perceives the sky or a vase. A coordinative representation occurs in a different way. There were dozens, maybe hundreds of sailors who sailed around Africa. None of them saw anything like the shape of Africa; they only collected data which they passed to the cartographers and the cartographers coordinated these different data and created the resulting representation. In a sense, the cartographer resembles the external observer of the projective form. The only difference is that he is not observing, but rather coordinating the data supplied by the sailors. Similarly, the sailors resemble the internal observer in Dürer's etching. Yet again, the parallel is not precise, because the sailor, in contrast to the painter depicted by Dürer, does not see the shape that is represented. He has access only to a rather limited amount of information, which is not "visual" but rather "positional." The cartographer is not so much interested in what the sailor saw but where he was positioned.

[33] Now we are in the position to answer the objection from footnote 33. We must realize that in the objection we have a *landscape*, then the *view* of the landscape as seen by the observer, and finally the *painting* that represents this view. Thus, we are in the situation depicted in Dürer's etching, i.e., in the projective form of language. The thesis that the horizon is an aspect of the pictorial form, and thus is displayed by the picture but cannot be depicted, concerns the *perspectivist form*. The projective form is created precisely by incorporating the form of the perspectivist picture into the language, thus turning it into an explicitly represented system. So yes, the horizon that belongs to the internal point of view (in Dürer's etching, the eye of the painter is represented in the etching) is explicitly present in the representation. If we imagined that the painter painted not a vase but a landscape, and so a horizon would appear in his painting, this horizon would not move when Dürer decided to lower his viewpoint and construct the entire etching from a much lower viewpoint. We would see the entire scene from a lower point, but the horizon on the painting would not move. So, in the projective form, the pictorial form of the previous stage is made explicit. The objection is thus based on a good observation, but it does not take into account that, if we consider the painting as a representation of the inner view, we change the entire situation and thus join Copernicus and Dürer in using the projective form.

We could go on and describe the principles of the five further pictorial forms as they occurred in the development of geometry from projective geometry through non-Euclidean geometry to topology. However, we will return instead to algebra and try to transfer the notion of a pictorial form, as well as the aforementioned three particular pictorial forms, from geometry to algebra.[34]

3.4 Transferring the Concept of Pictorial Form to Algebra

The history of algebra is the subject of intense historical research.[35] In 1842, Georg Nesselmann, in *Versuch einer kritischen Geschichte der Algebra*, introduced the distinction between *rhetorical*, *syncopated*, and *symbolic* algebra. This distinction became popular, and several historians of mathematics used it.[36] In *rhetorical algebra*, the solutions of algebraic problems are given in the form of verbal rules, like Cardano's rule given in Sect. 2.2. In *syncopated algebra*, the technical terms are stepwise replaced by their first letters, and for these abbreviations, a kind of calculus is created. In *symbolic* algebra, illustrated by formula (2), the abbreviations are replaced by genuine symbols. After symbolic algebra, we can distinguish *abstract algebra* that studies structures such as groups, rings, and fields, and *categorical* algebra, which studies morphisms between structures (van der Waerden 1985, Boyer and Merzbach 1989, Scholz 1990, Corry 2004, and Gray 2018).

The description of the pictorial forms in geometry in the previous section is sufficiently detailed to enable the identification of the corresponding sequence of pictorial forms in the development of algebra.[37] This is important because we are

[34] The interested reader can find more details concerning the notion of a pictorial form and its development in geometry in (Kvasz 2008). Nevertheless, these details are not important for an understanding of this chapter.

[35] See the works of Chemla (2003, 2005, 2012), Heeffer (2009, 2010), Hoyrup (1994, 2007, 2019), Oaks (2006, 2007, 2009, 2012), and Wagner (2010, 2017) in the list of references.

[36] In recent years, criticism of this periodization has appeared (Heeffer 2009). Nevertheless, as some linguists still use these terms (O'Halloran 2005, p. 57), we will stick to them as well. The focus of the criticism is *syncopated algebra*, which cannot be taken as a stage in the history of algebra because it overlaps to a significant degree with *rhetorical algebra* and is dependent on it. Nevertheless, from a semiotic point of view, syncopated signs can be the subject of study, under the proviso that they are not considered to form a historical period.

[37] One could object that the form of an algebraic expression is not an image in the Wittgensteinian sense of the word, i.e., the relations of the parts of an algebraic expression are not the same as those of its content. The relation of the sign $\surd$ and 8 are not analogous to what the parts of what $\sqrt{8}$ represents, just like the parts of a polynomial expression are not in the same relationship as the parts of what it represents. It is in a way the ability to express complex objects and relations without having to be the image of them that gives algebra its expressive power and its capacity to transform itself in the course of history. Nevertheless, this objection does not take into account the separation of the compositional and pictorial forms in our approach. Thus, in contrast with point 3 (that the compositional form is identical with the logical form), I consider algebraic symbolism to be a formula language with its own kind of compositional form. The compositional form of the language of algebra represents the functional structure of language, thus it represents $\sqrt{8}$ as the application of

unable to directly transfer to algebra the aspects of the pictorial form described in Sect. 3.2. Nevertheless, it is possible to transfer the pictorial forms from geometry to algebra. For example, the *perspectivist form* of the language of algebra seems to correspond to syncopated algebra. In syncopated algebra, only a number that satisfies the conditions of the problem was accepted as a solution to an equation. Thus, an algebraic equation was understood as a *picture* of a real situation. The *projective form* of language seems to correspond to the first stage of symbolic algebra (represented by Viète and Descartes) when, due to the introduction of substitutions, all numbers satisfying an equation were accepted as solutions of that equation, because they could be connected with the real situation by means of some substitution. The equation thus ceases to be seen as a picture of reality. Between the symbolism and the real situation, a distance was created that is similar to the difference between the external and internal points of view. Only some of the solutions of an equation have meaning in the real situation represented by the equation. This is analogous to the fact that only some aspects of reality as represented from an internal viewpoint correspond to some aspects of the same reality represented from an external viewpoint.

Thus, the identification of the historical sequence of pictorial forms in the development of synthetic geometry enabled the discovery of an analogous sequence in the development of algebra and thereby the transfer, to algebra, of the method of reconstruction of the development of the pictorial form.[38]

3.5 Aspects of the Pictorial Form of the Language of Algebra

Confronting our approach with the inspiring text of Brian Rotman (Rotman 1987) facilitated the transfer of some aspects of the pictorial form from geometry to equivalent aspects of the language of algebra. By an algebraic equivalent, we mean an aspect of the pictorial form of the language of algebra that has in that language a role that is equivalent to the role played by the corresponding aspect of the pictorial form of the language of geometry. The idea is that the pictorial form of a language is composed of the above six aspects. So, there is a *structural isomorphism*

the function of $\sqrt{}$ at the argument 8. Similarly, in the case of a polynomial, it represents the result of the particular operations as applied to any number. Furthermore, it is thanks to the fact that the algebraic magnitudes are in the same relations as the relations of the parts of the expression that the algebraic symbols have meaning. Thus, for instance, the quantity represented by the symbol $\sqrt{8}$ is the outcome of the operation $\sqrt{}$ applied at the argument 8, and thanks to that the algebraic symbol represents this quantity. So, if we understand the compositional form of the language of algebras to be a structure on its own, we can interpret its referential aspect in the Wittgensteinian sense (in agreement with points 1 and 2) and turn to the interesting question regarding which aspects of this compositional form remained implicit during a particular historical period. Thus, thanks to the separation of the compositional form from the logical form, we can transfer the notion of a pictorial form to the case of algebra.

[38] A more detailed reconstruction of the history of algebra as the development of the pictorial form of its language can be found in (Kvasz 2008).

between *identical* pictorial forms of *different* languages (i.e., for instance, the perspectivist form of the language of geometry and the perspectivist form of the language of algebra), which maps the epistemic subject of one language onto the epistemic subject of the other, just like it maps the relation of identity of one language onto the relation of identity of the other. Similarly, there is a *structural embedding* between *consecutive* pictorial forms of the *same* language (i.e., for instance, the perspectivist form and the projective form of the language of geometry), which maps the aspects of the earlier form (which are in that form only implicit) onto their explicit expressions in the later pictorial form.

It seems that the algebraic equivalent of the point of view can be identified (as Rotman convincingly showed) with *zero*, which is found in the standard form of algebraic equations on their right-hand side.[39] The algebraic equivalent of the horizon can be seen in the *domain of the coefficients*, i.e., the set of quantities that mathematicians accept as coefficients which can appear in equations. As mentioned, Stifel was one of the first to allow the coefficients in the equations to take on negative values (so he passed from natural numbers to integers as the domain of the coefficient). However, that was not the end of the story. Later, Lagrange realized that the addition of further quantities to the domain of the coefficients results in the decomposition of an irreducible polynomial into factors. The clarification of this problem was brought about later on by the notion of a Galois connection. The richness of the domain of the coefficients determines the scale of relationships that can be expressed in the language of algebra and so determines the limits of the world, in agreement with Wittgenstein's thesis, according to which the limits of language mean the limits of the world.

The algebraic equivalent of the relation of identity, which, in the language of geometry, was illustrated by the rules for diminishing the tiles forming a *pavimento*, could be the *rules of the equivalent transformations of equations*, such as Al Khwarizmi's *al jabr* (after which algebra was named), *al mukábala*, and *al rad*. The algebraic equivalent of the synonymy relations could be the *canonical forms and invariants*, such as the three forms of the cubic equations introduced by Cardano. With an expansion of the domain of the coefficients (for example, by accepting negative numbers), the rules of equivalent transformations are also enriched, which makes it possible to reduce the number of canonical forms, in the case of cubic equations, to one. The algebraic equivalent of the background could perhaps be interpreted as the *system of solutions*, i.e., what is considered to be a solution to an algebraic problem. Finally, the algebraic equivalent of ideal elements could be *complex numbers* and, in general, various algebraic extensions of the domain of numbers.

To indicate the complexity of the development of the pictorial form of the language of algebra and thus to allow an appreciation of the complexity of the task

[39] This supports the interpretation of the early stages of symbolic algebra (first of all the symbolism introduced by Descartes) as projective form, because in the projective form of language, the point of view of the previous pictorial form (the perspectivist one) becomes explicitly represented in language (as the zero on the right-hand side of an algebraic equation).

of giving a possibly complete sequence of pictorial forms in the development of algebra, we will list only the stages in the development of the fifth aspect, i.e., how the system of solutions of an algebraic equation was understood within the particular pictorial forms of the language of algebra.

To solve the equation $g(x) = 0$ means:

1. *To find a regula*, i.e., a rule written in ordinary language, which makes it possible to *calculate* the "thing," that is, the root of the equation.
2. *To find a formula*, i.e., an expression of the symbolic language, which makes it possible to *express* the root of the equation in terms of its coefficients, the four arithmetical operations, and root extraction. The symbols in the formula correspond to steps in the calculation, and so a formula is a representation of the *regula*.
3. *To find a factorization of the polynomial form*, i.e., to represent the polynomial form as a product of linear factors. Each factor represents one root of the equation, and so the number of factors is equal to the degree of the equation.
4. *To find a resolvent*, i.e., to reduce the given problem, by means of a suitable substitution, to an auxiliary problem of a lesser degree. A solution to the auxiliary equation can be transformed into a solution of the original problem. However, here, besides the n roots of the n^{th} degree equation, we also obtain all the associated quantities, in general, $n!$ numbers. By means of n of them, we can split the polynomial form into linear factors.
5. *To find a splitting field*, i.e., to construct the field $Q(\alpha_1, \ldots, \alpha_n)$ that contains all the roots of the equation. This field automatically contains all the associated quantities of the equation, and thus also all the roots of its resolvent.
6. *To find a factorization of the Galois group of the splitting field* $Q(\alpha_1, \ldots, \alpha_n)$, i.e., to decompose the group of symmetries of this field into blocks. Steps in the factorization of the group correspond to particular extensions of the field. Hence, from knowledge concerning the factorization of the group, we can draw conclusions about the field extensions.
7. *To construct a factorization of the ring of polynomials* $Q[x]$ *by the ideal* $(g(x))$, i.e., to find the residual classes of the ring of polynomials after factorization by the ideal that correspond to the equation we want to solve. One of these classes is the root of the equation, and so we have an abstract method for the solution of any algebraic equation.

This list illustrates the levels of abstraction that have been introduced in the history of algebra.[40]

[40] A similar development concerning the different interpretations of the notion of Dirichlet character is presented in Jeremy Avigad's paper *Mathematics and Language* (Avigad 2015, pp. 240–242). Dedekind and Weber played key roles in stages 6 and 7 of the development represented in (Fig. 2), so it is likely that the development of the notion of Dirichlet character may be parallel to some of the stages captured in (Fig. 2).

3.6 Objectification as a Fundamental Semiotic Process

Thanks to the analysis of the incorporation of the pictorial form into language, we can explain why the interpretation of mathematical expressions as rules is inadequate. Even if Cardano did understand algebra as a collection of rules, his syncopated algebra was only the first of the eight pictorial forms of the language of algebra indicated in (Fig. 2). Thus, the case of Cardano shows that the understanding of mathematical expressions as rules is in some cases adequate. Maybe this understanding is based on an illusion created by the fact that the pictorial form of language J_1 is incorporated into language J_2, and so on. Thanks to this incorporation, in any language based on practically any later pictorial form, we can find a fragment which can be translated back to J_1, in which algebra *was* a collection of rules – although for most of the new results obtained thanks to the special properties of the later pictorial forms, such a translation is not possible.

To solve the equation $g(x) = 0$ means:

1. *To find a regula*, i.e., a rule written in ordinary language, which makes it possible to *calculate* the "thing", that is, the root of the equation.
2. *To find a formula*, i.e., an expression of the symbolic language, which makes it possible to *express* the root of the equation in terms of its coefficients, the four arithmetical operations, and root extraction. The symbols in the formula correspond to steps in the calculation, and so a formula is a representation of the *regula*.
3. *To find a factorization of the polynomial form*, i.e., to represent the polynomial form as a product of linear factors. Each factor represents one root of the equation, and so the number of the factors is equal to the degree of the equation.
4. *To find a resolvent*, i.e., to reduce the given problem, by means of a suitable substitution, to an auxiliary problem of a lesser degree. A solution to the auxiliary equation can be transformed into a solution of the original problem. However, here, besides the n roots of the n^{th} degree equation we also obtain all the associated quantities, in general, $n!$ numbers. By means of n of them we can split the polynomial form into linear factors.
5. *To find a splitting field*, i.e., to construct the field $Q(\alpha_1, ..., \alpha_n)$ that contains all the roots of the equation. This field automatically contains all the associated quantities of the equation, and thus also all the roots of its resolvent.
6. *To find a factorization of the Galois group of the splitting field* $Q(\alpha_1, ..., \alpha_n)$, i.e., to decompose the group of symmetries of this field into blocks. Steps in the factorization of the group correspond to particular extensions of the field. Hence, from knowledge concerning the factorization of the group we can draw conclusions about the field extensions.
7. *To construct a factorization of the ring of polynomials* $Q[x]$ *by the ideal* $(g(x))$, i.e., to find the residual classes of the ring of polynomials after factorization by the ideal that corresponds to the equation we want to solve. One of these classes is the root of the equation, and so we have an abstract method for the solution of any algebraic equation.

Fig. 2 An overview of the possible interpretations of the notion of solution of an algebraic equation. (A description of the different pictorial forms of the language of algebra can be found in *Patterns of Change* (Kvasz 2008, pp. 165–200). The summarizing overview of the different interpretations of the solution of an algebraic equation presented in (Fig. 2) can be found on page 199 of that book)

Objectification may be seen as a mechanism of conceptual change in mathematics. In the perspectivist form (i.e., in its syncopated phase), algebra was based on operations, such as raising to the third power or extracting the third root. *The first objectification* consisted in transforming these operations into objects, into powers and roots, and representing them through special signs as done, among others, by Regiomontanus around 1460. Thanks to this first layer of objectification, more complex expressions can be created and, for them, operations of a new kind can be introduced: operations of the transformation of algebraic expressions. *The second objectification* consisted in the replacement of the numerical values of the coefficients by a new kind of symbol – parameters introduced, for instance, by Viète in 1591. Thus, a new algebraic object was born, a general algebraic expression, and with it also a new kind of operation, consisting of transformations into different canonical forms. One of these canonical forms was the one in which all terms were transferred to one side of the equation. However, this presupposed the objectification of negative numbers, i.e., their acceptance as real objects on a par with positive numbers and zero. This was *the third objectification* introduced, in one form, by Stifel in 1544. It took place independently of the second and again introduced new operations. The combination of the last two objectifications led to the formation of polynomials as a new kind of algebraic object. This step can be seen as *the fourth objectification*.

The formation of polynomials gave birth to new operations, the decomposition of a polynomial into factors. It gradually became clear that what enables the decomposition of the polynomial is the presence of specific quantities. *The fifth objectification* brings the objectification of the set of all quantities, which allows the decomposition of a polynomial into a product of linear terms. The set of these quantities is called the splitting field of the polynomial and was introduced, in an implicit form, by Lagrange. The objectification of the splitting field enables the introduction of new operations, such as permutations of the roots of the polynomial, which generate automorphisms of the splitting field. By objectifying these automorphisms (which is *the sixth objectification*), the Galois group of a polynomial is formed. Formation of the Galois groups makes it possible to introduce a new operation, the operation of their factorization. It is only at this sixth level of objectification that a remarkable property of fifth-degree polynomials is revealed: their group of automorphisms contains only one normal subgroup, the alternating group of five elements, which is simple and cannot be further factorized. This fact lies at the bottom of the insolvability of fifth-degree equations. Without the cascade of six objectifications, this fact is not easily discovered. Objectification is thus a *fundamental concept-forming mechanism in mathematics*.

4 Conclusion

In this chapter, we offered a model of semiotic analysis of the language of mathematics based on two components and illustrated this model on the language of algebra. The first component was termed the *compositional component* of

the language, and it was reconstructed by means of the logical, the expressive, the methodological, the integrative, the explanatory, and the constitutive power of the language. We believe that these six aspects of the language of a particular mathematical or scientific discipline are its objective features, which can be further analyzed and perhaps even quantified. Their growth may be responsible for the impression of progress, that many mathematicians and scientists perceive when they view the historical development of their discipline. One cannot deny that, from the point of view of the compositional component, the language of mathematics, say, makes an impression of continual growth and improvement.

The second component was called the *referential component* and was reconstructed by means of the picture theory of meaning. This component was reconstructed using notions like the point of view, the horizon, the relation of identity, the relation of synonymy, the background, and the ideal elements. It turns out that the gains at the compositional level are, in a sense, compensated by making these six aspects of the referential component more indirect, complicated, and difficult to comprehend. So, the development of the compositional component makes it more and more difficult to relate the expressions of the language to a real situation and understand their meaning.

Abstract

In this chapter, we use structuralist semiotics as a framework for analyzing mathematical textual practices. We begin with a short introduction, in which we operationalize certain key aspects of structuralist semiotics. This gives us a tool for semiotic analysis of real mathematical texts. We then illustrate this type of analysis with a concrete text, namely, *Über die Composition der binären quadratische Formen* by Richard Dedekind.

Keywords

Philosophy of mathematical practice · Mathematical textuality · Structuralist semiotics · Dedekind

1 Introduction

In this chapter, we assume as framework Wagner's discussion of structuralist and poststructuralist semiotics (▶ Structural Semiotics as an Ontology of Mathematics). To summarize, in this framework, *signs* emerge from an interaction of two (or more)

distinct levels or "streams," e.g., sound, visual perception, thought, or emotion. The interaction results in a simultaneous division or "articulation" of each level into units. One level becomes signifying units, called *signifiers*, and the other becomes signified units, called *signifieds*. A *sign* is defined as a connection between a signifier and a signified.

As an example, colors emerge from a division of the visual perception of a spectrum of electromagnetic radiation into subspectra. But we only form signs once we relate this division to another. If the other division happens in the aural stream of speech, the signs are the (sometimes quite subjective) connections of spoken words "red," "blue," "green," etc. to the visual perceptions. The words would be the signifiers and the perceptions the signifieds. However, if instead we correlate the subspectra with our experience of different types of weather, we may form signs where colors are signifiers of (changing) weather (a clear blue sky in winter may signify a freezing cold day ahead, a sudden darkening may signify thunder).

Colors are likely much more semiotically complex than this. But the example illustrates the central point that, as signs, colors do not exist in themselves but only in their differentiation from other colors. This is true for signs in general: From a structuralist perspective, signs only exist in systems of differences. The *meaning* of a sign is its value relative to other signs around it.

Here, our aim is to illustrate how a structuralist semiotic approach can be used to analyze an actual mathematical textual practice in the form of a "real" mathematical text. The essential method of structural analysis is the *commutation tests*, in which we exchange a segment of a stream and observe how a correlated stream changes in response.

In our case, the signifiers are the concrete textual expressions and the signifieds are the content of the text. We define content as an analytical category in the next section.[1] For now, as an example, consider the expression "0 is in {0, 1}." This can be read as a statement about signifiers, which says that "0" occurs in the concrete string "{0, 1}" (like "t" occurs in the string "the"). Alternatively, it can be read as saying that 0 is an element of the set {0, 1}, in which case it is a statement about signifieds.

To study the signs of actual texts, we perform commutations of textual expressions. We use two kinds of commutation tests. In the first, we commute expressions that actually occur in the text. For example, say that both of the following occur:

$$\text{“}0 \text{ is in } \{0,1\}\text{”}$$

$$\text{“}0 \text{ is in } 01110\text{”}$$

Then we might ask if the change between "{0, 1}" and "01110" at the level of signifiers makes a difference at the level of signifieds.

[1] The terms "content" and "expression" have a technical meaning in structuralist linguistics. We use the terms in a sense inspired by it but much simplified (cf. Hjelmslev 1953).

In the second kind of commutation test, we compare an expression that occurs in the text with one that we write ourselves. Suppose we are interested in the mathematical textual practice of mixing natural language with non-phonetic (e.g., symbolic) writing (like "is in" is mixed with numerals and braces in the expressions above). An approach could be to rewrite samples of actual text but using only non-phonetic writing and then note the differences, if any, at the level of signifieds.[2]

To illustrate what a structuralist semiotic analysis may look like, we apply a series of commutation tests to an actual mathematical text, *Über die Composition der binären quadratische Formen* by the mathematician Richard Dedekind. Our commutation tests are chosen with a more general question in mind: Can structuralist semiotics propose a notion of *mathematical textual practice* grounded in the study of actual textual material? It is beyond the scope of this chapter to address this question directly, but our reading of Dedekind's text will illustrate the idea. Specifically, we recapitulate a particular historical-philosophical debate regarding Dedekind's text. Based on this debate, we introduce a distinction between two different kinds of contents, namely, *arithmetical content* and *set content*. We conceive these contents as certain classes of signifieds. We apply commutations to Dedekind's text, which are designed to capture interactions between arithmetical and set contents and indicate how to analyze a textual practice in terms of such interactions.

2 Framing the Application

Dedekind's text is a famous piece of nineteenth-century algebra. It appeared as the tenth appendix or "supplement" to the second edition of Dirichlet's *Vorlesungen über Zahlentheorie* (Lejeune-Dirichlet 1871). For brevity, we refer to Dedekind's text as Dedekind (1964). In Dedekind (1964), Dedekind presents a theory of uniqueness of prime factorization for algebraic integers. We focus on the sections §§159–163 of Dedekind (1964), in which Dedekind introduces the notion of *an ideal*. In Dedekind's definition, an ideal is a special kind of "system"[3] of numbers that is closed under the algebraic operations of addition, subtraction, and multiplication (Dedekind 1964, 251).[4,5] Dedekind then

[2] Wagner (2009) gives examples of both kinds of commutation tests for analyzing the semiotics of "0."

[3] The German term is "System," but there are different translations in the secondary literature. Haffner (2017) translates "System" to "system," whereas, for example, Ferreirós (2007) translates it to "set."

[4] The numbers are *algebraic integers*, i.e., the elements of the ring of integers o of a general algebraic number field. In particular, o is an ideal consisting of all the algebraic integers under consideration – the ambient space, so to speak. In the special case of the field Q of rational numbers, the "algebraic" integers are simply the usual integers and o is Z.

[5] As an example, consider Z, the ring of integers of the field of rational numbers Q. The set of numbers of the form $3n$, where n runs through the integers, i.e., the set $\{\ldots, -6, -3, 0, 3, 6, \ldots\}$ is an ideal. Similarly, any set of numbers of the form αn, where α is a fixed integer, is an ideal.

gives a prime factorization for ideals and proves that the prime factorization is unique.[6]

Dedekind (1964) was the first version of the theory. Dedekind later reworked and republished it three times.[7] There is a consensus that Dedekind's successive reworking of ideal theory almost seems to encapsulate an anticipation of certain developments in mathematics during the twentieth century. Summarized by Avigad:

> Whereas Dedekind's first version remained fairly close to Kummer's computational style of presentation, the later versions became increasingly abstract and algebraic. As a result, the development is an early and salient example of a transition to types of reasoning (set-theoretic, algebraic, structural, infinitary, nonconstructive, and so on) that are characteristic of modern mathematical thought. (Avigad 2004, 2)

The cut is not clear, though. The precise relation in Dedekind's work between, on the one hand, the "new" ways of doing mathematics (set-theoretic, algebraic, structural, infinitary, nonconstructive…) and, on the other hand, the "old" ways remains a contested issue.[8] For our purpose, the important fault line in this debate is the interaction between arithmetic and set theory in Dedekind's writing.

According to Mehrtens (1979), the concepts that Dedekind introduces in Dedekind (1964) are abstract and their relationship to arithmetic is merely accidental (Mehrtens 1979, 76–77). The concepts may seem to be concretely arithmetical, but this is because they were "tailored to a specific frame of reference," not because they were not abstractly conceived. Haffner (2014, 2017, 2019) instead suggests that Dedekind uses "arithmetical rewriting" (2017, 32), a set of writing practices deliberately invoking arithmetic at several levels, including notation, conceptualization, and proof techniques. In this view, Dedekind establishes analogies to number theoretical concepts and methods, which would have been familiar to readers of the time.[9]

How novel was it to work with sets? Edwards writes:

> Indeed, despite the fact that Dedekind defines an ideal as a "system" of algebraic integers rather than a "set," the set-theoretic point of view is unmistakable and appears here well before the work of Dedekind's colleague Cantor on this subject […] [T]his theory of ideals (in 1871) can surely be regarded as the first appearance of the set-theoretic approach that was later to become so influential. (Edwards 1980, 346)

[6] For a full account (besides Dedekind's text itself), see (Edwards 1980, 1990) or Stillwell's introduction (Dedekind and Stillwell 1996).

[7] Dedekind published a second version of the theory in *Bulletin des Sciences Mathèmatiques et Astronomiques* 1876–1877, which already differs substantially from Dedekind (1964). The third and fourth versions came in the later editions of *Vorlesungen*, in 1879 and 1894, respectively.

[8] Loosely, the "old ways" would be constructive, computational, object-oriented, or focused on specific (geometric or arithmetical) problems.

[9] See also Corry (2004, esp. Chaps 2, 3, 5), Awodey and Reck (2002), Ferreirós (2007), Sieg and Schlimm (2005, 2017), Reck (2003, 2009), and Avigad (2006).

This is the debate that motivates our analysis. Dedekind's writing, and Dedekind (1964) in particular, lends itself to be read as two seemingly conflicting ways of doing mathematics. We suggest that structuralist semiotics can be used to grasp the relationship between them as a concrete mathematical textual practice.

In Dedekind (1964), if α is a number contained in an ideal a, then a is said to *divide* α (Dedekind 1964, 251).[10] An ideal b is said to *divide* an ideal a if b contains each of the numbers in a:

> If all the numbers of an ideal a are also contained in an ideal b, [...] we will say that a is a multiple of b or divisible by b, b is a divisor of a or divides a. (Dedekind 1964, 252)[11]

All of our examples are based on the following simple observations. Dedekind continues to use "contain" and "in" when writing about numbers in ideals. That is, sometimes he writes that an ideal contains a number and sometimes that the ideal divides the number. Given the definition above, we might expect the expressions "divide" and "contain" to be completely interchangeable, i.e., that commuting between signifiers "divide" and "contain" has no effect at the level of signifieds. However, Dedekind never writes that an ideal "contains" or "is contained in" another, only that it "divides" or is "divisible by" another.[12] This asymmetry in the actual use of expressions indicates that there is some difference at the level of signifieds.

Expressions such as "+," "−" frequently occur together with "divide" in arithmetical texts. We use such expressions to characterize what we call *arithmetical content*. Specifically, we call the following the *arithmetical expressions*: "addition," "subtraction," "division," "multiplication," "sum," "difference," etc. and verbs such as "to add," "to divide," etc. We include also "+," "−," the use of concatenation instead of "·", and fractions.[13] If an expression in Dedekind (1964) can be commuted with a construction (sentence or formula) of arithmetical expressions, we say that it has *arithmetical content*.

Similarly, we use the expressions "contain" and "in" that are used frequently in writing about sets or collections and their elements but less frequently in arithmetical writing to characterize what we will call *set content*. If an expression in Dedekind (1964) commutes with an expression of the form "X in Y" or "X contains Y," then we say that it has *set content*. We include expressions that can be "built" from the

[10] In what follows, we adopt Dedekind's use of lowercase Latin letters to denote ideals and lowercase Greek letters to denote numbers.

[11] All translations from the German original are mine.

[12] Consider again the example of the ideal of integer multiples $3n$, i.e., $\{\ldots, -6, -3, 0, 3, 6, \ldots\}$. This ideal divides (or contains) for example -3, and it also divides the ideal $\{\ldots -12, -6, 0, 6, 12, \ldots\}$ of integer multiples $6n$, but in Dedekind (1964), we do not find expressions such as "$\{\ldots, -6, -3, 0, 3, 6, \ldots\}$ contains $\{\ldots -12, -6, 0, 6, 12, \ldots\}$."

[13] For example, xy and $\frac{x}{y}$.

simple form, for example, "let k be any number contained in S." We call "in" and "contain" the *set expressions*.[14]

The starting point of our analysis is thus the concrete textual expressions rather than Dedekind's supposed intentions with the text. For simplicity, we sometimes speak about "Dedekind," but we do not mean the historical person – we only speak about the expressions and signs of the actual text.

The setup operationalizes the structuralist assumption that linguistic signs and their meaning can be studied – traced – by applying commutation test to actual use of expressions. To this we add the further assumption that written mathematics, including all its non-linguistic expressions, behaves like a language in this sense. As can be seen, our approach involves a sort of handheld implementation of the distributional hypothesis assumed in current NLP research (Sahlgren 2008). Such manual computational analysis is sometimes called "reading at a middle distance" to distinguish it from both close reading and the "long-distance reading" of automated corpus analysis (Moretti 2000, 2013).[15] The relationship between the distributional hypothesis and structuralism is discussed in Gastaldi (2021) and Gastaldi and Pellissier (2023). There has been very little work on mathematics in the structuralist semiotic tradition with Herreman (2000), Vinciguerra (1999), and Wagner (2009) as important exceptions, all of which show the different layers of meaning at work within the seemingly regimented semiotic systems of mathematical writing. We are essentially doing the same here with a distinction between two kinds of content as analytical tool.

3 First Example

Consider the following passage:

> The integer $\lambda = x\mu : \nu = \sqrt[e]{\mu x^{e-1}}$ is divisible by p but not by p^2; therefore λ^r is divisible by p^r but not by p^{r+1}, from which it also follows that the ideals p^r and p^{r+1} really are different. (Dedekind 1964, 257)

Here, Dedekind asserts that some specific (algebraic) integer λ is divisible by (the prime ideal) p but not by (the ideal) p^2 and, as a direct consequence, that (the algebraic integer) λ^r is divisible by (the ideal) p^r but not by (the ideal) p^{r+1}. Dedekind

[14] Dedekind does not use notation such as "$\subset$" or "$\in$," which today are standard ways of expressing containment, in Dedekind (1964).

[15] Middle-distance reading is nothing new in the humanities. It goes back at least to the work in the 1950s and 1960s of literary theorist Josephine Miles, e.g., Miles (1967). Miles observes that certain literary styles can be distinguished by certain proportions of word classes. This allows Miles to consider literary style in terms of (quantitative) relations between the words that occur in actual texts, instead of considering style as a reference to the nature of the subject matter of the text or as a product of the individual psychology of the author. See also Buurma and Heffernan (2018). Arguably, our analysis here is more subjective and idiosyncratic than Miles'.

does not explicate this inference further. Such gaps are ubiquitous in written mathematical proofs. Here, we focus on how, from a semiotic perspective, the proof may be sufficiently convincing despite its gaps.

We begin with some definitions from Dedekind (1964) and an important observation about the organization of ideal theory in that particular text. An ideal p is called a *prime ideal* if the only divisors of p are o and p itself (Dedekind 1964, 253).[16] The *simple ideals* are defined as follows:

> If μ is a number in o that is different from zero and not a unit, then [. . .] there always exists a number ν such that all the roots π of the congruence $\nu\pi \equiv 0\ (mod\ \mu)$ constitute a prime ideal. prime ideals that consist in all the roots of such a congruence we will call in what follows simple ideals. (Dedekind 1964, 255–256)[17]

Intuitively, the way Dedekind uses powers of λ and p in the presentation of the proof indicates that we are doing something like taking the rth power and that this operation preserves the relationship between λ, p, and p^2 (i.e., such that the relationship between λ^r, p^r, and p^{r+1} is the same as that between λ, p, and p^2).

Prior to the passage in question, Dedekind has defined the *rth power of p*, for p any simple ideal (i.e., a p given by a congruence as above):

> Now, if r is any whole, rational, non-negative exponent, then all the roots ρ of the congruence $\rho\nu^r \equiv 0\ (mod\ \mu^r)$ form an ideal, which is called the rth power of p and will be denoted by p^r. (Dedekind 1964, 256)

Simple ideals are prime by definition and Dedekind shows some pages later that every prime ideal is simple (Dedekind 1964, 257–258). So, from then on, this definition of power applies to prime ideals. For ideals in general, there will not be a notion of power until later in Dedekind (1964).

The passage in question involves a prime ideal p and the powers p^2, p^r, and p^{r+1}. But what is really the connection between a prime ideal p and the powers of p? We recall that Dedekind has already defined the multiples of an ideal: If p contains every number contained in some other ideal b, then b is a multiple of p. In rational arithmetic, we may consider say 5^r, the rth power of 5, to be obtained by iterated multiplication by 5, but it is not given that p relates to the powers of p by means of some "multiplication operation" in the way that 5 relates to the powers of 5 by arithmetical multiplication.

The problem is that rth powers of prime ideals precede the product of prime ideals in the concrete textual organization of ideal theory in Dedekind (1964). So what in

[16] The ideal $\{\ldots, -6, -3, 0, 3, 6, \ldots\}$ is prime; the ideal $\{\ldots -12, -6, 0, 6, 12, \ldots\}$ is not. In general, all and only the ideals $\{\ldots, -2p, -p, 0, p, 2p, \ldots\}$, where p is a prime number, are prime ideals in Z. However, this simple characterization does not generalize to other rings.

[17] The unit (German "Einheit") mentioned in the definition is any number in o with the property that it divides every other number in o (like 1 divides every integer). Equivalently, ε is a unit if there exists an ε' such that $\varepsilon\varepsilon' = 1$ (Dedekind 1964, 239).

the proof seems to be manipulation of powers of p comes before the establishment of an operation on ideals that would justify such manipulations. Indeed, at this point in Dedekind (1964), Dedekind has introduced "multiple" (and "divisible," "divisor," and "divides") for ideals but not multiplication or division in the sense of operations on ideals. At this point in the text, we thus cannot obtain in a rigorous way the powers of p by iterated multiplication by p, simply because Dedekind has not given a multiplication of ideals yet.[18] Rather, p^r is obtained from p by manipulating the congruence that determines p. When p is given by the roots π of $\nu\pi \equiv (mod\ \mu)$, then p^r is given by the roots ρ of $\rho\nu^r \equiv 0\ (mod\ \mu^r)$. In terms of rth powers, ν and μ are replaced by ν^r and μ^r, respectively.

Only toward the end of the pages devoted to ideals do we get the product of two ideals:

> If one multiplies all the numbers of an ideal a by all the numbers of an ideal b, then these products and their sums form an ideal divisible by a and b, which is called the product of the factors a and b and will be denoted by ab. From this statement it is immediately clear that $ao = a$, $ab = ba$; furthermore $(ab)c = a(bc)$. (Dedekind 1964, 259)

This construction defines a multiplication on ideals and allows us to take the r-fold product $ppp\cdots$ (r times), but what is not immediately clear is whether this $ppp\cdots$ (r times) is the same ideal as p^r. Because Dedekind has defined p^r independently of a notion of a product of ideals, the fact that the two ideals $ppp\cdots$ (r times) and p^r coincide is something that has to be shown.[19]

With this in mind, the way Dedekind uses powers of λ and p in the presentation of the proof might aim to make a reader anticipate an operational relationship between p and rth powers of p similar to that between λ and rth powers of λ. We now explore the idea of such "anticipation" using a commutation test. We have the following two expressions, in which powers of λ and p occur:

1. "$\lambda = x\mu : \nu = \sqrt[e]{\mu x^{e-1}}$ is divisible by p but not by p^2"
2. "λ^r is divisible by p^r but not by p^{r+1}"

[18] Since set-theoretic approaches were not standard when Dedekind wrote Dedekind (1964), we should not assume that Dedekind expects the reader to come equipped with an idea of a multiplication of ideals or other "systems" of numbers.

[19] To be precise, what Dedekind shows is that $p^a p^b = p^{a+b}$. The identity $p^r = pppp\cdots$ (r times) follows from $p^a p^b = p^{a+b}$ and associativity of the multiplication of ideals (Dedekind 1964, 259). Just in terms of sheer textual volume, the connection between powers and product suggested by the power notation is the fruit of a solid amount of work. In *Vorlesungen*, Sup X spans the pages 380–497. "Ideal" occurs regularly up to page 495 (included) but only the pages 452–462 are the introduction of ideal theory. The definition of ideals is at page 452; the definition of the product of ideals is not until page 459. After stating it, Dedekind relates products of ideals to powers of prime ideals (Dedekind 1964, 259–260) culminating with a theorem. Its proof relies on results established over the seven intermediate pages. The conclusion that the two ideals p^r and $pppp\cdots$ (r times) coincide for p prime (Dedekind 1964, 260) takes three pages to reach. In the end, this leads to the possibility of defining a notion of power for any ideal, not just the simple ones, which agrees with the initial congruence definition of p^r (Dedekind 1964, 260).

(1) concerns how p and p^2 relate to λ as divisors. (2) resembles (1), but λ is replaced by λ^r, p by p^r, and p^2 by p^{r+1}. Intuitively, Dedekind's presentation of (2) as derived from (1) may make it seem as if going from p to p^r and from p^2 to p^{r+1} is similar in some way to going from λ to λ^r.

In this sense, the multiplication of an ideal with itself as an operation – which satisfies the same rules of divisibility and manipulation of exponents as with arithmetical powers – exists as signified before it exists as a mathematical object. This is what we take away from this example: *Something may exist as signified before it exists as a rigorous mathematical object*.

We can view the change from expression (1) to (2) in terms of a commutation test, which replaces λ by λ^r, p by p^r, and p^2 by p^{r+1}. In the first commutation, λ^r is interchangeable with $\lambda \cdot \lambda \cdot \lambda \cdots \lambda$, the usual arithmetical product of λ with itself r times. But a similar commutation of the power of p, i.e., the replacement of p^2 by $p \cdot p$, p^r by $p \cdot p \cdot p \cdots p$ (r times) and p^{r+1} by $p \cdot p \cdot p \cdots p$ ($r + 1$ times), has a different effect at the level of signifieds. Changing p to p^r and p^2 to p^{r+1} is correlated with the change of λ to λ^r. Commuting λ with λ^r has arithmetical content so passing between the powers of p inherits arithmetical content. One way of expressing these different effects is by saying that the arithmetical content attached to the relation between λ and λ^r is a rigorous mathematical operation (taking the rth power of an algebraic integer), but going from p to p^r is not.[20]

There is still some work to be done before Dedekind can introduce a multiplication for ideals and show that the power of an ideal corresponds to iterations of that multiplication. This is the concrete organization of ideal theory in this specific text. The question then arises: Does the arithmetical content in the passage correspond to operations on ideals when multiplication of ideals will only be established later in the text?[21] If so, the operation seems to exist as signified before it exists as a mathematical object.

[20] Without the parallel occurrence of "λ" and "λ^r," perhaps we would have been more likely to consider the various powers of p in terms of replacing ν and μ by appropriate powers in the congruence that defines p. For the sake of contrast, the superscript r of p^r could also just be considered as an index, which indicates both a position in the sequence of ideals $p, p^2, \ldots, p^r, \ldots$, and the powers of the numbers μ and ν used in the congruence $\rho\nu^r \equiv 0 \ (mod\ \mu^r)$ to define p^r. The superscript r of p^r creates an index sign in the Peircean sense, since the superscript r of p points directly to the superscript r of μ^r and ν^r in the congruence $\rho\nu^r \equiv 0 \ (mod\ \mu^r)$.

[21] In a certain sense, it can only be established later in the text. In this example, changing the order of presentation is more complicated than simply giving some definitions in a different order. The different version of ideal theory testifies to this: The three later versions of ideal theory, Dedekind not only presents the theory differently but develops it in a different order. In Dedekind (1964), the notion of the product of two ideals comes at the end. Edwards notes: "In the second version – and all subsequent versions – Dedekind proceeded very differently. He defined products of ideals early in the development of the theory and elevated to the level of "the [principal] difficulty of the theory" the proof that if A and B are ideals and if $A \subset B$ then there is an ideal C such that $A = B \cdot C$. [...] In the original version, this theorem did not even appear, but it is a simple consequence of the theorems which did appear; [...] in connection with this, the *multiplicities* with which integers are divisible by a prime ideal are not defined in terms of powers of the ideal. (Edwards 1980, 350–351. Emphases in the original.). For more details, see Edwards (1980, 349–352).

The example suggests that it is worth taking the order of presentation into account as part of mathematical textuality. One could object that ideal theory has an intrinsic order and is interconnected in determinate but perhaps unknown ways. In this view, the different presentations of ideal theory would merely instantiate this order in seemingly different but ultimately accidental ways. The differences between presentations would be cognitive, aesthetic, cultural, historical, or other "auxiliary" factors, on which the intrinsic order of the theory would not depend. Even from that position, however, the recovery of a theory from its different instantiations can hardly be claimed to be trivial. Here, structural semiotics becomes relevant as tool to articulate differences.

4 Second Example

Dedekind defines two numbers ω, ω' to be *congruent modulo the ideal a* if a contains the difference $\omega - \omega'$. This is written $\omega \equiv \omega' \ (mod\ a)$. If a contains the number α, then α is said to be *congruent to zero modulo a*, which is written $\alpha \equiv 0 \ (mod\ a)$ (Dedekind 1964, 251). The notation is the same when the modulus is a number.[22]

We now have three expressions that would seem to be interchangeable: "a divides α," "a contains α," and "$\alpha \equiv 0 \ (mod\ a)$." However, ideal congruences can be manipulated: "[S]uch congruences can (according to I.) be added, subtracted, and (according to II.) multiplied, like equations" (Dedekind 1964, 251).[23] They can be manipulated not just like the congruences of rational arithmetic (when the moduli would be integers) but "like *equations*." At this point of Dedekind (1964), writing actual equations involving sums, differences, or products of ideals would be something of a leap since addition, subtraction, and multiplication have not been introduced for ideals yet. But "added, subtracted, and multiplied like equations" purports that the congruence notation can be used for arithmetical style computations with ideals. It is this "ideal arithmetic" made possible by the ideal theoretic congruence notation that we now explore.

In the following excerpt, Dedekind proves that the roots π of the congruence $\nu\pi \equiv 0 \ (mod\ a)$ constitute a prime ideal under a certain condition. We focus on three points, which we have marked **(1)**, **(2),** and **(3a–b)**:

> If the number η is not divisible by the ideal a, then there always exists a number ν not divisible by η such that all roots π of the congruence $\nu\pi \equiv 0 \ (mod\ a)$ constitute a prime ideal. **(1)** All the roots β of the congruence $\eta\beta \equiv 0 \ (mod\ a)$ constitute an ideal b dividing a. If b is not a prime ideal, that is, if there exist two numbers η', ρ' not divisible by b, for which their product $\eta'\rho' \equiv 0 \ (mod\ b)$, **(2)** then all the roots γ of the congruence $\eta'\gamma \equiv 0 \ (mod\ b)$, i.e., the congruence $\eta\eta'\gamma \equiv 0 \ (mod\ a)$, constitute an ideal c dividing b, [. . .]; if c is a prime ideal, then

[22] Also when the modulus is a so-called module, which (like ideals) are a specific kind of systems of numbers and which Dedekind introduces and discusses in §161–162 in Dedekind (1964).

[23] I and II refer to the two conditions in the definition of an ideal. I: An ideal contains the sum and difference of any two numbers that it contains. II: Any product of a number in the ideal with a number in o (the universe) is again a number in the ideal (Dedekind 1964, 251).

> the theorem is proven. If however c is not a prime ideal, then one can continue in the same way; eventually **(3a)** in the sequence of ideals b, c, d, ... [...] a prime ideal p must occur, which consists in all the roots π of the congruence $\nu\pi \equiv 0 \ (mod\ a)$, where **(3b)** $\nu = \eta\eta'\eta'' \ldots$ is divisible by η. (Dedekind 1964, 255)

The proof begins with the construction of an ideal b by means of a congruence $\eta\beta \equiv 0 \ (mod\ a)$. The first of our focus points **(1)** is that this ideal b divides the ideal a. The point **(2)** is that the roots γ of the congruence $\eta'\gamma \equiv 0 \ (mod\ b)$ are the same as the roots γ of $\eta\eta'\gamma \equiv 0 \ (mod\ a)$. That is, the ideal b divides $\eta'\gamma$ if and only if the ideal a divides $\eta\eta'\gamma$. We note that Dedekind does not explicate these inferences beyond what is contained in the excerpt above.

In **(2)**, Dedekind moves directly from $\eta'\gamma \equiv 0 \ (mod\ b)$ to $\eta\eta'\gamma \equiv 0 \ (mod\ a)$,[24] which might be an actual example of what Dedekind means by treating ideal congruences "like equations": Multiplying both sides with the same factor preserves equivalence. The move presents the change of modulus from ideal b to ideal a as equivalent to multiplication by η, as if the difference between the ideals a and b amounts to a factor η. This is at a point in the text where something like an operation of the form ηb has not been introduced. A simple commutation test confirms this impression. If we view the expressions "$\eta'\gamma \equiv 0 \ (mod\ b)$" and "$\eta\eta'\gamma \equiv 0 \ (mod\ a)$" as a commutation, then the change from $\eta'\gamma$ to $\eta\eta'\gamma$ is correlated with the change from $(mod\ b)$ to $(mod\ a)$. Commuting $\eta'\gamma$ and $\eta\eta'\gamma$ has arithmetical content (multiplication by η). By correlation, commuting b with a would seem to inherit arithmetical content. The equation-like appearance of moving directly from one congruence to the other is thus important for the textuality of this concrete proof.

In **(3a)**, ideals b, c, d, ... are generated until the output is a prime ideal (the procedure for generating c from a and b is explained in the proof; d is generated by applying the same procedure to b and c and so on).[25] A commutation test suggests that the sequence b, c, d, ... has arithmetical content: First, generating the next ideal of the sequence can be viewed as the commutation of a term in the sequence b, c, d, ... with its successor. Second, this commutation is correlated with the exchange of the expression "$\nu = \eta\eta'\eta'' \ldots$" in **(3b)** with a similar expression having one more term "$\eta^{(i)}$" (for appropriate i) at the rightmost end. The latter commutation has arithmetical content (multiplication by $\eta^{(i)}$). In this sense, we correlate the sequence of ideals with arithmetical multiplication of numbers.[26]

[24] a contains all numbers of the form $\eta\beta$ for β in b by construction of b, so taking a number in b and multiplying it with η is sure to bring us inside a, but a might also contain numbers that are not of this form.

[25] Dedekind uses the so-called norm, which associates a unique positive integer to any ideal, in order to associate the sequence of ideals b, c, d, ... with a strictly decreasing sequence of positive integers, all of which are strictly greater than 1. Such sequence of integers necessarily stops and thus the sequence of ideals also stops. At the same time, the procedure that produces the sequence of ideals stops if and only if the output is a prime ideal, so this proves the existence of the prime ideal asserted by the theorem.

[26] Note also that the order of the sequence and the order of factors together may make it seem as if we "move into" the next ideal when we multiply by $\eta^{(i)}$, while in fact we multiply by $\eta^{(i)}$ to make sure that the product remains an element in a.

Is the ideal congruence purely arithmetical? From a formal point of view, there is no difference between "divide," "contain," and "congruent with 0." But Dedekind uses all three expressions – if anything, their formal identity obscures this practice. What difference does using the congruence notation make when there is no formal difference? For this, we are looking for a difference between the signifieds of "divide" and "contain." Our strategy to approach this question is to write possible verifications of **(1)** and **(2)** beyond what the excerpt contains, i.e., to fill out some of the gaps in Dedekind's proof. We then apply commutation tests to the text of the verifications. Specifically, we write one version using the arithmetical expression "divide" and another using the set expressions "contain" and "in." We avoid using congruences altogether. This strategy allows us to describe the congruence notation as signs in terms of differences between the arithmetical version and the set version.

Possible verification of **(1)** using "contain" and "in":

> Let b be the ideal containing precisely those numbers β for which $\eta\beta$ is in a. We show that b contains every number contained in a. Let α be in a. Then a contains $\eta\alpha$. Thus, by definition of b, b contains α. Thus, b contains every number that a contains. So b divides a.

Possible verification of **(1)** using "divide":

> Let b be the ideal dividing precisely those numbers β for which $\eta\beta$ is divisible by a. We show that b divides every number divisible by a. Let α be divisible by a. Then a divides $\eta\alpha$. Thus b divides α. Thus, b divides every number that a divides. So b divides a.

In the version where we used set expressions, we (implicitly) appeal to one of the defining characteristics of ideals and to Dedekind's definition of division as containment. Even when we use "divide," we appeal (implicitly) to the definition of an ideal and of division of ideals. This introduces set content. The question is now, what happens if we "bracket" this set content and consider only the arithmetical content of "divide." Concretely, we supress the set content by applying one more commutation to the "divide" justification. We replace "(the ideal) a" by "(the integer) α'" and "(the ideal) b" by "(the integer) β'" in accordance with Dedekind's use of Latin letters to denote ideals and Greek letters to denote numbers. In this sense, we "pretend" that the passage is about ordinary integers rather than ideals. If we can do this without changing anything else in our text, it might suggest that, in the original excerpt, the argument requires the plane of set content in an irreducible way to make sense.

> Let β' be the number dividing precisely those numbers β for which α' divides $\eta\beta$. We show that β' divides every number that α' divides. Let α be divisible by α'. Then α' divides $\eta\alpha$. Thus β' divides α. Thus, β' divides every number that α' divides. So β' divides α'.

In this arithmetical version, what happens with the appeals to the ideal theoretic definitions? Concretely, if we had made these appeals explicit, we would have the expression "Then by the definition of an ideal, a contains $\eta\alpha$" instead of just "Then a contains $\eta\alpha$." But it is not clear what we should write instead of "by the definition of an ideal." Two immediate candidates are "by the definition of an integer" and "by

the definition of division." The first emphasizes the relational aspect ("by the definition of division"), and the second emphasizes the object aspect ("by the definition of an integer"). If we allow ourselves some speculation, perhaps this unclarity can be seen in relation to the tension between object-oriented mathematics on the one hand and relational or structural mathematics on the other. Gathering more examples like this one might be used as textual support for discussing the idea that in ideal theory, objects are defined relationally. The "vanishing" of objects, suggested by some scholars, from Dedekind's mathematics might here be expressed as the doubt, or the choice, between two clearly separate possible substitutions for "by the definition of an ideal," one that emphasizes the relational aspect ("by the definition of division") and one that emphasizes the object aspect ("by the definition of an integer"). In ideal theory, these choices might collapse into one, whereas they might be relatively separate in traditional arithmetic.

In the arithmetical version, we have instead the inference that if β' divides every number that α' divides then β' divides α'. This seems almost trivial, since α' divides itself (we consider integers to divide themselves). So if β' divides every number that α' divides, then α' is one among the numbers that β' divides. From this perspective, β' divides α' follows from β' divides every number that α' divides as a particular case from the general case.

The set version seems to work differently. For ideals a and b, "b divides every number that a divides" does not include "b divides a" as a special case; it is the definition of ideal divisibility. From this perspective, "if b divides every number that a divides then b divides a" is not an inference but the repetition of a definition given earlier in Dedekind (1964).

This suggests that the commutation between "(ideals) a and b" and "(integers) α' and β'" has an effect at the level of signifieds, expressed here as a difference between inferential structures**.** Where the proof using "(ideals) a and b" and set expressions appeals to a definition, the proof using "(integers) α' and β'" and the arithmetical expression "divide" infers a special case from the general. This difference can be taken to suggest that the passage in its original form does not rely only on arithmetical content. Rather, the passage in its original form would seem to indicate a set content that is not directly translatable to arithmetical content at this point in the text (but which may be put in rigorous correspondence later in the text or by other means). We do not exclude that the passage can be read purely arithmetically, i.e., a reading treating the ideals as a kind of arithmetical objects (as numbers, basically). Neither do we exclude a purely set-theoretic reading of the passage. But we may say that the space of possible readings includes at least one more option, which combines set theory and arithmetic, despite the fact that the two perspectives are not aligned in terms of explicit axioms or definitions at this point in the Dedekind (1964).

We explore this third possible reading by commuting possible verifications of **(2)**.

A possible proof of **(2)**:

> If $\eta'\gamma \equiv 0 \ (mod\ b)$ then b contains $\eta'\gamma$ so, by definition of b, $\eta'\gamma$ is a root β such that $\eta\beta \equiv 0 \ (mod\ a)$, i.e., $\eta\eta'\gamma \equiv 0 \ (mod\ a)$. Conversely, if $\eta\eta'\gamma \equiv 0 \ (mod\ a)$, then $\eta'\gamma$ is a root β of $\eta\beta \equiv 0 \ (mod\ a)$ so, again by definition of b, b contains $\eta'\gamma$, i.e., $\eta'\gamma \equiv 0 \ (mod\ b)$.

Under the same commutation as in we applied to the proof of **(1)**, we get:

> If $\eta'\gamma \equiv 0 \ (mod\ \beta')$, then β' divides $\eta'\gamma$ so, by definition of β', $\eta'\gamma$ is a root β such that $\eta\beta \equiv 0 \ (mod\ \alpha')$, i.e., $\eta\eta'\gamma \equiv 0 \ (mod\ \alpha')$. Conversely, if $\eta\eta'\gamma \equiv 0 \ (mod\ \alpha')$, then $\eta'\gamma$ is a root β of $\eta\beta \equiv 0 \ (mod\ \alpha')$ so, again by definition of β', β' divides $\eta'\gamma$, i.e., $\eta'\gamma \equiv 0 \ (mod\ \beta')$.

This proof relies on the definition of β' by the congruence $\eta\beta \equiv 0 \ (mod\ \alpha')$, just as the argument for ideals relies on the definition of the ideal b by the congruence $\eta\beta \equiv 0 \ (mod\ a)$. Neither argument appeals to definitions of divisibility. It was precisely around the use of this definition in our proof of **(1)** that we found the discrepancy between the arithmetical and the set version. When we commute "divide" with "contain" and Greek letters with Latin, we would expect to get a change at the level of content. But compared to the change we observed when we did the same commutation in the verification of (1), here something seems to stay the same under the commutation. This indicates that another part of what we called the inferential structure above is not sensitive to variation between "contain" and "divide." This suggests that part of the inferential structure does not depend on the specific kind of content (set or arithmetical).

This lack of effect leaves us in the open with regard to a specification of the signified of the congruences. We could not find it above, since inserting "divide" and "contain" for "$\equiv 0$" did not give enough of a difference at the level of content. Perhaps our analytical framework is inadequate to describe the congruence as sign. But another way to view the invariance would be that the signified of the congruence notation is intentionally underspecified so as to create a sign that mediates between set theory and arithmetic. Perhaps Dedekind's point is that the two kinds of content must interact even at a point when they are not compatible. We test this idea by a commutation designed to test what happens if we bracket one kind of content completely and consider only the other. In other words, we consider two "extreme" readers: an extremely arithmetical reader and an extremely set-oriented reader.

(i) The arithmetical reader may interpret the arithmetical content of **(2)** as a direct multiplication of an ideal b by a number η, ignoring the set content of b. This reader interprets the arithmetical content of concatenation by η as the "quotient" of a by b, that is, effectively treats a and b as integers.
(ii) The set-oriented reader translates the arithmetical content of concatenation by η into arithmetical multiplication of η with the elements of b.

Option (i) is in conflict with the inferential structure of **(1)**, which changes if we interpret the ideals as integers. Option (ii) is a total transition to set content, effectively ignoring the presence of arithmetical content, including the "equation-likeness" of the manipulations of the congruences.

Based on this, Dedekind's choice of notation thus seems to enable a mediation between the two kinds of content, rather than to encourage a total transition to any one of them. This may be possible precisely because of the congruence notation as sign remains underspecified, which in turn may be because Dedekind does not

justify the statements **(1)** and **(2)** further. Our counter-textual arguments for **(1)** and **(2)** brought to the surface some tensions between set content and arithmetical content that are not explicit at the level of expression of Dedekind's text. But with the level of detail of the original text, the reader does not need to articulate a signified that captures how set content and arithmetical content interact in the passage.

Dedekind's notational choices thus seem to give rise to a new signified mediating between arithmetical and set content. If we require mathematical signifieds to be rigorous, this mediating signified is not quite mathematical. If we consider the signified to be mathematical, this mathematical object is not rigorous in the way rigor is usually conceived. By the end of Dedekind (1964), Dedekind will have provided the reader with the means to a rigorous reconstruction of this mediating signified; our examples illustrate the functioning of a mathematical textual practice, which may or may not adhere to such reconstruction.

5 Conclusion

At the heart of this chapter is a single analytical move: The semiotic analysis produced different possible readings of the same passage of text. These readings were set up against each other. By opposing and mediating between the different readings, certain semiotic features of the text emerged.

Perhaps the most important feature was the underspecified mediating signified: a possible gap between, on the one side, the signifieds of the text and, on the other side, rigorous mathematical reconstructions. By pointing out this gap, we do not question the possibility of rigorous reconstruction. But we emphasize how Dedekind's writing seems to initiate, while at the same time depend upon, interpretative interaction with a reader and the reader's intervention is not necessarily a rigorous reconstruction (or rigorously reconstructable). From the perspective of our structuralist semiotic approach, the underspecification illustrates (dare we say explains) how mathematical text can be read before the mathematical content suggested along the way is rigorously established.

Abstract

As idealized descriptions of mathematical language, there is a sense in which formal systems specify too little, and there is a sense in which they specify too much. On the one hand, formal languages fail to account for a number of features of informal mathematical language that are essential to the communicative and inferential goals of the subject. On the other hand, many of these features are independent of the choice of a formal foundation, so grounding their analysis on a particular choice of a formal system introduces unnecessary specificity. This chapter begins to map out the design features of mathematical language without descending to the level of formal implementation, drawing on examples from the mathematical literature and insights from the design of computational proof assistants and their libraries.

Keywords

Mathematical language · Formalization · Proof assistants

1 Introduction

Mathematics is governed by a network of norms that determines what we can say and how we are supposed to say it. Learning how to speak about mathematics properly is an important part of learning to do mathematics. But, when pressed, it turns out to be surprisingly hard to say what it is we are talking *about*; mathematics seems to be, as the title of a book by John Burgess and Gideon Rosen proclaims, a subject with no object. And without making sense of what we are talking about, it is hard to see how we can make sense of what we are thinking about. The outward manifestations of mathematical thought are found in the way we communicate mathematics to others.

Here we adopt the view that an important way to make sense of what we are talking about is to develop a better understanding of mathematical language itself. From a grammatical point of view, the language of mathematics is rather simple. There are no subtle variations of tense, modality, or aspect, and the subject is generally devoid of subjunctives and counterfactuals. Mathematical statements make claims as to what is true, always has been true, and always will be true, and mathematical proofs back these claims up with more statements of the same sort. The subtleties of mathematical language stem rather from the features that render it suitable for reasoning about abstract objects and properties.

Formal languages provide informative models of mathematical discourse. It is by now well understood that ordinary mathematics can be formalized in various ways in first-order logic and the language of set theory, in variants of simple type theory or dependent type theory, or in category-theoretic foundations. These variations provide complementary perspectives and serve as bases for formalization in proof assistants like Mizar (Grabowski et al. 2010), Isabelle (Nipkow et al. 2002), Coq (Bertot and Castéran 2004), HOL Light (Harrison 2009), Metamath (Megill 2006), and Lean (de Moura et al. 2015).

As valuable as they are, there is a sense in which formal languages specify too much, and there is a sense in which they specify too little. The fact that an ordinary mathematical text can be represented equally well in any of the foundations above shows that these foundations should be viewed as alternative *implementations* of mathematics. It is therefore reasonable to look for descriptions of mathematical language and patterns of inference that abstract away the superficial differences and clarify the specifications that the implementations are designed to meet.

Formal languages specify too little in the sense that many essential features of ordinary mathematical language are not addressed by a formal specification. Instantiating the formal foundation is only the first step in implementing a mathematical proof assistant, and the bulk of the work then goes into supporting the interactions that make them usable in practice. Such systems have to parse user input, disambiguate notation, manage libraries of theorems and definitions, and keep track of algebraic structures and relationships between them. They need to provide convenient manners of expression and support efficient inference. The design of a proof assistant requires countless engineering decisions that bear on the system's usability, and these decisions can, in turn, be viewed as attempts to capture the functionality of informal mathematical language and inference. We might optimistically seek a better philosophical understanding of this functionality, one that can help us make sense of the implementation goals.

Another approach to thinking about mathematical language is to view it as a part of natural language, albeit a part of natural language with its own characteristic features. Ganesalingam (2013) leans in this direction, which allows him to bring the methods of generative linguistics to bear on the analysis of ordinary mathematical texts. Various systems of *controlled natural language* offer a complementary approach, presenting structured languages with enough flexibility to incorporate a range of natural language constructs, so that users can write texts that read like natural language but can be translated to the language of an underlying formal system (Paskevich 2007; Cramer et al. 2009).

Here we will not try to account for the range of grammatical and stylistic variation that one finds in natural language. We will rather seek idealizations that illuminate the features of mathematical language that are specifically adapted to supporting mathematical activity. One way of describing what we are after is to say that we are looking for a description of mathematics as a *semiformal language*. We want a description that renders it regimented and precise, like a formal language, designed to support certain types of abstraction and inference. At the same time, we want a model that is more informative than formal logic, one that tells a story of how

mathematical language serves to support the processes that are needed to track mathematical objects and the relationships between them. Our overarching goal will be to develop such a design specification for mathematical language without descending to the level of a fully formal implementation.

This chapter falls short of that goal, but it aims to make progress by cataloging some of the features of mathematical language that are essential to its communicative and inferential aims. It also describes some of the mechanisms that contemporary proof assistants use to model those features and support those aims. The interaction between informal and formal mathematics gives rise to a fruitful dialectic: the engineering efforts clarify the nature of mathematical language and inference, and, conversely, philosophical understanding guides the implementation.

2 Perspectives

2.1 Philosophical Orientation

Philosophy of mathematics has traditionally been concerned with the nature of mathematical objects, knowledge, and thought. Talking about these in a rigorous way requires some sort of conception of mathematics itself, and some sort of understanding of the features of mathematical practice that fall under the scope of the analysis. Toward forming such a conception, what we have the most direct access to is the mathematical literature: the historical record of statements, questions, arguments, definitions, and other textual artifacts that are constitutive of the subject. These artifacts, rooted in language, form the starting point for philosophical study.

No matter how we ultimately try to characterize the goals and methods of mathematics; we have to start with language. Whether we view mathematics as the practice of solving problems, abstracting from experience, or getting at a certain type of truth, what we say about that practice has to fit with what we see in the mathematical literature. We need to understand how mathematical language enables us to carry out those activities and how those activities are manifested in language.

One central thesis of this chapter is that, when we study mathematical language, it is important to understand not just what is *allowed*, but also what is *desired*. Formal systems specify rules that tell us when a formula is well-formed and when an inference is justified, but it doesn't tell us which definitions are good definitions, or which among the myriad inferential steps that can be taken at any given point are most worthy of our attention. Mathematics calls upon its practitioners to carry out complex tasks and to do so creatively, efficiently, and reliably. Reflection on mathematical practice should help explain how it helps us manage complexity and carry out fruitful exploration.

Another central thesis of this chapter is that it is helpful to view mathematical language as the object of *design*. Mathematical language and methods have evolved over the centuries, presumably for good reasons. Some features of mathematical language and method have remained remarkably stable, again, we may presume, for good reasons. Mathematics provides powerful means for abstraction and for

managing information, making data salient when it is needed and suppressing it when it is a distraction. Recognizing that mathematical language has evolved to serve such purposes should encourage us to try to understand the general principles by which it succeeds, and, conversely, understanding how it functions can help clarify the nature of mathematics itself. Thinking of mathematical language in terms of design is not at odds with viewing it as the outcome of an organic evolutionary process; some have even found it profitable to think about natural language in design terms (Chomsky 2005; Hockett 1960a, b).

2.2 Methodological Orientation

With respect to the goal of developing a semiformal description of mathematical language, how can we tell whether we are on the right track? This chapter uses two sources of data as touchstones.

The first is the mathematical literature itself. In the sections that follow, I will frequently resort to examples pulled from a random sample of textbooks. There is nothing exceptional about the examples I chose; the point is that they represent patterns that one can find in virtually any mathematical text. A theory of mathematical language should help us make sense of the instances of mathematics that we find all around us.

The second source of data comes from contemporary proof assistants, and from the formal methods that have been developed to support mathematical communication and inference in that setting. Processing a mathematical text requires tokenizing, parsing, and elaboration, and a variety of methods are used to infer information that is generally left implicit, including class inference, canonical instances, and unification hints (Wenzel 1997; Sozeau and Oury 2008; Asperti et al. 2009; Garillot et al. 2009). Theories and libraries are organized using environments, modules, and namespaces. Decision procedures support domain-specific reasoning, and indexing techniques provide fast ways of locating relevant information for automated search (Robinson and Voronkov 2001). Ongoing research is bringing the methods of machine learning to bear on mathematical reasoning (Gauthier et al. 2021; Lee et al. 2020).

Describing this technology in detail would take us too far afield. (For overviews, see Hales (2008); Avigad and Harrison (2014); Avigad (2018); Blanchette and Mahboubi (n.d.).) The technological developments are informative, however, because they make explicit the challenges that need to be met in order to bridge the gap between informal mathematics and its formal representation. Highlighting these challenges helps clarify the features of informal mathematical language that are essential to mathematical practice. A second measure of success for the analysis here, then, is the extent to which it helps us understand these features and meet the technical challenges.

We will focus on contemporary mathematical language. It is also worthwhile to study the way mathematical language has changed over time and to try to understand the reasons behind those changes, but I will make no attempt to do that here. When I refer to historical sources in this chapter, it is either to highlight features of

mathematical language that have remained fairly stable over time or to highlight features of mathematical language that are relatively new. In both cases, the aim is to characterize mathematical language as it is used today.

3 Fundamentals

This section deals with features of mathematical language that are close to the basic grammar of the subject. It considers the way that mathematical objects fall into categories that shape the way we talk about them, the expressions that we use to name objects, and the ways that we talk about the relationships between such objects.

3.1 Sorts

We start with the simple observation that mathematical objects fall into categories. Consider the first proposition of Euclid's *Elements*:

> Proposition 1. *On a given straight line to construct an equilateral triangle.*
> Let *AB* be the given finite straight line.
> Thus it is required to construct an equilateral triangle on the straight line *AB*.
> With centre *A* and distance *AB* let the circle *BCD* be described;
> again, with centre *B* and distance *BA* let the circle *ACE* be described;
> and from the point *C*, in which the circles cut one another, to the points *A*, *B* let the straight lines *CA*, *CB* be joined. (Euclid 2002, p. 3)

The proof refers to a number of different kinds of objects: points A, B, and C, a finite straight line AB, a circle BCD, and the equilateral triangle that is under construction. Some objects arise in the course of the proof: given the point A and the finite straight line AB (now construed as a distance), a circle is described, and given the points C and A, the straight line CA is joined. Objects bear relationships to one another: two circles can cut one another at a point C, and an equilateral triangle can lie on a straight line.

It is informative to consider the way that objects are introduced into contemporary mathematical discourse.

> Let X be a locally convex topological vector space and F a closed convex subset. (Royden 1988, p. 241)

> Let p and q be odd primes. (Ireland and Rosen 1990, p. 53)

> Let k be a field, and let $k[x] = k[x_1, \ldots, x_n]$ be a finitely generated ring over k. Let $\varphi : k \to L$ be an embedding of k into an algebraically closed field L. (Lang 2002, p. 378)

> Let $\mathfrak{M}$ be a maximal ideal of $k[x]$. Let σ be the canonical homomorphism $\sigma : k[x] \to k[x]/\mathfrak{M}$. (Lang 2002, p. 378)

> Let $\tau_2 = n$; let t_1 be the smallest k such that $X_k \geq \alpha$, if there is one, and n otherwise. (Billingsley 1995, p. 5)

The first three examples appear in the statements of theorems, whereas the next two are taken from the beginnings of proofs. The point is simply that we would not expect to see a theorem or proof begin with the words "let p and q be objects" or "let p and q be things." Mathematical variables always range over a *sort*.

It is not always clear what we should take the fundamental sort of an object to be and what we should view as ancillary attributes. It seems sensible to say that an equilateral triangle is fundamentally a triangle that happens to have the property of being equilateral, and it seems sensible to say that a prime number is a number that is prime. But is a nonnegative integer an integer that has the property of being nonnegative, or a number that has the property of being nonnegative and integral? Is a finite straight line in the *Elements* a straight line that happens to be finite? A maximal ideal of $k[x]$ can be construed as an ideal of $k[x]$ that has the property of being maximal, or a subset of $k[x]$ that has the property of being a maximal ideal, or simply a set that has the property of being a maximal ideal of $k[x]$. In axiomatic set theory, everything is a set, but that stance is not more informative than considering everything an object.

The fact that objects belong to sorts is not specific to mathematics. Aristotle distinguished between an object's *essential* and *accidental* properties. Socrates was both human and short, and we can imagine what ancient Greece might have been like had Socrates been a few inches taller, but when we try to imagine Socrates as anything other than a human being, it's hard to argue that we are still thinking about Socrates. The ascription of sorts to mathematical objects, however, has specifically mathematical uses.

- It can be used to disambiguate notation. The expression x^y might denote exponentiation, but it might also denote conjugation in a group. The expression $x \cdot y$ can denote multiplication in any structure, so its meaning depends on the sort of objects that x and y are.
- It can be used to determine meaning. An element x can be *maximal* only if it is viewed as an element of a structure with an associated ordering. A function f is *surjective* only with respect to a specification of its codomain, *continuous* only with respect to a topology on its domain and codomain, a *homomorphism* only with respect to algebraic structures on those, and *essentially bounded* only with respect to a measure on the domain and an ordering of the codomain.
- It can be used to justify an expression as meaningful; for example, $\sqrt{x}$ makes sense if x is a nonnegative real number, and $1/x$ is meaningful if x is a nonzero real.
- It can be used to support immediate inference. If $f : G \to H$ and $g : H \to K$ are group homomorphisms, their composition is again a group homomorphism. If we view them fundamentally as functions, then their composition is merely another function, and we need an additional inference to conclude that they are again homomorphisms.
- It can be used to support higher-level inferences and heuristics. Knowing that we are dealing with integers or real numbers or triangles or elements of a group cues us to a body of methods and background knowledge that are relevant to the inferential tasks at hand.

We can designate the sorts of objects that occur in the passage from Euclid with tokens like *Point*, *Line*, and *Circle*. In the theory of programming languages and in a number of computational proof languages, it is common to view these as *data types*, or, more simply, *types*. We can write $A : Point$ to express that a variable or expression A is a point, and write $L, M : Line$ to express that L and M are lines.

In formal axiomatic foundations like *simple type theory* and *dependent type theory*, every expression denotes an object of some type. Proof assistants based on those foundations therefore have built-in mechanisms for *type inference*, which is the task of determining the type of a given expression, and *type checking*, which is the task of checking whether the type of an expression matches an expected type. The latter can be used to report errors when users apply operations to the wrong sorts of arguments, or when the system cannot infer the information it needs to make sense of an expression. Even systems based on set theory sometimes incorporate notions of type. *Soft typing* refers to the use of a typing discipline separate from the axiomatic foundation to infer meaning and to report errors.

3.2 Operations

Mathematical operations provide constructions or descriptions of objects. Two points A and B determine a line segment AB and, in the excerpt from the *Elements*, ACE is specified as the circle with center B and radius equal to the distance AB. The first operation may be modeled with a constant $segment\text{-}of : Point \to Point \to Segment$, where the type indicates that *segment-of* can be applied to two points to yield a segment. The convention in proof assistants is to take the arrows to associate to the right, so that the type above is read $Point \to (Point \to Segment)$. This means that when *segment-of* is applied to a point A, the result, *segment-of A*, has type $Point \to Segment$. When this is applied to another point B, the resulting expression, *segment-of A B*, has type *Segment*. The constant *segment-of* in *segment-of A* is said to be *partially applied*, and considering such expressions is natural in some mathematical contexts but not others.

The second operation may be modeled by a constant $circle\text{-}of : Point \to Segment \to Circle$, or perhaps $circle\text{-}of : Point \to Point \to Circle$ if it turns out that the distance in question is always measured from the center. Arithmetic offers other prototypical examples of mathematical operations: we can refer to the sum of two numbers, $x + y$, the square x^2 of x, or the greatest common divisor *gcd x y* of x and y.

In most formal foundations, a function f has an intended domain A and an intended codomain B, which is what is expressed by writing $f : A \to B$. In ordinary mathematics, it is well understood that the interpretation of the codomain is fluid: the specification $f(x) = x^2$ can be viewed equally well as defining a function $f : \mathbb{R} \to \mathbb{R}$ and as defining a function $f : \mathbb{R} \to \mathbb{R}^{\geq 0}$, where $\mathbb{R}^{\geq 0}$ denotes the nonnegative real numbers. More confusingly, the interpretation of the domain is also fluid: in a mathematical context, $f(x) = x^2$ may be viewed as a function defined on the complex numbers, real numbers, rationals, integers, or natural numbers, or any other domain with a multiplication. These considerations bear on whether we take the squaring

function to be injective, surjective, both, or neither. In mathematical contexts there is generally a broadest construal of the domain that makes sense, and circumstances dictate when we need to pass to a restricted interpretation.

The fact that the dot in $x \cdot y$ can denote multiplication in any of a number of structures and that an expression *intersection X Y* may denote the intersection of two lines, two circles, or a line and a circle shows that mathematical notation and terminology are *overloaded*. In these cases, information about the sorts of the arguments can be used to disambiguate meaning. In some cases, it is natural to view information like the structure in which multiplication occurs as an *implicit argument* to the notation. Proof assistants invariably have mechanisms to infer such information. A semiformal specification of mathematical language should say something general about how ambiguities are resolved and how and when implicit information is inferred.

3.3 Predicates and Relations

If we use *center-of* to denote the relation of being the center of a circle, computer scientists are apt to write *center-of A* γ to express that A is the center of γ. In a proof assistant, we might write

$$\textit{center-of} : \textit{Point} \to \textit{Circle} \to \textit{Prop}$$

to specify the type of the relation. We continue to interpret the arrows as associating to the right, so that *center-of A* γ denotes a proposition, namely, the proposition that A is the center of γ. Modeled in this way, relations can take any number of arguments. A relation that takes only one argument is usually called a *predicate* or *property*. For example, *equilateral T* expresses that a triangle T is equilateral, and *even n* expresses that an integer n is even.

Notation and terminology for relations, like notation and terminology for operations, can also be overloaded. We can use a symbol $\textit{on} : \textit{Point} \to \textit{Line} \to \textit{Prop}$ to express that a point A lies on a line L, and a symbol $\textit{on} : \textit{Point} \to \textit{Circle} \to \textit{Prop}$ to express that a point A lies on a circle γ. Similarly, $x \leq y$ can be used to denote an order comparison in any structure that has such an order. And we have already seen that predicates can rely on implicit information. A predicate *maximal x* depends on the order structure with respect to which x is judged to be maximal, and *continuous f* depends on the topologies with respect to which f is judged to be continuous.

3.4 Definedness and Partiality

Another complication that arises in the formalization of mathematics is that mathematical language often uses operations that can only meaningfully be applied to some of the objects in the natural domain of interpretation. Euclid can only speak of the intersection of two circles when the two circles intersect, and the phrase "the

greatest common divisor of x and y" only makes sense when x and y have a greatest common divisor, which is not the case when x and y are zero.

Set theory allows us to view each of these as a partial function, whose value may or may not be defined at a given input. Formally, a partial function from A to a B is a function from some subset of A to B. Proof assistants sometimes provide mechanisms for defining *subtypes* or adding *preconditions*, namely, proof obligations that must be fulfilled every time such a function is applied. For example, one can insist that every inscription a/b is accompanied by a proof that b is nonzero.

In ordinary mathematics, however, the implicit preconditions can be subtle. Consider a statement of the prime number theorem:

> Let $\pi(x)$ be the number of primes between 1 and x...
>
> $$\lim_{x \to 1} \frac{\pi(x)}{x/ln(x)} = 1.$$
>
> (Ireland and Rosen 1990, p. 2)

The expression in the limit is undefined when x is negative, equal to 0, or equal to 1. None of this matters because to determine the limit, we can restrict attention to arbitrarily large values of x, but in a formal foundation, the range of relevant values and the interpretation of the expression at those values have to be made explicit. Similarly, consider the statement of Bézout's theorem in an introductory number theory textbook:

> ... Thus the greatest common divisor (b, c) is defined for every pair of integers b, c except for $b = 0$, $c = 0$, and we note that $(b, c) \geq 1$.
>
> **Theorem 1.3**. If g is the greatest common divisor of b and c, then there exist integers x_0 and y_0 such that $g = (b, c) = bx_0 + cy_0$. (Niven and Zuckerman 1980, p. 7)

Here, the phrase "the greatest common divisor" is rendered meaningful by an implicit assumption that b and c are not both zero.

One always has the option of modeling a partial operation as an operation on a smaller sort. For example, one can take the variable x in the statement of the prime number theorem as ranging over positive real numbers. This often leads to problems; we should be able to supply a positive real number in any context where a real number is expected. (See the discussion of *identification* in Sect. 4.) But in other contexts, it is more natural. The product $M \cdot N$ of two matrices makes sense only if the number of columns of M is equal to the number of rows of N; in other words, if M is an $m \times k$ matrix and N is a $k \times n$ matrix for some m, k, and n. One can interpret multiplication as a partial operation on matrices, but formalization is often smoother if we interpret it as a family of total operations indexed by m, k, and n, and take these values to be implicit in the expression. This requires that a variable like M can range over a sort *Matrix m k* of $m \times k$ matrices, or even *Matrix R m k*, where R specifies a ring of underlying

elements. Such a sort is said to be a *dependent type*. The fact that *Matrix R n n* can be viewed as a ring for every $n > 0$ provides additional support for viewing *Matrix R m k* as an independent sort of objects rather than a predicate on a larger one.

4 Abstract Objects

Mathematics is the art of rigorous abstraction. Mathematization amounts to identifying the features that are essential to the inferential and calculational steps that are needed in specific reasoning contexts and making them explicit. This results in *modularization* and *encapsulation*: the objects and assumptions on which an argument depends are presented as part of the interface, and the argument can then be applied to any data that instantiates the relevant hypotheses.

Abstracting and modularizing in this way serves two purposes (Avigad 2020). The first is to manage complexity. If an argument about a geometric object only depends on the fact that it is a triangle, presenting it as such means we can temporarily ignore other information we have about it, such as its particular dimensions or its relationship to other objects in a diagram. If an argument about the roots of an equation only depends on the fact that the set of permutations of those roots is a group, presenting the argument in group-theoretic terms allows us to set aside everything else we know about equations and roots. If an argument about a complicated space of functions depends only on the fact that it is a convex Banach space, presenting it as such allows us to suppress specific details of the space that are irrelevant to the argument.

The second purpose is, of course, generality. A theorem about triangles holds of all triangles, not just the one in a particular diagrammatic configuration. A group-theoretic result holds of all groups, of which there are many, and a theorem about convex Banach spaces holds of every convex Banach space. An abstract argument can be applied not only in settings we are currently interested in, but also in settings we cannot yet even imagine.

In Sects. 6 and 7, we will consider the ways that set-theoretic language and the use of algebraic structures, respectively, support these goals. But first, it is helpful to think about the way we talk about abstract objects in general, and the role that abstract objects play in mathematical thought.

4.1 Numbers

For centuries, mathematics was understood to be the general science of *quantity*, with continuous quantities, or *magnitudes*, as the subject matter of geometry, and discrete quantities, or *numbers*, as the subject matter of arithmetic. The first mention of magnitudes occurs in Book V of Euclid's *Elements*, which introduces the theory of ratios:

> A magnitude is *part* of a magnitude, the less of the greater, when it measures the greater. The greater is a *multiple* of the less when it is measured by the less. (Euclid 2002)

In the *Elements*, two magnitudes may be equal, or one may be less than another. A magnitude a is a *part* of a magnitude b if b can be *measured* as some whole number multiple of a. Book VII extends the terminology to *numbers*:

> An *unit* is that by virtue of which each of the things that exist is called one.
> A *number* is a multitude composed of units.
> A number is *a part* of a number, the less of the greater, when it measures the greater. (Euclid 2002)

Today, we are apt to interpret Euclid's magnitudes as nonnegative real numbers and his numbers as natural numbers. But Euclid's presentation and the early history of mathematics bring some interesting differences to light. One curious feature of the *Elements* is that the smallest number is 2; one sheep does not make a multitude. This fact is manifest in the first two propositions of Book VII, which describe the Euclidean algorithm for calculating the greatest common divisor of two numbers. The first proposition deals with the case where the result is a unit, whereas the second deals with the case where the two numbers have a common measure.

A more significant difference is that, in Euclid, a magnitude is always a magnitude of some type. It makes sense to add and compare lengths, areas, and angles, but not to add a length to an area or compare a length to an area. Even toward the end of the sixteenth century, we find François Viète, in the *New Algebra*, insisting that only homogenous quantities can be compared or added. So if x is a length, instead of $x^3 + x$, we must consider $x^3 + ax$ for some area a. Descartes' landmark *Geometry* of 1637 resolved the problem of comparing lengths and areas by providing a geometric construction that reduces products to lengths, modulo a choice of a unit.

Although today we consider numbers to be relatively concrete mathematical objects, we should keep in mind that they nonetheless represent a substantial abstraction. Mathematics allows us to add the average temperature in Pittsburgh on April 19, 2020 to the number of moons of Jupiter, and then multiply the result by the length of the Nile river, whether or not the resulting number is useful or interesting. The fact that we consider such a quantity to be a legitimate mathematical object says something significant about the nature of mathematical abstraction.

4.2 Dedekind Abstraction

A parable by Paul Benacerraf imagines two children who, thanks to a solid logical upbringing, each possess a set-theoretic definition of the natural numbers (Benacerraf 1965). The definitions serve each of the children well until they come to realize that although the definitions denote isomorphic set-theoretic structures, they are not identical. Since every object of set theory is, fundamentally, a set, mathematical objects have ancillary properties qua sets. So we can imagine that according to one definition, 2 is an element of 3, and according to the other, it is not. Since the structures are isomorphic, the two students are in a position to come to agreement regarding all substantive claims about the set of natural numbers. But the

identification of abstract numbers with concrete set representations forces us to the unsettling conclusion that, if the natural numbers really are sets, then either 2 is an element of 3 or it isn't, and any definition we give has to adjudicate the matter.

The title of Benacerraf's paper, "What numbers could not be," is a nod to an essay by Richard Dedekind from 1888, titled "Was sind und was sollen die Zahlen?" (roughly, "What are numbers and what should they be?"). That essay, and Dedekind's 1871 construction of the real numbers, foreshadow the problem. Dedekind explicitly addressed the issue in a letter to Heinrich Weber in 1888, in which he resists identification of the real numbers with his particular construction as a system of *cuts*:

> . . . I would advise that by [real] number . . . one understand not the class itself . . . but something new (corresponding to this class) which the mind creates. We are a divine race and undoubtedly possess creative power, not merely in material things (railways, telegraphs) but especially in things of the mind. This is precisely the same question that you raise at the end of your letter in connection with my theory of irrationals, where you say that the irrational number is nothing other than the cut itself, while I prefer to create something new (different from the cut) that corresponds to the cut and of which I say that it brings forth, creates the cut. . . . The rational numbers also produce cuts, but I would certainly not call the rational number identical with the cut it produces; and after the introduction of the irrational numbers one will often speak of cut-phenomena with such expressions, and ascribe to them such attributes, as would sound in the highest degree peculiar were they to be applied to the numbers themselves. Something quite similar holds for the definition of cardinal number . . . as a class; one will say many things about the class (e.g. that it is a system of infinitely many elements, namely, of all similar systems) that one would apply to the number only with the greatest reluctance; does anybody think, or won't he gladly forget, that the number four is a system of infinitely many elements? (Dedekind 1888)

These circumstances have led a number of philosophers to adopt a *structural* view of mathematics (Resnik 1997; Shapiro 1997; Reck 2003; Parsons 2004), which holds that when we say something about the number two, we are never talking about a unique object, but, rather, an element of an axiomatically characterized natural-number structure. Some go so far as to give the notion of a place in a structure a metaphysical standing of its own. The more sober mathematical practice, inaugurated by Dedekind, is to characterize mathematical structures uniquely up to isomorphism, provide a specific mathematical construction that shows that such a structure exists, and then refer to the structure only in terms of its axiomatic characterization, so that anything one says about the structure holds equally well of any isomorphic copy.

Perhaps there is no harm in identifying mathematical objects like numbers with particular set-theoretic objects if one then subsequently restricts oneself to the proper mathematical statements about them, but we should recognize that mathematical language obeys this restriction. Proof assistants implement various mechanisms to support this. In a number of proof assistants, once one has a construction of the real numbers as Dedekind cuts (or equivalence classes of sequences, or whatever), one can introduce a new type, $\mathbb{R}$, with an abstraction function *abs* from the type of representatives to $\mathbb{R}$, and a representation function *repr* in the other direction. These

are assumed to satisfy *abs* (*repr y*) $= y$. The type $\mathbb{R}$ provides the "new things" suggested by Dedekind. The function *abs x* maps every representation to the abstract thing it represents, and the axiom says that every real number has a representation, not necessarily unique.

Inductive types in a proof assistant allow one to declare the natural numbers axiomatically as a type that is freely generated by zero and a successor function. Such declarations are underwritten by a set-theoretic interpretation, but the form of the declaration in the system helpfully abstracts away the specifics. Alternatively, some systems, like Agda and Coq, offer systems of *modules*, which allow users to declare constants and properties axiomatically, reason about them, and instantiate them later on.

4.3 Equality

We will see in the next two subsections that mathematics allows us to substitute one expression for another in contexts that respect the sense in which we can treat them as the same thing. The equality relation in mathematics is generally reserved for substitutions that are allowed in all mathematical contexts. Saying $a = b$ means that we should be able to substitute a for b in any meaningful mathematical statement *salva veritate*, that is, preserving the truth of that statement. Frege's "On sense and reference" (Frege 1892) famously provides examples of linguistic contexts, like ascriptions of knowledge or belief, where identity and substitutability come apart. One of the hallmarks of mathematical language is that it is devoid of such modalities.

If we assume that any meaningful mathematical statement about an object x describes a property of x, the requirement above follows from the principle that if two arguments are equal, they have all the same properties. Conversely, if two objects have all the same properties in common, then they must be equal: being equal to x is a property of x, so if y has all the same properties that x does, it is equal to x as well. This characterization of equality is known as the *Leibniz principle* or the *principle of identity of indiscernibles*.

Leibniz' principle says something about equality in general, but nothing about what it means for two objects to be equal in particular. It is perfectly reasonable to ask when two natural numbers are equal to each other; the inductive characterization of the natural numbers provides an answer to that, namely, that they are equal if they are both zero or have equal predecessors. Similarly, if we define the real numbers as equivalence classes of Cauchy sequences, asserting the equality of two real numbers is tantamount to saying that the Cauchy sequences representing them are equivalent. Questions of equality involve representations of objects, and settling such questions can require substantial mathematical knowledge.

We have seen that foundational approaches often overspecify mathematical objects. In set theory, we can ask whether $1 + 1$ is equal to the set $\{\emptyset, \{\emptyset\}\}$, a mathematical variant of Frege's Julius Caesar problem. Dedekind's abstraction helps; in most implementations of type theory, a proposition $s = t$ is grammatically acceptable only when s and t are objects of the same type.

One thing that plagues proof assistants is that, in addition to substantial judgments of equality, there are also implicit equality judgments that are so fundamental that they have a silent bearing on the very grammar of the language. For example, if x and y are column vectors of length 3, then concatenating them results in a vector of length 6. In a mathematical text, one might use

$$M \cdot \begin{bmatrix} x \\ y \end{bmatrix}$$

to denote the product of an $n \times 6$ array with that vector. Strictly speaking, the concatenation of x and y yields a vector of length $3 + 3$, and a tiny bit of mental arithmetic is needed to see that the expression is well-formed. Accepting this fact opens the door to allowing any background mathematical knowledge to bear on such determinations, and it isn't clear where to draw the line. Systems of type theory that allow ordinary mathematical expressions to occur in an expression's datatype (like $\mathbb{R}^{3+3}$ and $\mathbb{R}^6$) distinguish between *definitional equality*, which is the kind that the system needs to recognize in order to judge whether an expression is well formed, and *propositional equality*, which is the more substantive kind. Informal mathematics does not make the distinction, and we need to better understand how to model the identifications that mathematicians are not even conscious of performing.

4.4 Identifying Objects

If there is any such thing as a concrete mathematical object, the number two should fit the bill. But we have seen that even the number two is a rather abstract thing, and its nature is slippery. There are a 2 in the integers and a 2 in the rationals, and also 2s in the real numbers and complex numbers. Set theory tells us that we have $\mathbb{Z} \subseteq \mathbb{R} \subseteq \mathbb{C}$, so we can view these all as the same 2. But such a view is hard to maintain as the 2s proliferate. There are also 2s in the quaternions and octonians, and there is a 2 in the ring of p-adic integers for every prime number p. In fact, there is a 2 in every ring. In $\mathbb{Z}/2\mathbb{Z}$, we have $2 = 0$, so that particular 2 probably isn't the same as the integer 2. Even if we restrict attention to rings of characteristic zero, which contain an isomorphic copy of $\mathbb{Z}$, it is hard to maintain that all the 2 s are the same. The 2 in the ring $M_2(\mathbb{R})$ of 2×2 matrices over $\mathbb{R}$ is

$$\begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix},$$

and it is hard to see how that can be equal to the integer 2.

The general mathematical stance is that what we are really doing is *identifying* all the isomorphic copies of the integers, allowing us to transfer properties between them. In particular, identifying the integers with a subset of the real numbers means that we can consider an object n to be an integer and a real number at the same time. So, in an expression like $3x^2 + 2x + 7$ we can view the coefficients as integers, we

can view x as a real number, and we can view the multiplication as the usual multiplication operation on the real numbers. But each number domain has its own special character. We can prove a general expression involving a natural number n by induction on n only if we view n as a natural number and not a real number, and we can use the implication from $n < m + 1$ to $n \leq m$ when we know m and n are integers. When we write the binomial theorem,

$$(x + y)^n = \sum_{i \leq n} \binom{n}{i} x^i y^{n-i},$$

we understand that i ranges over natural numbers, or, equivalently, nonnegative integers, x and y are elements of any commutative ring, and the apparent multiplication by $\binom{n}{i}$ is interpreted as an action of integers on ring elements. In fact, in the identity

$$\binom{n}{i} = \frac{n!}{i!(n-i)!}$$

we recognize that the division symbol is justified a priori because any integer can be viewed as a rational number, though at the same time we are aware of the fact that in this case, the operation keeps us within the integers.

The fluidity with which we pass between views of mathematical objects poses challenges for formalization. We will consider some of the practical mechanisms used to cope with this in Sect. 4.6.

4.5 Identifying Structures

We also identify structures. Any mathematician will tell you that the set $\{0, 1\}$ with addition modulo two is the two-element group, and that the set $\{1, -1\}$ with multiplication is also the two-element group. The reflexivity of equality tells us that the identity element of the two-element group is equal to the identity element of the two-element group. By substitution, we can conclude that 0 is equal to 1.

As a mathematical joke, this isn't a very good one. There is nothing mysterious going on here: mathematicians are well aware of the fact that we can treat distinct objects as being the same only insofar as we limit ourselves to operations and properties that respect the senses in which they are the same and avoid talking about the differences. The two structures in the last paragraph are the same only insofar as we talk about them as groups. If we allow ourselves to talk about the elements of the carrier set, they are patently different.

In logical terms, it is permissible to identify isomorphic structures in the sense that any statement that can be expressed in the language of the structure's signature cannot distinguish between them. But then it is important to recognize that the

relevant signature depends on the reasoning context at hand. Keränen (2001) challenged the philosophical view that mathematical objects are merely places in structures with the observation that some structures have nontrivial automorphisms. If the complex number i is just a place in a structure, which one is it? Anything that can be said about i can be said equally well about $-i$, so there is nothing to distinguish the two.

Keränen used this observation to reject a metaphysical stance, *realist structuralism*, which holds that references to elements of a mathematical structure should be interpreted at face value, in terms of an ontology of *places* in abstract structures. He takes the problem to rule this out in favor of a more mathematically familiar stance, *nominalist structuralism*, in which terms refer to elements in any system of elements that satisfies the relevant structural axioms. But the question remains as to how an expression like i can refer to any particular structure in which its denotation is ambiguous, and Keränen does not address that problem.

Mathematical practice itself suggests a straightforward solution: when we talk about the complex numbers, we know full well that there are two square roots of -1, and that i can be designated to be either one. So the best way to construe talk about the complex numbers while viewing them as an algebraically characterized structure is to view them as a structure with a fixed choice of i. With that choice, the structure is rigid, and the problem is solved. But this calls for a more robust account of how and when such choices should be viewed as having been fixed, implicitly, by the mathematical context, and what ensures that the various implicit choices are coherent with one another. We will see a variation on this problem in Sect. 7.2.

4.6 Managing Abstraction

The conclusion of the previous subsection is that it is safe to identify structures as long as suitable linguistic hygiene is maintained. But mathematicians don't go around declaring languages and signatures; in any given context, they simply know what is allowed. When we formalize mathematics with a proof assistant, we have to operationalize that. It's not enough to make vague gestures at reasoning contexts; the rules need to be spelled out in enough detail that a proof assistant can supply the relevant axiomatic justification. We also need to make sure the different contexts interact, so that we can establish mathematical claims once and for all and then apply them wherever it is appropriate to do so.

In this subsection, I will describe four general strategies that are used in formal libraries to support the application of abstract theorems in the various contexts in which they can be applied. The four strategies are as follows:

1. Generalize.
2. Use equality.
3. Use algebra.
4. Use coercions.

The first strategy can also be phrased in negative terms, in which case it sounds like cynical advice to a young politician: avoid saying anything specific. For instance, proof assistants usually establish $x + y = y + x$ as a general property of a suitable class of algebraic structures. That means that when we need to use the fact that $2 + 3$ is equal to $3 + 2$, we don't have to worry about whether this is a fact about integers or real numbers, or even whether they are the same fact or not. Nor do we have to worry about transferring the result from one domain to another. We just need to know that the relevant algebraic hypotheses are satisfied.

For that reason, mathematical libraries tend to favor theorems about commutative rings and ordered fields over theorems about specific number structures. Other opportunities for generality often crop up in unexpected ways. Theorems of multivariate analysis hold of the structure $\mathbb{R}^n$ of n-tuples of natural numbers, which we can view as maps from the set $\{0, 1, 2, \ldots, n-1\}$ to $\mathbb{R}$. But this can lead to the annoying need to reindex when we try to view $\mathbb{R}^n$ as a subspace of $\mathbb{R}^{m+n}$. In fact, most theorems one might want to prove about $\mathbb{R}^n$ remain true if we interpret n as an arbitrary finite set, and we can interpret the $+$ in $\mathbb{R}^{m+n}$ as disjoint union. This avoids the need to treat any particular n-element set as canonical. If we incorporate this design decision into a formal library, we don't need to identify one n-element set with another because our theorems hold for all of them. In a similar way, Buzzard et al. (2022) found it advantageous to reason about arbitrary localizations of a ring R at a submonoid S rather than any particular representation.

Nonetheless, there are invariably times when we want to consider a mathematical structure as both an entity in its own right and a substructure of a larger one. It is often convenient to have the integers be a subset of the reals. For a more striking example, consider the number field obtained by adjoining both $\sqrt{2}$ and $\sqrt{3}$ to the rationals. We can describe this structure as $\mathbb{Q}[\sqrt{2}][\sqrt{3}], \mathbb{Q}[\sqrt{3}][\sqrt{2}]$, or $\mathbb{Q}[\sqrt{2}, \sqrt{3}]$. These describe distinct mathematical constructions, any of which may come up in practice, leaving us struggling to identify them when the contexts clash. But viewed as subsets of the real numbers, they are the same subset, and any element of one is an element of the other.

A variation on this second strategy played a fundamental role in the celebrated formalization of the Feit–Thompson theorem (Gonthier et al. 2013). The formalization of group theory used for that project might more accurately be called a formalization of *subgroup* theory because theorems in the underlying library were phrased as theorems about subgroups of a larger ambient group. Every group is a subgroup of itself, so, mathematically, there is no difference. But an element of a group can generally be viewed as an element of multiple subgroups of interest, and centering the library on the concept of a subgroup avoids the need to mediate between the different views.

The third strategy in the list is really a special case of the first: sometimes the right way to generalize a theorem involves adopting a proper algebraic perspective. Mathematicians are well aware of the fact that any abelian group A can be viewed, equivalently, as a $\mathbb{Z}$-module, which means that it comes equipped with an action $n \cdot x$ of $\mathbb{Z}$ on A. On the additive part of any ring R, this action coincides with multiplication by image of n in R. Reasoning in terms of scalar multiplication means that we don't have to worry about this identification; often the properties of the action

are all we need. Similarly, instead of reasoning about a subring R of a ring S, it is more convenient to view S as an R-algebra. This is equivalent to saying that there is a homomorphism from R to S, namely, the one that maps each element r in R to $r \cdot 1$. Any subring is a homomorphic image of the identity map, so, once again, there is no substantial mathematical difference. But building a library around images of morphisms rather than substructures avoids the need to identify one structure with another; the identification is built into the theorems. (See Baanen et al. (2021) for a nice instance of this.)

In fact, reasoning about structures and mappings between them from a structural algebraic perspective often makes it unnecessary to reason about elements at all. Every subspace of a vector space is the image of a linear map, and it is often natural to build a library around properties of morphisms and maps. There is no need to worry about identifying elements if the theorems are about the identifications themselves.

Finally, there are times when it is impossible to avoid identifying two distinct structures and transferring results between them. Sometimes we really need to identify the real numbers with the one-dimensional vector space over the reals, and sometimes we really need to identify the elements of an algebraic number field with their representations in the complex numbers. In that case, proof assistants often use *casts* or *coercions* from one structure to another. There are various mechanisms that can be used to infer the need for such coercions and insert them automatically, as is done in most programming languages. There are also mechanisms that can be used to translate statements across an embedding or isomorphism (Barthe et al. 2003; Huffman and Kuncar 2013; Lewis and Madelaine 2020). Coercions are generally not required to be injective; so in a sense, elements of the source are identified with one another as well as with their images. (See also the discussion of quotients in Sect. 6.3.) Homotopy type theory offers another solution, based on an axiom known as *univalence* (Univalent Foundations Program 2013).

It may seem disappointing that I have offered a grab-bag of ad hoc approaches to managing identification, especially when mathematicians seem to do it so effortlessly. Surely, one might think, there must be a simpler explanation as to how mathematicians manage to transfer results from domain to domain without violating foundational norms. But it is a mistake to look for an easy explanation. Mathematics requires extensive training, and learning to do mathematics requires learning how to manage abstraction appropriately. The strategies I have described are all natural, though partial, explanations of what is going on under the hood. The fact that mathematicians have internalized the allowable moves does not mean that we cannot make them explicit. In that respect, formalization can help us understand the inner workings of the practice.

5 Mathematical Theories

So far, we have focused on some of the basic components of mathematical statements. These, in turn, are used to formulate definitions, state theorems, and prove them. Collections of definitions and theorems are then structured into mathematical theories. This section considers some of the syntactic mechanisms that the subject uses to structure knowledge in this way.

5.1 Definitions

Mathematical definitions are often set apart typographically, but they are also often introduced on the fly, in the flow of a mathematical text.

> **Definition 2**. R is said to be a *principal ideal domain (PID)* if every ideal of R is principal. (Ireland and Rosen 1990, p. 9)

> **Definition**. Given a point x of a set X and an open set U of the space Y, let
>
> $$S(x,\ U) = \{f | f \in Y^X \text{ and } f(x) \in U\}.$$
>
> The sets $S(x, U)$ are a subbasis for a topology on Y^X, which is called the *topology of pointwise convergence* (or the *point open topology*). (Munkres 2000, p. 281)

> By a *measure algebra*, we mean a Boolean σ-algebra $\mathcal{A}$ together with a nonnegative real-valued function μ defined on $\mathcal{A}$ such that $\mu(A) = 0$ if and only if $A = 0$ and
>
> $$\mu\left(\bigvee_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} \mu A_i$$
>
> if $A_i \wedge A_j = 0$ for $i \neq j$. (Royden 1988, p. 398)

In either case, the text serves to associate the body of the definition, the *definiens*, to the *definiendum*, which is the word or phrase being defined. In the first and third examples, the body of the definition associates a predicate on the type of objects it describes, in the first case, a ring R, and in the second, a pair $(\mu,\ \mathcal{A})$ of the kind indicated. In other cases, a definition describes a new object or structure.

Making sense of a definition by description requires recognizing that there is exactly one object meeting the description. When a function is defined in a programming language, the definitional apparatus itself guarantees the existence of a function, or at least a partial function, meeting the specification. Modern mathematics, however, allows for more liberal descriptions, and it is often not obvious that the object described has been well-defined. Indeed, it is a common procedure to justify such a definition explicitly by first proving existence and uniqueness. (And sometimes uniqueness means uniqueness up to isomorphism, along the lines described in Sect. 4.5.)

Sometimes a definition is a construction – we speak of the construction of the Haar measure or the Radon–Nikodym derivative or a direct limit. The definition of a function sometimes comes with an implicit algorithm (see Sect. 8.2), but mathematics tends to favor definitions that characterize the concept's role in a theory over the means of computation. In other words, the definition of the greatest common divisor of two integers or the Legendre symbol may or may not be accompanied by an algorithm to calculate it.

5.2 Theorems

Theorems are the building blocks of theories. They are noteworthy accomplishments in their own right and stepping stones to even greater ones. The word "proposition" is generally reserved for smaller theorems, facts that are generally unsurprising but which form the basis for more substantial results. A "lemma" is a fact established expressly to support the proof of a theorem, and the label "corollary" is used to denote a straightforward consequence.

Setting out the inferential structure of a mathematical theory requires having ways of referring to theorems that have previously been established. In a journal article or textbook, theorems generally have unique identifiers like "Theorem 5.3" or "Proposition 4.2.3," and these can be used across publications, as in "Theorem 4.3 of [5]." Some fundamental results have names, like the prime number theorem, the ergodic theorem, the dominated convergence theorem, and the fundamental theorem of algebra. Some names celebrate their authors, like Birkhoff's theorem, Picard's theorem, Szemerédi's theorem, Whitehead's theorem, Minkowski's inequality, and the Hilbert basis theorem. Some, like the Yoneda lemma, König's lemma, and Zorn's lemma, show that apparently minor results can take on added significance after the fact.

Sometimes a theorem is referred to descriptively, like the compactness of S^n, the uniqueness of Haar measure, the existence of an orthogonal complement, the monotonicity of the exponential function, and the fact that a positive semidefinite matrix has real eigenvalues. Using such a description suggests that supporting references are not hard to come by, and that the results are assumed to be part of a common background knowledge.

5.3 Proofs

In mathematical texts, proofs are often introduced with the label "*Proof*" and closed with a box at the end, a notational device introduced by Paul Halmos. The flow of information is generally linear. The primary justification for a claim typically comes from the statement or two preceding it, though additional background knowledge is often needed, and occasionally facts established earlier in a proof. Statements of fact are generally favored over the reasons that they hold, though a number of devices are used to indicate the latter.

> Hence the closure of S in E is $\overline{E} \cap S$. (Royden 1988, p. 151)

> By our previous results the first case obtains when $p \equiv 1 \bmod 4$ and $p \equiv \pm 1 \bmod 12$. (Ireland and Rosen 1990, p. 54)

> Because H is connected, the fiber F over $\gamma(0) = \gamma(1)$ is connected. (Duistermaat and Kolk 2000, p. 175)

> Now we can see that all the maps f_* and $\overline{f}_*$ in the commutative diagram of transfer sequences are isomorphisms by induction on dimension, using the evident fact that if three maps in a commutative square are isomorphisms, so is the fourth. (Hatcher 2002, p. 175)

> From $P[Y \in D_f] = \mu(D_f) = 0$ it follows that $f(Y_n) \to f(Y)$ with probability 1, and so by change of variable (see (21.1)) and the bounded convergence theorem, $\int f\, d\mu_n = E[f(Y_n)] \to E[f(Y)] \to \int f\, d\mu$. (Billingsley 1995, p. 335)

> Using Hilbert's theorem 90 again, together with the fact that $|\sigma\alpha| = |\alpha|$ for all $\alpha \in K^*$ we see that $H = K^{*1-\sigma}$. (Lang 1994, p. 189)

Sometimes the justification for a claim is an explicitly named theorem, like the bounded convergence theorem or Hilbert's theorem 90. Sometimes it is a named property, like the commutativity of addition or the compactness of a space. Sometimes it involves repeating a fact previously established. Sometimes it requires a few words of explanation, and sometimes it involves reminding the reader of something they already know.

The biggest difference between informal proofs and the proofs that are parsed by proof assistants is the amount of justificatory information that is left implicit in the informal ones. Every fact in a formal library, no matter how mundane or trivial, has a unique identifier, and one of the hardest parts about using a proof assistant is that one generally has to learn the names of facts in the library and refer to them explicitly when needed. Justificatory steps are also spelled out in far greater detail in a proof assistant, whereas ordinary mathematics has fewer resources for naming facts and composing them. Informal proofs rely instead on contextual hints and cues that enable a reader with sufficient expertise to spell out the details. This helps explain why expertise is so important; checking an informal proof is far from a mechanical process.

Sometimes the justification for a later inference is flagged in advance.

> Note that adjoining a copy of $\mathbb{Z}$ induces an injection on π_1 since the induced homomorphism is the free product of the injection $\pi_1(A) \to \pi_1(\mathbb{Z})$ with the identity map on the complementary free factor. (Hatcher 2002, p. 172)

> Note that each set U_n' is open, being the difference of an open set U_n and a closed set $\cup_{i=1}^n \overline{V}_i$. (Munkres 2000, p. 201)

Consider the significance of *noting* as a cognitive act; the proof asks the reader to keep the fact close at hand so that it can be deployed when needed, often without further comment. Mathematical texts call on us to perform other cognitive acts as well:

> Expressing each generator as a sum of homogeneous elements, ... (Lang 2002, p. 428)

> We can choose the indices i in such a way that $\sigma_i A_1 = A_i$. (Lang 2002, p. 183)

> Now identify $\mathfrak{g}$ with $\mathbb{R}^3$ by means of an orthonormal basis with respect to the Ad G-invariant inner product on $\mathfrak{g}$. (Duistermaat and Kolk 2000, p. 169)

> . . . consider the n simplex $[\nu_0, \ldots, \nu_n]$ with ν_0 at the origin and ν_k the unit vector along the kth coordinate axis for $k > 0$. (Hatcher 2002, p. 270)

> We now apply the bilinear form of Parseval's identity (Lemma 1.5, Chapter 3) to the integral defining $\mathcal{A}$. (Stein and Shakarchi 2003, p. 104)

To make our way through a proof, we have to express things, choose things, identify things, consider things, and apply things. (See Avigad (2006), especially Sect. 3.2, as well as Tanswell (n.d.) and Weber and Tanswell (2022).) Traditional logic doesn't account for these acts, only the result of performing them, which should be a network of inferences that takes us from a theorem's premises to its conclusion.

Logicians are fond of representing proofs diagrammatically as trees that branch at inference rules that have more than one premise. But the flow through an ordinary mathematical proof is remarkably linear. Sometimes the application of a theorem requires checking side hypotheses that are dispensed with quickly, and the base case in a proof by induction is usually dismissed easily. Occasionally, one comes across a case split where the cases have equal footing, and in those situations, the branching nature of the proof is made clear.

> If $d \equiv 2$ or 3 (4) then. . .
> If $d \equiv 1(4)$ . . .. (Ireland and Rosen 1990, p. 191)

> There are three cases. If $m < n$ then $f^{-1}(C)$ closed implies $C \cap X^{n-1}$ closed, hence $C \cap \overline{e}^m_\beta$ is closed since $-e^m_\beta \subset X^{n-1}$. If $m = n$ then e^m_β is one of the cells e^n_α, so $f^{-1}(C)$ closed implies $f^{-1}(C) \cap D_\alpha$ is closed, hence compact, hence its image $C \cap -e^n_\alpha$ under f is compact and therefore closed. Finally there is the case $m > n$. (Hatcher 2002, p. 521)

Such case splits, however, are few and far between.

Although a proof is generally presented as a sequence of factual assertions, the narrative has to pull off the difficult task of enabling us to determine how each successive statement follows from what has come before. Mathematical language supplies an array of devices that can be used to suggest inferential patterns, flag relevance, and indicate the necessary connections. Some of these devices are implemented in proof assistants. The Mizar proof language (Grabowski et al. 2010) was a pioneering effort in this sense, providing the first formal representation of informal proof vernacular. (See also de Bruijn (1987).) Most proof languages today contain similar means for structuring formal proofs. Those who design the languages have to balance competing goals, such as making proofs easy for users to write, making proofs easy for users to read, and making proofs easy for the system to process. But there is still more to be learned, and paying closer attention to the literature should provide better insight as to how well-chosen language supports mathematical inference.

5.4 Notation

Mathematical texts often introduce new notation.

> Let V, V' be two vector spaces, and suppose given a mapping
>
> $$V \times V' \to K$$
>
> denoted by
>
> $$(x, x') \mapsto \langle x, x' \rangle$$
>
> for $x \in V$ and $x' \in V'$. We call the mapping *bilinear* if ... (Lang 2002, p. 144)

> We define the *convolution* $f \star g$ on $[-\pi, \pi]$ by ... (Stein and Shakarchi 2003, p. 44)

> We define the *Dirichlet L-function associated to* χ by the formula
>
> $$L(s, \chi) = \sum_{n=1}^{\infty} \chi(n) n^{-s}.$$
>
> (Ireland and Rosen 1990, p. 254)

Exploring what makes for good notation would take us too far afield, but it is worth recognizing that good notation has remarkable staying power (Cajori 1993). Even fonts and letter choices tend to stick around: the use of π goes back to the early eighteenth century, and the use of $f(x)$ and $g(x)$ for functions in analysis, as well as the use of e, i, and φ for the familiar mathematical constants, goes back to Euler. We still speak of Riemann's ζ function and a Dirichlet L series, and we tend to use Fraktur letters $\mathfrak{a}, \mathfrak{b}$, and $\mathfrak{c}$ for ideals, following Dedekind.

One challenge for proof assistants is that notation, like identifiers, can be overloaded. The addition symbol in $x + y$ can refer to addition in the integers or reals, but also to addition in any ring or additive group. The addition symbol can also be used to denote the pointwise sum $f + g$ of two functions, or the sum $\mu + \nu$ of two measures.

When a symbol is used in two unrelated ways, computer scientists refer to it as ad hoc polymorphism. In all the examples above, one can view the domains over which the addition is defined as being instances of an additively written semigroup, which makes them instances of *parametric polymorphism*. We can therefore interpret them as the same addition, where only the semigroup itself is left implicit. We will return to this when we discuss algebraic language in Sect. 7. Computational implementations of mathematical language use various mechanisms to infer the relevant structure. Even ad-hoc uses of an addition symbol can be used as instances of an "addition structure" (Wadler and Blott 1989).

5.5 Calculation

Once seen as the essence of mathematics, calculation is now often associated with applied mathematics, but it plays a role in pure mathematics as well. Here is an excerpt from a proof of the ergodic theorem:

$$\begin{aligned}\int_{[|a_n|>\lambda]} |a_n|\, dP &\le \frac{1}{n}\sum_{k=1}^{n}\int_{G_\lambda} |f(T^{k-1}\omega)|P(d\omega)\\ &\le \frac{1}{n}\sum_{k=1}^{n}\left(\int_{|f(T^{k-1}\omega)|>\alpha} |f(T^{k-1}\omega)|\,P(d\omega) + \alpha P(G_\lambda)\right)\\ &= \int_{|f(\omega)|>\alpha} P(d\omega) + \alpha P(G_\lambda)\\ &\le \int_{|f(\omega)|>\alpha} P(d\omega) + 2\frac{\alpha}{\lambda}E[|f|].\end{aligned}$$

(Billingsley 1995, p. 318)

In this case, the calculation is a chain of equalities and inequalities. Formal systems rarely specify syntax for calculations or distinguish them from other types of arguments, but proof assistants generally provide special mechanisms to support them.

6 Set-Theoretic Abstraction

Sets, functions, and relations are so fundamental to contemporary mathematics that it is easy to forget that they are recent additions to the subject. In the middle of the eighteenth century, Euler grounded calculus on the notion of a function, but the term did not take on anything approximating its contemporary significance until late in the nineteenth century. Similarly, it is hard to find anything like the modern notion of a set before that time.

The goal of this section is to characterize the contemporary notions of set and function and consider their role in mathematical language. In large part, set-theoretic language evolved in the nineteenth century as a means of supporting algebraic abstraction, which is discussed in the next section.

6.1 Functions

In the early nineteenth century, mathematicians dealt with a number of mathematical objects that we view as instances of the general function concept today, but were not then seen as such. These include sequences, series, geometric transformations, and permutations of roots of an equation. The word *function* and its cognates in western

languages were used exclusively for functions that are defined on the real or complex numbers and take values in one of those domains (Monna 1972; Youschkevitch 1976/77; Avigad and Morris 2014). Even number-theoretic functions, like the Euler ϕ function or the totient function, were described as *symbols* or *characters* rather than functions. The general view of a function as a mapping between any two domains first emerged later in the nineteenth century, in Dedekind's supplements to Dirichlet's *Lectures on Number Theory* and Frege's *Begriffsschrift*.

The modern concept of function has these features:

1. A function $f : A \to B$ maps elements from a domain A to a codomain B.
2. Any description that associates a unique element of B to each element of A serves to define a function. There need not be any algorithm or procedure for producing an element of B from an element of A; in fact, there need not be any means of representing particular elements of A in a way that an algorithm can act on them.
3. The axiom of choice allows us to consider functions for which we don't even have a means of description.
4. Two functions from A to B are considered to be the same when they take the same values at every argument. There is nothing more to a function than the association of output values to inputs.

Foundational accounts differ as to whether the specification of the codomain is part of the function, for example, whether the function $f(x) = x^2$ from $\mathbb{R}$ to $\mathbb{R}$ is simultaneously a function from $\mathbb{R}$ to the nonnegative reals. Mathematicians freely identify the two. Logical foundations often differ as to whether applying a function f to an element outside its intended domain is a syntactic error or a semantic one, that is, whether it is grammatically incorrect or only mathematically dubious.

In set theory, a function $f : A \to B$ is usually defined to be a set of ordered pairs, where $f(x) = y$ means that the pair (x, y) is an element of f. A function $f(x, y, z)$ with multiple arguments is generally viewed as a function $f : A \times B \times C \to D$. In type-theoretic foundations, the notion of a function $f : A \to B$ is a primitive notion, and the type of inputs and the type of the outputs are both an inherent part of the syntactic specification. We have seen that in type theory, a function $f(x, y, z)$ is commonly represented as an object of type $A \to (B \to (C \to D))$ and application is commonly expressed by writing $f\,x\,y\,z$, where x, y, and z are of type A, B, and C, respectively. This has the sometimes useful side effect that an expression like $f\,x\,y$ denotes an object of type $C \to D$, in which case, f is said to be *partially applied*. In type theory, it is harder to view a function that takes values in the integers as simultaneously a function that takes values in the real numbers. In compensation, the fact that the type of an expression like $f\,x$ is unambiguous is often useful.

The modern viewpoint allows us to treat functions as objects in their own right, on par with other mathematical objects, like natural numbers. We can quantify over functions the same way we quantify over numbers, we can define structures whose elements are functions just as we can define structures whose arguments are numbers, and we can define functions (also known as *functionals*) whose arguments are functions. This is what distinguishes the discussion of functions here from the discussion of

operations in Sect. 3.2. We can talk about multiplication as an operation on the integers, but when we talk about the multiplication *function* on the natural numbers, we are talking about a first-class object. Any implementation of mathematical language has to mediate between these two views, that is, the treatment of functions as objects and the treatment of functions as operations in the sense of Sect. 3.2.

6.2 Sets

In his book, *Labyrinths of Thought*, José Ferreiros observes that in the nineteenth century, there was no standard terminology to denote the set concept (Ferreirós 1999, page xx). Although French quickly settled on *ensemble*, Italian on *insieme*, and Spanish on *conjunto*, German terminology was not as uniform. Dedekind used words like *System* and *Gebiet*, while Cantor tended to favor *Mannigfaltigkeit* and *Menge*. It is interesting to read the following snippet from a letter from Dedekind to Cantor.

> (incidentally, I should like to see the shorter and equally Riemannian word "domain" [Gebiet] given clear preference over the clumsy word "manifold" [Mannigfaltigkeit]. . .). (Ewald 1996, p. 870)

The term *manifold* has, of course, survived, though it is used to describe sets with a specific geometric structure. Language and notation for sets in general are found everywhere in mathematics.

> Let $A_0 \subset C_0$ be the set of cubes disjoint from K, and inductively, let $A_k \subset C_k$ be the set of cubes disjoint from K and not contained in cubes of A_j for $j < k$. (Hatcher 2002, pp. 525–526)

> Consider the set of ideals $\{A^i \mid 1 \leq i \leq h_F + 1\}$. (Ireland and Rosen 1990, p. 179)

> W acts transitively on the set of connected components of $G^{\text{reg}} \cap T$. (Duistermaat and Kolk 2000, p. 154)

> Let $\{e_1, \ldots, e_m, \ldots\}$ be a basis of F. . . (Lang 2002, p. 521)

> A set A is a μ-continuity set if it is a Borel set and $\mu(\partial A) = 0$. (Billingsley 1995, p. 335)

Talk of sets is often implicit in the definitions of mathematical spaces and structures because they are often defined by specifying the underlying set.

> The space of bounded linear functionals on a normed space X is called the *dual* (or conjugate) of X and is denoted X^*. (Royden 1988, p. 326)

> Given a map $f: A \to B$, let E_f be the space of pairs (a, γ) where $a \in A$ and $\gamma : I \to B$ is a path in B. (Hatcher 2002, p. 407)

> Let $[M]$ denote the isomorphism class of a finite module M. We define the sum to be the direct sum. Then the isomorphism classes over the ring form a monoid. (Lang 2002, p. 139)

Any implementation of mathematical language has to make it easy to describe sets and reason about them.

In axiomatic set theory, the notion of set is basic; everything is a set, and a function is a set of ordered pairs. In axiomatic type theory, in contrast, the notion of a function between types is basic. A predicate on a data type α is viewed as a function from α to truth values, and sets are in one-to-one correspondence with predicates: given a predicate like *Even* on the natural numbers, we can form the set of even numbers, and, of course, given any set s, we can consider the property of being an element of s.

There is an important difference between set theory and type theory. In set theory, any collection of objects can form a set. We can consider the set consisting of the number π, the multiplication function on the integers, and the Eiffel Tower. In type theory, any set is a set of objects of some fundamental type. We can consider a set of integers or a set of functions, but there is no notion of a set of *arbitrary* mathematical objects. Whereas this is mathematically natural, the distinction between sets and types in type theory forces us to distinguish between the integers as a fundamental type and the integers as a subset of the real numbers. But, as we have seen in Sect. 4, the problem of identifying objects and structures is not limited to type theory. It poses challenges for set-theoretic foundations as well.

6.3 Quotients

In a familiar set-theoretic construction, if A is a set and $\equiv$ is an equivalence relation on A, the quotient $A/\equiv$ is defined to be the set of equivalence classes of A. Functions and relations on A that respect the equivalence relation descend to functions and relations on $A/\equiv$. (Confusingly, computer scientists often use the term "lift" instead of "descend.") This construction provides a useful way to treat equivalent objects as identical.

Quotient constructions come up often.

> We denote by $P_{\mathfrak{c}}$ the subgroup of P consisting of those principal fractional ideals (α) with $\alpha \in k_{\mathfrak{c}}$. Then it is clear that $P_{\mathfrak{c}}$ is a subgroup of $I(\mathfrak{c})$. The factor group $I(\mathfrak{c})/P_{\mathfrak{c}}$ will be called the group of c-*ideal classes*. (Lang 1994, p. 125)

> From the diagram above, $H_n(X)$ can be identified with $H_n(X^n)/\text{Im } \delta_{n+1}$. (Hatcher 2002, p. 140)

> Let X be the mapping torus of f, the quotient space of $\left(S^2_\alpha \vee S^2_\beta\right) \times I$ under the identifications $(x, 0) \sim (f(x), 1)$. (Hatcher 2002, p. 589)

> Let $\mathfrak{M}$ be the class of measurable subsets of [0, 1], $\mathfrak{N}$ the class of subsets of measure zero, and m Lebesgue measure. Then $\langle \mathfrak{M}/\mathfrak{N}, m\rangle$ is a separable measure algebra without atoms. (Royden 1988, p. 399)

> The equivalence classes of fractional ideals form a finite group, . . . which we call the *ideal class group*. (Lang 1994, p. 123)

> Because the canonical projection π: $M \to G\backslash M$ is continuous and maps open subsets of M onto open subsets of $G\backslash M$, the orbit space $G\backslash M$ is locally compact. (Duistermaat and Kolk 2000, p. 104)

Mathematicians often pass silently between talking about elements of a quotient and talking about representatives in the quotiented set. For example, it is common to conflate functions with equivalence classes of functions up to almost everywhere equivalence in a function space.

7 Algebraic Abstraction

Algebra involves calculating with variables that range over elements of some domain, using rules that are valid for that domain. The practice was used in the late sixteenth century by Viète, who saw the algebraic method as the foundation for a universal science. In the seventeenth century, Descartes and Leibniz held similar views.

We obtain modern algebra by making the rules explicit and abstracting the underlying domain, so that variables range over any domain that obeys the general laws, and the theorems we prove can be applied to any such domain. In other words, we get modern algebra (also known as *abstract algebra*) when we treat the objects under consideration as elements of an algebraic structure. This is a powerful means of abstraction that makes the properties that are relevant to a particular reasoning context explicit.

Conventional terminology wavers between using the expression "algebraic structure" to describe a class of mathematical structures and using it to describe any particular instance. In other words, sometimes we call the group concept an algebraic structure and sometimes we call a particular group an algebraic structure. For clarity, here I will reserve the term "structure" for the individual instances, and use the phrase "abstract structure" for the axiomatically characterized concept. With that terminology in place, we can describe the general practice: we define an abstract structure by specifying a linguistic signature and a collection of properties, and this allows us to reason uniformly about all its instances. The process of reasoning about such algebraically characterized classes becomes an art unto itself, and it is worthwhile to consider how mathematical language supports it.

7.1 Implicit Structure

An abstract structure is specified with a signature. We start by specifying that it has one or more carrier sets, and then we specify the functions and relations that are to be found in any instance, together with the axioms they are assumed to satisfy. A group

$(G, \cdot, e, \cdot^{-1})$ is any structure with a carrier set G, an element $e \in G$, a binary operation $\cdot$ on G, and a unary operation $\cdot^{-1}$ on G, all satisfying the group axioms. A partial order (X, R) consists of a transitive, reflexive, and antisymmetric relation R on a set X. An abstract structure can sometimes refer to higher-order objects over the carrier sets. A topological space consists of a pair $(X, \mathcal{T})$ where $\mathcal{T}$ is a collection of subsets of X satisfying the axioms for a topological space, and a hypergraph (X, E) consists of a set X and an arbitrary collection E of nonempty subsets of X.

When a mathematical object is an element of the carrier set of a structure, properties ascribed to the object often implicitly invoke the signature of the ambient structure. An element $a \in X$ of a partial order (X, R) is *minimal* if it is R-related to every other element of X. Similarly, properties of a function $f: X \to Y$ between carrier sets of two structures or a subset $A \subseteq X$ of the carrier set of a structure often make implicit reference to those structures. Saying that a set $A \subseteq X$ is *closed* or *compact* presupposes that there is a topology on X, saying that $f : X \to Y$ is continuous presupposes that there are topological structures on X and Y. This is an important sense in which sorts make a difference: to make sense of a statement like "a is minimal" or "f is continuous," it is not enough to view a as an object and f as a function; we have to view them as objects of appropriate sorts, and we have to view those sorts as coming equipped with ambient structures.

In a mathematical text, the relevant structures are often determined implicitly by the context. The same can be said for operations like the maximum function on an order or the closure operation on sets in a topology, and for notation like $x \cdot y$ and x^y. In proof assistants, various methods are used to infer implicit structure (Wenzel 1997; Asperti et al. 2009; Sozeau and Oury 2008; Garillot et al. 2009; Selsam et al. 2020). A good semiformal description should clarify the means by which the relevant associations are registered by a mathematical text.

7.2 Algebraic Hierarchies

Abstract structures bear relationships to one another. An abstract structure can add axioms to one described previously. A *total order* is a partial order (X, R) such that for any two elements a and b of X, either $R(a, b)$ or $R(b, a)$ holds. A *well-founded partial order* adds a different assumption, and a *well-founded total order* retains both. An *abelian group* is a group in which the group operation is commutative. Adding an axiom to an abstract structure means that the resulting class of instances is contained in the class of instances of the prior one, which is to say, any instance of the class of structure with the additional axiom is an instance of the class without it. This is one way in which structures form a hierarchy.

An abstract structure can also extend another by adding additional data. For example, a *pointed topological space* is just a topological space $(X, \mathcal{T})$ with an additional point $a \in X$. More commonly, an abstract structure will extend another with both additional data and additional axioms. A *group* is a monoid with an inverse; an *ordered group* is a group with a partial order on the carrier that is compatible with the group operation. A *ring* $(R, \cdot, +, 1, 0)$ is best described as the

combination of a monoid $(R, \cdot, 1)$ and an abelian group $(R, +, 0)$, satisfying the distributivity axioms.

Viewing a network of abstract algebraic structures and the relationships between them as a hierarchy supports modularity and abstraction in the sense of Sect. 4. A definition made in the context of one abstract structure instantly carries over to any others that inherit that structure, and a theorem proved about an abstract structure immediately applies to any of its instances. The reason that this is relevant to our discussion of mathematical language is that the transfer is built into the grammar. Any concepts defined in the context of a group can be interpreted in any abelian group or any ordered group, and, in practice, such concepts are deployed without comment or explanation. So a semiformal description of mathematical language has to specify not only how implicit algebraic structure is inferred, but also how algebraic relationships are tracked and used to make sense of mathematical statements.

The combined need to infer structure and to track relationships in the algebraic hierarchy gives rise to an interesting problem, namely, the *diamond problem*, that has been made manifest by the practice of formalization. It arises from the fact that, given a complex hierarchy, structure can be inferred in multiple ways, and the coherence of the practice relies on the fact that the results agree.

Here is an example of the phenomenon. Every metric space is an instance of a topological space; given a metric space, there is a unique topological space that is determined by the metric space. Given topological spaces with carriers X and Y, there is a canonical topology on their product, $X \times Y$. If X and Y are metric spaces, there are various natural ways of imposing a metric on $X \times Y$ that induces the same topology. Suppose we fix one and let f be a function from $X \times Y$ to some other space, and suppose we then say that f is continuous. We have seen that this requires us to view $X \times Y$ as a topological space. The question is: what is the topological space that is implicit in the statement?

The problem is that there are two ways to find such a space. Given that X and Y are metric spaces, we can view them as topological spaces, and then take the canonical topology on $X \times Y$. Alternatively, we can view $X \times Y$ as a metric space, and take the metric-space topology on $X \times Y$. Now, assuming we have chosen the metric on $X \times Y$ to have this property, the two choices coincide. But it may be a nontrivial mathematical *theorem* that they do. Suppose, in proving a theorem, we establish the continuity of f using one understanding of the relevant topological space, and then apply a theorem that presupposes the continuity of f using the other. We can hardly expect our proof assistant to run off and prove a substantial mathematical theorem just to infer that the two statements are the same. This is yet another instance of the identification problem raised in Sect. 7: mathematicians are comfortable shifting between equivalent readings of a statement once they have internalized the equivalence, but explaining what is going on formally requires some effort.

One solution found in the literature (Buzzard et al. 2020; Affeldt et al. 2020) is to take the structure of a metric space to include a specification of the associated topology, together with a proof that the topology is compatible with the metric. That makes it possible to ensure that both paths yield answers that are easily seen to

be the same. But more experimentation is needed to determine whether this is a viable way of solving all the diamond problems that crop up in practice, and whether the method can be made principled and general enough to become part of our semiformal specification.

Diamond problems serve to highlight fundamental questions about meaning and reference. As in Sect. 4.5, in cases where these are underspecified by the surface syntax, we would like to say that the mathematical context supplies the information needed to fix meaning and reference appropriately. But then we need a better story of how that works, and, in particular, a story about what ensures that the "canonical" interpretations that the context supplies are coherent. Implementations of mathematical language in proof assistants clarify the problem and open the door to philosophical analysis.

7.3 Structures as Objects

What gives an entity the status of a mathematical *object*? Section 3 presented some of the hallmarks: variables can range over objects, objects bear properties and relationships to one another, and mathematical operations build new objects from old ones. In Sect. 4, we observed that objects can be identified with other objects in various ways. The current section provides yet another aspect of objecthood: mathematical objects are, or can be seen as, elements of axiomatically characterized structures.

In contemporary mathematics, individual structures themselves are mathematical objects in all these senses. We quantify over groups, rings, and fields the same way we quantify over numbers and points on the Euclidean plane. We talk about products, powers, and limits of sequences of algebraic structures the same way we talk about products, powers, and limits of sequences of numbers. Various operations can be used to build new structures out of old ones; the automorphisms of a group, ring, or field form a group, the square-integrable real-valued functions on any measure space form a Hilbert space, and for every field F and natural number n, the structure F^n is a vector space. We identify structures, though here the relevant notion of "sameness" is isomorphism, which is coarser than the notion of equality that derives from viewing a structure as a tuple consisting of a carrier set and some functions and relations. And algebraic structures can be inhabitants of larger algebraic structures. The category of abelian groups (or abelian groups in a fixed set-theoretic universe) is an algebraic structure whose elements are abelian groups, a sheaf of rings is a collection of rings bearing an algebraic structure, and measure-theoretic probability allows us to consider measures on spaces whose elements are themselves measures.

This means that algebraic structures play dual roles. We can treat a group G as a mathematical object, and at the same time consider elements x and y of G. In the latter case, G specifies the sorts of objects that x and y are, and this is used to make sense of expressions that involve them. This duality is handled in various ways by proof assistants. One approach is to take a group, G, to consist of a structure, one

component of which is the carrier type, *carrier G*. The statement that x and y are elements of G is interpreted as shorthand for saying that x and y are elements of *carrier G* by coercing G to its carrier. An alternative is to use *type classes*, which provide a means of using context to associate information with a given data type. In that case, the statement that G is a group is interpreted as saying that G is a data type with an associated group structure. The statement that x and y are elements of G is interpreted as just that; but an expression like $x \cdot y$ is interpreted as making reference to an ambient structure that is inferred from the context.

8 Other Aspects of Mathematical Language

There are a number of important aspects of mathematical language that we have not even begun to address. We use language to state conjectures, raise questions, launch research programs, describe methods, and assess the value of mathematical contributions and artifacts. In this final section, we briefly consider some other aspects of mathematical communication.

8.1 Diagrams

Diagrams and images are important components of mathematical language. They are used to justify and explain, often more efficiently and effectively than text-based representations. In the last couple of decades, there has been a substantial literature on the use of diagrams in reasoning; see Giaquinto (2007); Manders (2008); De Toffoli and Giardino (2014); De Toffoli (2017); Hamami and Mumma (2013) for a representative sample. Work like this provides a diagrammatic analogue of the type of textual analysis proposed here, by developing a taxonomy of representational devices and their uses.

Given the size of the literature on mathematical diagrams, it is reasonable to ask why the analysis of textual communicative devices is lagging. One possibility is that the differences between diagrammatic representations and formal logic are so dramatic that it is clear that there is something interesting going on, whereas, in contrast, it is easier to convince ourselves that formal logic captures the essence of text-based reasoning. I hope this chapter has made the case that the mechanisms employed in text-based reasoning are just as elaborate, subtle, and mysterious as the ones employed in diagrammatic reasoning, and that they are just as worthy of study, if not more so.

8.2 Algorithms

For most of its history, mathematics was algorithmic in nature. Euclid's *Elements* provided recipes for constructing geometric objects, early algebraists were concerned with recipes for calculating quantities of interest, early probabilists were

concerned with calculating odds in games of chance, and early analysts were concerned with calculating the motions of the planets.

Pure mathematics tends to keep computation at arm's length, relegating questions about how to calculate quantities described or guaranteed to exist by a theory to the realm of application. A contemporary textbook on modern algebra might well prove that every matrix can be put in Jordan canonical form without saying explicitly how to do it (Lang 2002, p. 559). Still, algorithms sometimes creep into textbooks in pure mathematics.

> As a first application of quadratic reciprocity we show how, in conjunction with Proposition 5.1.2, it can be used in numerical computations of the Legendre symbol. (Ireland and Rosen 1990, p. 54)

> *Example 4L.3. Stable Splittings.* The formula ($\star$) tells us how to compute Steenrod squares for $\mathbb{R}\,P^\infty$, hence also for any suspension of $\mathbb{R}\,P^\infty$. (Hatcher 2002, p. 491)

Numerical and symbolic computation are an important part of mathematics, and the language that textbooks and journal articles use to describe such algorithms should be viewed as an important part of mathematical language.

Fortunately, computer science has developed ample means of representing algorithms formally – this is precisely what programming languages do. And proof assistants are commonly used for software verification, so there is a vast literature to draw on when thinking about mathematical algorithms.

8.3 Plans

Our discussion of proof in Sect. 5.3 ignored a number of narrative elements that are found in mathematical texts. A proof serves as a tour guide, drawing our attention along, highlighting key facts, and shaping the experience of understanding. A good proof reminds us where we have been, and it gives us a sense of where we are going and what we need to have with us on the way.

> Now let c be a connected component of t^{reg}. (Duistermaat and Kolk 2000, p. 147)

Think about the significance of the word "now." It is hard to pin down its inferential significance, but it plays an important role. It tells the reader that the part that has come before has been preparatory to that moment; it asks us to check our footing, and prepare ourselves for the next phase of the ascent.

> To show that ψ is onto, it is sufficient to show that ...
> ...
> Having shown that ψ is onto, we now investigate the kernel. Clearly, $\ker \psi = A_1 \cap A_2 \cap \cdots \cap A_g$. We must show that under the hypotheses the intersection is equal to the kernel. (Ireland and Rosen 1990, p. 181)

> Thus it only remains to show that (ii) ⇒ (iii). To do this. . . (Royden 1988, p. 206)

> We are now in a position to state the main theorem of this chapter. The proof will be spread out over the next three sections. (Ireland and Rosen 1990, p. 251)

> There would be no difficulty if we could write $B = A[\alpha]$ for some α. This is true only locally. Hence we shall use the approximation theorem to reduce our problem to the local case. (Lang 1994, p. 63)

Rebecca Morris has observed that we expect a proof to be *motivated*, in the sense that the structure of such a proof should make it clear how each step might have been anticipated, and how each step gets us closer to the goal (Morris 2020). Her work explores some of the devices that contribute to that aim. Morris and Yacin Hamami have argued that good proofs show evidence of a rational *plan* (Hamami and Morris n.d.). We tend to understand other people's behavior by assuming that they have particular goals and by interpreting their actions in relation to plans that achieve those goals. In a similar way, we make sense of proofs by interpreting them in terms of a systematic overall plan. Proof assistants give us languages for expressing definitions, theorems, and proofs. What can we say about the components of mathematical language that are used to put forth a plan?

I am grateful to David Waszek for pointing out that, contrary to a claim I made in the introduction, the last quotation includes an instance of a modality: "There *would be* no difficulty if *we could* write $B = A[\alpha]$ for some α." One also sometimes sees modal language in proofs by contradiction, for example: "We need to show x is even. Suppose x *were* odd. . .." In each case, modal language is used to modify the reasoning context by temporarily introducing a new assumption before drawing out conclusions. Logically and mathematically, such hypothetical reasoning is easy to explain, and it is telling that mathematicians more often avoid the use of subjunctive or counterfactual language in the second case, writing, instead, "suppose x *is* odd. . .." It may well be that the closest thing to the notion of a possible world in mathematical discourse is the notion of a temporary reasoning context, one that is related to a more primary reasoning context in some fashion. It is an interesting question whether conventional philosophical ways of thinking about modal language can shed light on the way we pass between such contexts.

8.4 Intuitions and Heuristics

Seventeenth century mathematicians like Descartes and Leibniz were enamored of the prospect of having methods of solving mathematical problems, like geometric construction problems and optimization problems. One can view this as a search for computational algorithms. But one can view their interest more broadly as having a body of *heuristics* that limit the search space and guide reason to its desired end. The mathematical literature is filled with such offerings.

> The methods to be used are identical with those already developed in the previous sections. (Ireland and Rosen 1990, p. 103)

> Two corollaries, interesting in themselves, will make clearer the structure of the proof of sufficiency given above. (Billingsley 1995, p. 350)

> The next section treats a general scheme for dealing with path-function questions by in effect replacing an uncountable time set by a countable one. (Billingsley 1995, p. 503)

> We now return, for the remainder of the chapter, to the consideration of various methods for imposing topologies on sets. (Munkres 2000, p. 112)

> The notions of a Galois extension and a Galois group are defined completely algebraically. Hence they behave formally under isomorphisms the way one expects from objects in any category. (Lang 2002, p. 264)

> This section contains a general discussion of invariant densities, especially on homogenous spaces. Although in the next section this is only used in a relatively simple case, the general discussion will be useful for future reference. (Duistermaat and Kolk 2000, p. 179)

> Notice that if f already sends some vertices of K to vertices of L then we may choose g to equal f on these vertices, and hence the homotopy from f to g will be stationary on these vertices. This is convenient if one is in a situation where one wants maps and homotopies to preserve basepoints. (Hatcher 2002, p. 179)

Statements like these do not make precise mathematical claims. Instead, they convey information that is meant to shape the way we organize, categorize, and store the knowledge we have, and the way we deploy that knowledge in the future.

Automated reasoning depends crucially on using heuristics to limit the space of options and fruitfully guide a search through a combinatorial explosion of possibilities. Successful machine learning algorithms seem to acquire representations that also structure spaces of options in fruitful ways. If we focus on mathematical statements like the ones above and think about what they are doing, we may be in a better position to design systems that provide better support for mathematical reasoning.

9 Conclusions

Understanding mathematical language can help us formalize mathematics, design better automated reasoning tools, and harvest data mechanically from mathematical texts. But mathematical language is also interesting in its own right, and understanding how it works adds to our appreciation of mathematics. A good piece of mathematics is a work of art, and there is a deep satisfaction to be had in admiring the creativity and insight that went into it. But that is not at odds with studying the mechanics of the underlying language. Whether we view that language as the medium for mathematical thought or merely an outward manifestation, understanding how it works is an important part of understanding the nature of mathematics itself.

Abstract

Recent years have seen a remarkable development of deep neural network techniques for data analysis, along with their increasing application in scientific research across different disciplines. The field of mathematics has not been exempted from this general trend. The present chapter provides a survey of recent applications of neural models to mathematics and assesses their philosophical significance, related to the role of language in mathematics.

1 Introduction

On February 15, 2023, Yuhuai (Tony) Wu, researcher in Artificial Intelligence at Google at that time, gave a talk at the UCLA Institute for Pure & Applied Mathematics (IPAM).[1] In his talk, Wu presented his most recent results in the automatic formalization of proofs through deep neural networks. The workshop was organized by a small and highly select committee, including two Fields Medalists, and the audience was composed of well-established world specialists in the field of automated theorem-proving. While explaining the details of the neural model in question and providing elements for its epistemological guarantees to this intrigued yet somewhat skeptical public, Wu affirmed: "We know for sure that the informal proof, the natural language proof, is correct because it is produced by a human." The statement was followed by a second of sincere bewilderment in the room, only resolved by one glorious collective laugh. Unable to hide his confused embarrassment, Wu tried, however, to reassure the crowd by adding: "Ok, so, we make sure that the human. . . we scrape the solutions from the Internet!" inevitably provoking a new burst of laughter, this time sounding like a redemption.

Wu's statement is not improvised or misguided, nonetheless. Let alone isolated. For a proof, take the official presentation of the second version of Google's Large Language Model PaLM (Ghahramani 2023), released shortly after Wu's talk. In it, one can read the following passage, flagged as "weird" by the renowned researcher at the Santa Fe Institute, Melanie Mitchell:

> PaLM 2's wide-ranging dataset includes scientific papers and web pages that contain mathematical expressions. As a result, it demonstrates improved capabilities in logic, common sense reasoning, and mathematics. (Ghahramani 2023)

The rapid proliferation of this peculiar kind of statement in the current state of research at the crossroads of mathematics and computing is not as much anecdotal as it is *symptomatic*. As is symptomatic the perplexed reaction of well-established specialists in the fields concerned. Both are the symptom of the surge of a perspective on mathematical knowledge and practices radically at odds with the one that governed our image of mathematics for more than a century. This circumstance is the effect of an ongoing revolution in the field of machine learning resulting from the remarkable development of Deep Neural Network models (DNNs) during the last two decades. As it has been widely observed, the fact that tech corporations are the main actors of this technological revolution entails that most research efforts

[1] Wu's talk was part of a Workshop on Machine-Assisted Proofs held between February 13 and 17, 2023. The recording of the talk is available on the website of the IPAM.

associated with this process are inseparable from the development of market products and the increase of profit under the brand of "Artificial Intelligence" (AI). However, the past years have also witnessed the application of the new neural methods to various aspects of scientific research across the disciplinary spectrum, from natural to social sciences. Significantly, mathematics has not been the exception to this general trend. Indeed, since the mid-2010s, many efforts have been dedicated to treating numerous aspects of mathematical knowledge using DNNs of various kinds.

Mathematics has been in the sights of AI champions since the very emergence of the AI program. In his pioneering 1948 paper on "Intelligent Machinery," for instance, Turing (1948/2004) already considered mathematics a privileged field for the application of "thinking machines." And the celebrated 1955 Dartmouth project proposal included a supplement by Newel and Simon with a plan to extend to "learning, self-programming and the self-selection of theorems to be proved (innovation)" their work on "Mathematics Machines" that "discover proofs in the propositional calculus [...] by employing search procedures that appear at least grossly similar to those used by humans in dealing with the same problems" (Newell and Simon 1956). At any rate, considering the conception of intelligence motivating the AI program, one should not be surprised that mathematics falls within its scope.

However, given the nature of recent neural techniques and the unexpected results they can afford, as natural as it may be for the AI ideology to address mathematical tasks, the very possibility of their successful application to mathematical knowledge cannot but come as a surprise from a conceptual and philosophical perspective. Hence, faced with the results of the renewed AI momentum, it seems inevitable for well-established conceptual positions to return to their foundations and reopen old questions: Wasn't the whole idea of proof assistants and automated theorem provers to *prevent* the frailty of human proving practices instead of *reproducing* them and *relying* on them as a gold standard? Wasn't mathematical competence a *condition* to write and read scientific papers and mathematical expressions rather than their miraculous *effect*? Wasn't natural language the *cause of* rather than the *solution to* the multiple problems preventing mathematics from achieving higher degrees of precision? And more generally, didn't the *formal* nature of mathematics, finally conquered by the logical regulation of its symbolic means, make it impassive to the strong *empirical* position assumed by connectionist approaches guiding the application of DNNs?

In the current state of the art, it is not possible to determine who will have the last laugh. Yet, whatever the outcome, the rapid spread of deep learning techniques will likely have, for better or worse, a significant impact on future mathematical practices. For this reason, the current situation represents a most exciting moment in the eyes of the historian and philosopher of sciences – a moment where established certainties can and need to be regarded afresh to assess if they hold still in a context that suddenly is no longer the same. Hence, even as the symptom of a bewildered state, the philosopher can only rejoice at the reopening of those fundamental epistemological questions, hoping that a philosophical treatment of the latter can

contribute to critically assessing the stakes of the new situation and indicating novel orientations.

The present chapter intends to make a first step in this direction. As such, its primary purpose is to offer a survey of the many recent applications of neural machine learning techniques to different aspects of mathematical knowledge, calling attention to what can be of significance for a philosophy of mathematics. It will appear that, disregarding traditional boundaries in the mathematical landscape, the orientations in this emerging research area tend to be distributed following different mathematical *practices*. Yet, despite their apparent dispersion across those practices, all applications share, if only unwittingly, a common philosophical assumption. It is this assumption that the statements opening these pages announced. Namely, the idea that whatever we do when we do mathematics, we do it with *words*. More precisely, the analysis of different mathematical applications of DNNs shows that their potential success should force us to revise our conception of the relation mathematics maintains with language, and understand that and how *natural language, in its most immediate and unaffected expression, constitutes a decisive component of mathematical knowledge*.

Accordingly, the plan of the chapter is as follows. In Sect. 2, we provide a brief presentation of deep neural network models. Section 3 constitutes the principal contribution of this chapter, offering a survey of recent applications of DNN models to mathematical tasks. The section is organized into four parts, featuring four distinct lines of research identifiable in the field, according to the task assumed by researchers to characterize mathematical practice: proving theorems, manipulating objects, acquiring skills, or addressing open problems. Finally, in Sect. 4, we address the philosophical significance of those results, focusing on the relation between mathematics and natural language and the challenges for a theory of language where the semantic aspects of mathematical knowledge can be inferred from pure syntax. We conclude in a programmatic tone, indicating the perspectives open to a language-driven philosophy of mathematical practice.

2 What Are Deep Neural Nets?

A detailed presentation of DNNs falls outside the scope of these pages. Our account will thus remain deliberately simplistic, offering the elementary features needed to grasp the main characteristics of their application to mathematical tasks in the following section. Fortunately, owing to the growing popularity of AI applications in recent years, a wide range of resources are now readily accessible to the interested reader, featuring different levels of granularity and difficulty. In particular, for a systematic and detailed presentation, we refer the reader to Goodfellow et al. (2016) or Brunton and Kutz (2022). Also, Williamson (2023) does an excellent job at providing a rigorous yet brief and accessible introduction to neural nets intended for the uninformed working mathematician.

From a bird's-eye view, artificial neural networks are *parametric functions between two vector spaces*. Therefore, their application to any field relies on the

possibility of encoding some information as a vector (i.e., a list of numbers), feeding the latter into the function as an argument (i.e., the "model" 's input), and retrieving a target vector as output, to be decoded as some other kind of information. The nature of the information is assumed to be of little significance as long as it can be encoded as a vector and a vast set of examples of pairs of input and target vectors is available to train the model. Indeed, neural network architectures have been proven to be universal function approximators (Hornik et al. 1989). Therefore, given enough examples of input and target vectors, a neural net will approach a function transforming one into the other. The hope is that such an approximation will perform in some expected way for arguments outside the training data.[2] To encourage this "out-of-distribution generalization," neural models are typically trained on only a fraction of the available data (typically around 90%) and tested on the remaining held-out part.

In the most elementary cases, the internal structure of the model is composed of a series of transformations, each having a similar configuration: a linear transformation (i.e., a matrix), a bias (an added vector), and an activation (nonlinear) function. More precisely, a DNN can be described as a function $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ explicitly expressed as a composition:

$$f : \mathbb{R}^n \xrightarrow{f_1} \mathbb{R}^{n_1} \xrightarrow{f_2} \ldots \xrightarrow{f_K} \mathbb{R}^{n_K} \xrightarrow{g} \mathbb{R}^m \tag{1}$$

with

$$f_i(\mathbf{x}_{i-1}) = a(\mathbf{M}_i \mathbf{x}_{i-1} + b_i) \tag{2}$$

where $\mathbf{x}_i = f_i(\mathbf{x}_{i-1})$; $\mathbf{x}_0$ is the input vector; the $\mathbf{M}_i$ are $n_i \times n_{i-1}$ matrices representing the linear functions; the $b_i \in \mathbb{R}^{n_i}$ are the biases; the a is the nonlinear activation function; and g is the output function.

Each one of these complex transformations (i.e., each f_i) constitutes a *layer*. Hence, when a vector is fed into a layer, it is multiplied by the matrix, the bias vector is added, and the nonlinear function is applied element-wise. The *deep* character of neural nets is determined by the composition of many of these layers so that the output of one layer becomes the input of the next one until a final output vector is produced.

Finally, the model is *trained* by iteratively updating the components of the matrices and bias vectors (or *weights*) of the different layers. This is achieved by performing a gradient descent on a *loss function*, that is, on a function that measures the error between the vector output by the model and the target vector provided by

[2] This does not mean that any task is solvable by means of neural models, as a significant part of the AI community tends to think. Many problems, maybe most of them, do not accept being constructed as a predictive task based on a finite number of supposedly similar cases expressible as vectors. Problems in politics, law, art, and many other domains of social life cannot, by their nature, be framed in such terms without transforming, if not wholly obliterating that very nature.

the training set. Through an algorithm known as backpropagation, the weights of different layers are progressively adjusted so that the average error over the set of examples hopefully converges to some minimum value.

There exist many training strategies. In *supervised learning*, the target vectors are handcrafted to encode a property of the data encoded in the input vector. In *self-supervised learning* (sometimes mistaken for unsupervised learning), the target vector is some part of the input vector masked when the latter is fed to the model. Finally, in *reinforcement learning*, each output by the model receives a score through a carefully designed reward function, and the model's objective is to maximize that score.

As we said, the scheme presented here corresponds to the most elementary neural models. In recent years, DNNs have become increasingly complex and diversified, from convolutional neural nets (CNNs) and recurrent neural nets (RNNs, LSTMs) to transformers and diffusion models, to name only the most popular architectures. Those architectures remain particularly sophisticated cases of the basic model presented above. Due to their significance in the current state of the art, the case of *transformers* deserves special mention. Introduced by Vaswani et al. in 2017 and popularized by models like BERT (Devlin et al. 2018) and GPT-3 (Brown et al. 2020), the transformer architecture is characterized by the implementation of an *attention* mechanism. Simply put, the idea is to enhance each layer f_i of the net with a set of vectors capable of determining, for each component of the input vector $\mathbf{x}_{i-1}$, which other components of that vector are relevant to compute the correct output vector (i.e., which other components the component in question "attends" to). Like the linear components of the architecture, attention vectors are randomly initialized and jointly trained with the rest of the model. Among other technical advantages, the attention mechanism allowed the exploitation of parallelism during training, significantly reducing the training time and paving the way for a massive increase in scale, both of model size (parameters) and training data through self-supervised learning. Since their introduction, transformers have exhibited surprising capabilities across the most diverse tasks and domains and have been widely adopted, defining the state of the art at the moment of writing these pages.

3 How to Do Maths with Neural Nets

Applying DNN models to the processing of mathematical knowledge is not a straightforward and unambiguously defined task. As is usually the case with current AI applications across domains, craftsmanship in computational models is sometimes more prominent than proficiency in the objects those models are expected to analyze. Accordingly, the different DNN applications to mathematics are determined less by a refined elaboration on the nature of mathematical objects and knowledge than by the AI researcher's implicit assumptions as to what characterizes a mathematical task. Given the current exploratory state of a field that evolves at a remarkable speed, the answers to this unraised question are multiple, with new results and sometimes original perspectives released on a monthly basis. Any ambition to

provide an exhaustive account of the current state of the art is, therefore, doomed to fail from the start. Hence, we will content ourselves with presenting what we recognize as the main trends underlying these developments. Significantly, those trends are informed by their implicit understanding of what it is that we do when we do mathematics. From this perspective, it is possible to identify four main trends in the field, depending on whether the research is oriented toward finding *proofs*, manipulating *objects*, acquiring *skills*, or supporting *heuristics*. The following sections present each one of these orientations, providing some details of what we identify as their respective seminal papers, and briefly accounting for a few landmark results and developments.[3]

3.1 Proof-Oriented

What can certainly be taken as the first significant attempt to apply by then well-established DNN models to the solution of mathematical tasks dates back to 2016, with the *DeepMaths* paper by Alemi et al. (2016). This work pioneered a prolific line of research oriented by the implicit assumption that theorems are the key to mathematical knowledge and theorem proving constitutes, therefore, the heart of mathematical practice. Accordingly, from this perspective, the main goal is to train DNN models to find *proofs*. Ideally, one would train a neural net on an extensive corpus of existing proofs, after which one could feed a yet unproved mathematical statement (a "conjecture") to the model, which would output a proof, if any. Notice that this is not the same as constructing a logical framework for automatic theorem proving because there is no definition of an explicit logical system in this case. One could imagine logical systems to be just a specific kind of function – even if a partial one – mapping the domain of statements onto that of proofs, and we are asking the neural model to approximate such a function.

Researchers within this trend tend to think that solving this task is practically sufficient to automate mathematical practice altogether. Indeed, in a paper significantly entitled *Towards the Automatic Mathematician*, Rabe and Szegedy (2021) affirm: "Ideally, we could simply talk to an automatic mathematician like a colleague, and it would be able to contribute to mathematical research, for example by publishing papers without human support." While the authors vaguely mention other tasks such as "formulate and explore its [the automatic mathematician's] own theories and conjectures," theorem proving is acknowledged as "an important instrument of our plan" and, indeed, the only strictly mathematical task considered in their manifesto.

[3] The reader should keep in mind that, despite our efforts to cover as much of the field as possible, the following constitutes only a partial view on the state of the art, biased toward works exhibiting philosophical interest. A more precise perspective can be obtained by inspecting the "Related Work" section usually included in the papers we will present. Lu et al. (2023) also provide a useful systematic survey of DNN models for mathematical reasoning.

In practice, however, things are more subtle. Actual research in this direction has focused chiefly on specific subtasks identified within the framework of existing interactive or automated theorem provers (ITP/ATP), such as E, HOL Light, Mizar, Metamath, Isabelle, or Lean. The focus is mainly put on those tasks that represent computational bottlenecks. In particular, there has been intensive research on *premise selection*, namely, "the selection of a limited number of most relevant facts for proving a new conjecture" (Alemi et al. 2016, p. 1). This task was the one motivating Alemi et al.'s (2016) pioneering work, where it was implemented as establishing the pairwise relevance between conjecture and axioms by learning to predict the usefulness of given axioms in the proof of given conjectures. The overall strategy consists in feeding both a conjecture and an axiom into the model, processing the input vectors independently through different network architectures producing intermediate vector representations of various kinds, concatenating those vectors, passing them to a fully connected DNN, and outputting a probability measure of the usefulness of the axiom for proving the conjecture (see Fig. 1). The dataset used was the Mizar Mathematical Library, a library of almost 60K theorems proved in Mizar, together with unnamed top-level lemmas. The input axioms and conjectures were then the strings (i.e., sequences of digital characters) representing the first-order logic formalization extracted from the Mizar Library (see Fig. 1 for an example). The authors tested two ways of feeding these texts into the model: character by character and word by word (token by token). In the latter case, tokens recognized as identifiers were mapped onto their already processed definition. Other than that, the expressions were fed sequentially with no parsing information. For each conjecture, the model was trained to produce a probability distribution over the set of possible premises. To evaluate the model, the authors assessed the number of conjectures that could be proved from the top-k premises in the corresponding probability distributions (for different values of k) using the E automated prover. They also evaluated the ranking quality, measuring if relevant premises appeared at the top of the rank. Such measures were then used to compare the different DNN architectures.

The results obtained by the best of those early models exhibited a slight increase in performance compared to existing benchmarks. Although modest, the outcome was far from wholly unreasonable, showing neural models could compete with more

classically engineered techniques and handle mathematical proofs to some extent. This work sparked then a series of other studies in the same direction, where the integration of neural techniques within ITPs and ATPs can be seen to increase. For example, Loos et al. (2017) provided evidence that integrating neural techniques for premise selection in the proof search procedure of the E ATP results in an increased amount of theorems proved under time and memory constraints. On the training side, Kaliszyk et al. (2017) proposed a new dataset for higher-order theorem proving, comprising over 2 million training examples of proof steps extracted from almost 11,400 proofs formalized by humans in the HOL Light ITP. The authors also provide a series of benchmarks for different machine learning models over that dataset. HOL Light was also used by Bansal et al. (2019) to propose a different training strategy, adding to the usual supervised learning on human proofs a reinforcement learning step. Instead of being trained to predict the correct premise, the model interacts as an "artificial agent" with the ITP, proposing both a tactic to be applied and a rank over the set of possible premises. The success or failure of the ITP to apply the received tactics on the premises is then used as a reinforcement signal to train the model to predict pairs of tactics and premises.

With the evolution of this line of work, researchers started considering a wider range of theorem proving subtasks. Kaliszyk et al. (2017), for example, mention, among others: "Predicting whether a statement is useful in the proof of a given conjecture," "Predicting whether a statement is an important one (human named)," "Predicting the name given to a statement," or "Generating the conjecture the current proof will lead to" (p. 4). Bansal et al. (2019) add some others to that list, such as predicting the same tactics as the human proofs or predicting goals and subgoals. Also, *tactics prediction* has gained increasing attention due to the significance of ITPs and ATPs in the concrete developments of this research orientation (Bansal et al. 2019; Paliwal et al. 2019; Lee et al. 2020). More generally, recent years have seen a proliferation of datasets, models, and benchmarks, which contribute to the expansion of this perspective.

The arrival of the *transformers* architecture (Vaswani et al. 2017) brought about new developments in neural theorem proving. As we saw, transformers are designed to deal with sequential data in a self-supervised and highly scalable way. Their success in the field of AI is inseparable from the surprising capabilities exhibited in the processing of natural language, motivating the emergence of so-called *Large Language Models* (LLMs). We will have the opportunity to say more about LLMs in the *Skill-Oriented* section below. For now, it is sufficient to note that, encouraged by their linguistic capabilities, researchers have explored multiple ways to utilize transformer-based models for neural theorem proving.

A noteworthy case is *GPT-f* (Polu and Sutskever 2020), an automated prover and proof assistant for the Metamath language, which was capable of significantly outperforming the state of the art in neural theorem proving at the moment of its publication. *GPT-f* is based on a model architecture similar to GPT-2 and GPT-3, the celebrated LLMs by OpenAI. It is designed to perform backward proof search, starting from a root goal and exploring tactics possibly leading to such a goal. The process may involve identifying other subgoals for which new tactics are explored

iteratively (with a prespecified bound on the iterations) while keeping track of the tree structure. The neural model is therefore trained to predict a "proofstep" (i.e., a tactic and the corresponding subgoals) for a given goal, both encoded as strings, which are then passed on to the Metamath kernel for formal verification. The use of transformers has the advantage of unifying the neural architecture, as opposed to using complex combinations of different architectures as in previous models. It also allowed for pretraining as a language model over various kinds of corpora (cf. LLMs in the *Skill-Oriented* section), including the mathematical fragments of *arXiv* and *StackExchange* as well as computer code from *GitHub*. Other than achieving a new state of the art for Metmath (56.22% closed proofs in the test set vs. 21.16% for the best existing models at the time), the authors could show that, within this framework, both language modeling pretraining (especially on mathematical corpora) and increased model size result in improved performance. Interestingly, *GPT-f* could generate 23 shortened proofs of existing statements in the Metamath library, reported as enthusiastically received by members of the Metamath community. For the authors, this was "the first effective contribution of a deep learning system to a formal mathematics library" (Polu and Sutskever 2020, p. 14).

One of the drawbacks of transformer architectures is that their high performance is conditioned to training over a massive amount of data, orders of magnitude larger than existing hand-crafted mathematical libraries. A common strategy has been to augment the latter with synthetic data generated in various ways out of known mathematical properties and algorithms (cf., for instance, Wang and Deng 2020). However, Polu and Sutskever (2020) showed that scaling the portion of synthetic data up to 5% of the training data actually hurt the performance of their model. While the authors did not inquire into the reasons for this empirical behavior, they proposed an alternative way to circumvent the scarcity of proof data by training a "value function" helping to guide the proof search more efficiently. Essentially, such a function predicts the probability that a subgoal is actually used in the final proof. The function is trained on a synthetic dataset produced by sampling proofs *from the trained neural model itself*, keeping *only those that the formal verifier can prove*. Their experiments show that the iterative use of this procedure, also known as *expert iteration,* leads to significantly better results, suggesting a strategy of "continuous self improvement." Following this line of research, Lample et al. (2022) showed that replacing this iterative process with an *online training* over proofs generated by the model and verified by an ITP results in substantial performance gains.

In recent years, the success of DNN models – and transformers in particular – in the processing of natural language motivated what can be conceived as a subtle but notable reorientation of the research efforts within proof-oriented approaches toward what came to be known as *autoformalization*. In a highly programmatic paper, Szegedy (2020) defines an autoformalization system as "an automated system that is capable of automatically formalizing significant portions of mathematics from a natural language input and verifying it automatically" (p. 4). From this perspective, formalizing essentially means expressing statements as computer programs susceptible to be verified computationally following transformation rules. Implicit assumptions concerning the nature of mathematics within this body of work become here

explicit: "Mathematical reasoning is just reasoning about anything specified formally" (p. 4). Yet, this recent turn pushes these assumptions further and presents autoformalization as a natural step toward AI models endowed with "general reasoning" capabilities. In this way, mathematical practice, which had already been reduced to formalizing practices, is spontaneously raised to the level of "the discipline of pure reasoning": "Mathematical reasoning is not about mathematics per se, it is about reasoning in general" (p. 3). The distance between thought and mathematical thought becomes thus so misty it is then "natural to ask: Will we ever arrive at the point where an AI agent can learn to do reasoning as well as the best humans in the world in most established domains of mathematics" (p. 4).

However, all these prejudices about mathematics, reasoning in general, and the best humans in the world should not divert our attention away from an essential fact: This somewhat unexpected emergence of informal mathematics through natural language at the heart of the most extreme attempts to fully automate theorem proving looks more like an admission of weakness than a *tour de force*. Indeed, when one examines the recent evolution of DNN models, it is easy to identify a subtle glide away from highly measurable functions toward more informal tasks, such as text and image generation. For the latter, unforeseen capabilities can be achieved across multiple fields, including mathematics and programming. Yet, the counterpart of that originality is a loss of robustness and reliability, all the more fundamental that failure is intrinsically more difficult to assess in informal settings (how can a poem or a picture be "incorrect"?). The very nature of this success, *informal by design*, together with the relative scarcity of formal proof corpora, left AI researchers little choice other than focusing on bridging a gap secretly undesirable for most of them between formal methods on one side and neural linguistic models on the other.

Besides explicit or implicit motivations, recent explorations of natural language expressions of mathematical statements such as Ferreira and Freitas (2020, 2021) and Welleck et al. (2021), and autoformalization tasks in particular, are of interest in their own right. A noteworthy work concerning the latter is that of Wu et al. (2022), exploiting the "few-shot learning capabilities of LLMs" to produce translations into Isabelle code of natural language mathematical statements and problems contained in the MATH (Hendrycks et al. 2021b) and MiniF2F (Zheng et al. 2022) mathematical competition datasets. The relative success of this approach is nonetheless remarkable considering the negligible amount of aligned pairs of informal-formal expressions expected to be present in the vast training corpus of the LLMs. Autoformalization faces, however, the challenge of articulating the high-level structure of informal proofs with the low-level details required for automated proving. To address this difficulty, Jiang et al. (2023) proposed a method where an initial informal statement is associated with an informal proof *draft* (either through available data or through automatic generation by an LLM), which is, in turn, broken down by an LLM into a formal proof *sketch*, i.e., a high-level structure of formal statements, to be then passed on to an ATP. The experiments on the miniF2F dataset suggested that this strategy is indeed capable of successfully guiding the ATP and boosting its proving capabilities, with comparable results for the cases where the informal drafts were produced by humans or LLMs.

Considering the development of this research orientation from its inception up to the current state in 2023, one thing seems clear: Despite a declared inclination toward end-to-end black-boxed models inherited from AI perspectives and coated with multiple ideals of intelligent machines and dispensable humans, DNN applications to theorem proving have actually become increasingly reliant on existing (nonneural) interactive or automated theorem provers. To the extent that, as of today, it is hard to imagine how the latter could be dispensed with. And yet, against all odds, neural techniques have proved to contribute to the performance of formal theorem proving within those frameworks. So much so that a hybrid strategy, integrating neural techniques and I/ATPs, appears today as a promising research program for the years to come. In this sense, Jiang et al. (2022) proposed a framework for neural models to interact with any hammer-enabled ITPs, showing that neither the neural model nor the ITP alone can match the performance achieved by their careful integration. However modest and far from its promises the contribution of neural nets may be, the latter have at least succeeded in making such contributions through means that were entirely out of the radar of traditional formal methods. From a philosophical standpoint, the leveraging of informal expressions resulting from various mathematical practices, and the reliance on natural language in particular, are distinctive features of this approach, to which we will have the chance to return. For now, let us say that, despite the significant challenges and the ideological noise surrounding AI applications to theorem proving, DNNs have shown that they can do *something* with mathematical proofs.

3.2 Object-Oriented

A second research orientation for applying DNN methods to mathematics shares a similar use of the learning models with the first. However, the focus is put on manipulating mathematical *objects* rather than statements. Admittedly, proofs can also be understood as mathematical objects, in which case proof-oriented approaches could also fall under this category. At any rate, as learning models, DNNs are, in principle, indifferent to this distinction. Yet, both from a philosophical and a formal standpoint, there is arguably a significant difference between, say, manipulating numbers to perform arithmetical operations and proving a general arithmetical property for a possibly infinite set of numbers.

In line with the neural models' general setting, the goal in object-oriented mathematical applications is to feed the expression of a mathematical object (e.g., equation, terms of a series, etc.) into the model and expect the latter to output some specific result or property associated with it (e.g., solution, recurrence relation, etc.).

The most elementary case of this strategy is given by arithmetical operations and their corresponding results. Early assessments of deep neural models already showed that recurrent architectures (RNNs) could be trained to perform integer addition and multiplication based on binary representations with strong generalization capacities (Łukasz Kaiser and Sutskever 2016). Those results were extended to include decimal multiplication through a binary encoding of each decimal digit (Freivalds and Liepins

2017). Notice that, in all cases, from the model's perspective, input numbers are simply *tokens*, so there is no reason a priori that their numerical content is preserved when represented as the usual sequence of digits, hence the binary representation preferred by these early approaches. Indeed, Trask et al. (2018) showed that other numerical representations exhibit serious difficulties generalizing outside the range of values seen in training and proposed to enhance neural models with a specific architecture designed to incorporate an inductive bias for numerical computation.

More recently, researchers have explored the capabilities of DNNs to perform numerical calculations on more complex mathematical objects. A landmark in this sense is the work by Charton (2021), training transformers to compute solutions to linear algebra problems, including transposition, addition, multiplication, and inversion of matrices, as well as eigenvalues, eigenvectors, and singular value decomposition (SVD). His results showed the models can indeed compute approximate solutions with high accuracy, generalizing out of their training distribution under certain conditions and even extrapolating to larger numbers. Unlike most of the work presented in the previous section, models were here trained on synthetic corpora specially tailored for the intended tasks. This work is emblematic of an object-oriented approach; therefore, it is worth examining it more closely.

The input and output in Charton (2021) are, then, matrices of real numbers. However, their representation was carefully designed to fit the kind of data on which transformers are known to exhibit high performance, namely, sequential data. Matrices were thus encoded as sequences of coefficients prefixed with the matrix dimensions. Remember that each term in a sequence is simply a token. For this reason, numerical coefficients were also encoded following very precise rules. Based on the general principle that real numbers can be represented by a triplet of a sign, a mantissa, and an exponent, four alternative encodings were proposed for that purpose: base 10 and 1000 encoding of the mantissa, signed base 1000, and floating point (see Table 1 for Charton's (2021) original examples). Datasets were produced by online sampling dense random matrices, from 5×5 up to 15×15 dimensions, with coefficients sampled uniformly within the interval (–10, 10). The data was used to train a transformer for the various tasks studied. For all tasks, an output sequence of tokens was considered a correct solution if it could be decoded as a matrix and represented a correct solution within a predetermined numerical tolerance.

Under those conditions, the study showed that DNNs can perform matrix transposition – which does only involve permutations of tokens in the sequence, without arithmetic operations – with practically perfect accuracy. This is also the case with

Table 1 Examples of different encodings for numerical coefficients in Charton (2021)

Encoding	3.14	$-6.02.10^{21}$	Tokens/ coefficient	Size of vocabulary
P10	`[+, 3, 1, 4, E-2]`	`[-, 6, 0, 2, E21]`	5	210
P1000	`[+, 314, E-2]`	`[-, 602, E21]`	3	1100
B1999	`[314, E-2]`	`[-602, E21]`	2	2000
FP15	`[FP314/-2]`	`[FP-602/21]`	1	30000

matrix addition up to 10 × 10 dimensions and 1% tolerance, with a slight decrease in performance for matrices of larger sizes. The model's accuracy dropped noticeably when trained over matrices of different sizes. Although more complex, matrix multiplication presented very similar results to addition, but only for the first two numerical encodings. The study also exhibited surprisingly high performance in the much more complex task of eigenvalue computation. The correct prediction of eigenvectors remained restricted to matrices of small sizes. However, the accuracy increases with the numerical tolerance, indicating that *errors are not random but somewhat akin to rough approximations*. Matrix inversion proved to be hard for DNNs, with no more than 80% accuracy at 5% tolerance. Finally, while achieving high performance on 4 × 4 matrices, SVD could not be predicted for matrices of 5 × 5 or more dimensions.

The fact that the properties of the objects under analysis are well-known contributed to providing many principles of interpretability for these results, both for the success and the failure cases (Charton 2021, 2022). In this way, Charton could show that, for eigenvectors, even when the predictions were incorrect, the model correctly learned some underlying properties, such as their unit norm and their orthogonality. Also, a fine-grain analysis of the metric used in matrix inversion could show that failures were to be attributed to the computation of matrix inverses rather than the neural model itself. The study also provided evidence against the possibility that the results depend on the model simply memorizing the data and could point to strong predictors of success or failure for some of the most challenging tasks. Overall, this work showed that the success of DNNs in performing numerical calculations on matrix operations is highly dependent on the encoding (the best being P1000 and FP15), with greater difficulty for increasing matrix size and the capacity of generalizing out of the training distribution if the latter is carefully chosen.

The solution of partial differential equations through DNN techniques has also been the object of much research effort. Blechschmidt and Ernst (2021) provide a survey of approaches to numerical solutions. However, Lample and Charton (2020) introduced an original perspective, testing the DNNs' capabilities to solve differential equations and integration *symbolically*. The overall strategy of this seminal paper was to feed a function or a first- or second-order differential equation as input and require the model to output its integral or its solution, respectively. Here, too, we find that the training corpora were carefully designed for the intended tasks. In particular, mathematical expressions of functions and differential equations were represented as binary trees, where the internal nodes represent operators, while the leaves can represent either numbers, constants, or variables. The trees were then sequentialized through prefix (i.e., Polish) notation by enumerating nodes in prefix order and then encoded as a vector to be fed into the model (see Fig. 2 for an example). As the authors observe, using trees to represent expressions also provides a principled way to tackle the otherwise thorny problem of sampling from an expression space. Training and test datasets were carefully constructed using Mathematica to produce pairs of equations and solutions, which were then turned into the chosen representation and carefully cleaned up to eliminate any possible source of noise. The model used was an early version of a transformer, considered by the authors as a sequential model aimed at natural language translation.

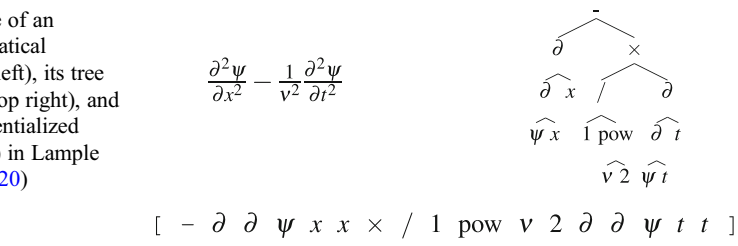

Fig. 2 Example of an original mathematical expression (top left), its tree representation (top right), and the latter's sequentialized version (bottom) in Lample and Charton (2020)

Relying on all this careful handcrafting of the mathematical object's representations, the authors trained models on five tasks, each one relying on a dedicated synthetic dataset: integration of randomly generated functions solvable by a computer algebra system; integration of derivatives of randomly generated functions; integration of the composition of one random function and the derivative of another random function (i.e., integration by parts); first-order differential equations; and second-order differential equations. Under the precise conditions established by the authors, the corresponding models exhibited surprisingly high scores across those tasks, with close to 100% accuracy for the different kinds of integration and around 80% and 40% for ODEs of orders 1 and 2, respectively. The latter could be brought up to around 94% and 73% when considering if at least 1 of the top 10 hypotheses output by the model was correct (and 97% and 81% for the top 50). These results outperformed those of computer algebraic systems such as Mathematica (under runtime constraints), Matlab, and Maple. Generalization outside the training distribution proved challenging. However, the authors showed that the reason was a systematic bias toward specific lengths for the expressions of problems and solutions in different datasets. Training on mixed datasets substantially increased the performance on problems outside the training distribution.

While neural frameworks had been shown to successfully process symbolic properties of mathematical propositions and numerical properties of mathematical objects – at least to some extent – the relevance of Lample and Charton's (2020) work lies in the capacity of bridging the gap between both orientations by operating on objects through their symbolic expression. The application of DNNs to *symbolic regression* provides another significant confirmation of this potential. Symbolic regression is the task of finding the symbolic expression of a function given some of its values. Before the emergence of current DNN models, symbolic regression methods relied on evolutionary algorithms. Early applications of deep neural techniques to this task include Martius and Lampert (2016); Udrescu and Tegmark (2019); Kim et al. (2019); and Petersen et al. (2021), where different kinds of DNNs are used to improve the exploration of the space of possible mathematical expressions, in search of the one that best fits the set of given values. Martius and Lampert (2016), for instance, propose a model where, activation functions correspond to symbolic operators acting on different dimensions of each layer, in such a way that, after training the model through backpropagation, the symbolic expression can be read out of the learned coefficients. Petersen et al. (2021) adopt a different

strategy, where syntactic properties of symbolic expressions are encoded as constraints within a generative recurrent architecture, which is then trained through reinforcement learning. In all these cases, training takes place within one set of values (i.e., corresponding to one function) so the learning procedure only concerns the selection of the symbolic expression for those values. More recently, an alternative approach has been proposed, more in line with current trends in AI: The model is trained on pairs of sets of values and corresponding symbolic expressions, learning to predict the latter from the former (Biggio et al. 2021; Valipour et al. 2021; d'Ascoli et al. 2022; Kamienny et al. 2022). From this perspective, *the symbolic expression appears as yet another property of a mathematical object* (e.g., a function) initially given through numerical expressions. Significantly, symbolic regression thus becomes a special case of language modeling, as Valipour et al. (2021) point out: "Symbolic mathematics behaves as a language in its own right, with well-formed mathematical expressions treated as valid 'sentences' in this language. It is natural, therefore, to consider using deep language models to address tasks involving symbolic mathematics" (p. 2).

A notable case of this recent orientation is that of d'Ascoli et al. (2022), where a neural model is trained to discover the recurrence relation holding between the first terms of a numerical sequence. The data is generated by sampling symbolic expressions of functions to produce a recurrence relation and compute the first 25 terms of a sequence. Symbolic expressions were encoded as sequentialized trees, following Lample and Charton (2020), while numbers (integers and floats) were encoded as in Charton (2021) (cf. above). A simple transformer architecture is then trained to predict a symbolic expression. Since many equivalent expressions could correspond to the initial function, a prediction is considered correct if the difference between the n following terms in the sequence computed with the predicted expression and those calculated with the initial expression is smaller than a given tolerance error. The authors showed their model could achieve an in-distribution accuracy of over 90% for integer sequences and over 70% for floats for the prediction of the following five terms (falling to 78% and 43%, respectively, for ten terms), outperforming numeric methods. The model was also evaluated on the Online Encyclopedia of Integer Sequences (OEIS, Sloane (2007)) for out-of-domain generalization, where, even if performance dropped substantially, it showed some significant results and outperformed existing methods for this task in Mathematica.

Overall, despite many limitations and somewhat modest results often concerning relatively simple and well-known mathematical objects, this line of work has shown that the generic approach provided by DNNs can meaningfully manipulate, to a significant extent, both numeric and symbolic properties of mathematical objects of different kinds (arithmetical, algebraic, analytic, etc.). Admittedly, the relative simplicity of the objects under study, whose properties are in most cases well-known, is such that these results cannot be expected to replace or even compete with existing methods and practices (at least not anytime soon). But as Charton (2021) makes it clear, this is not the purpose of this work either. Its significance lies elsewhere, namely, in showing that those well-known practices are not entirely orthogonal to the seemingly unrelated principles of neural nets. At any rate, this line of research

demonstrates that if DNNs can do something with mathematical proofs, the same can be said for mathematical objects.

3.3 Skill-Oriented

A third group of works applying neural methods to mathematical knowledge follows a different strategy than the previous two. The idea is not so much to solve specific tasks involving mathematical statements (e.g., premise selection) or mathematical objects (e.g., symbolic integration) but to endow the neural model with general mathematical *skills* so that, once trained, it becomes capable of spontaneously solving mathematically related problems.

Stated in those abstract terms, one could wonder how such a goal could have any chance of success. However, hope in this research orientation is motivated by the turning point operated by transformer architectures in the field of natural language processing (NLP) and AI more generally. The original transformer model introduced by Vaswani et al. (2017) was conceived to improve machine translation performance while significantly reducing the training time. Its superiority compared to previous models had been demonstrated in practically all NLP tasks. Moreover, when trained as a *language model*, that is, as a model producing probability distributions over words or tokens given other tokens, Saxton et al. (2019) showed they could significantly outperform the best recurrent models on a variety of mathematical tasks (including algebra, arithmetic, calculus, and probability, among others). To that end, transformers are trained on synthetic corpora where mathematical tasks are expressed in terms of natural language question answering, processed as a sequence of characters, e.g., (p. 2):

Question: `Let x(g) = 9 * g + 1. Let q(c) = 2 * c + 1. Let f(i) = 3 * i 39. Let w(j) = q(x(j)). Calculate f(w(a))`
Answer: `54 * a - 30`

However, the true power of transformers was revealed with the emergence of what came to be known as *Large Language Models* (LLMs). Taking advantage of the scaling capabilities of transformers, primarily due to their exploitation of parallelization, the distinctive feature of LLMs lies in their training strategy. Popularized thanks to the BERT model (Devlin et al. 2018), the idea is to train, or "*pre-train*" as it is referred to in the field, a transformer architecture in a highly generic self-supervised fashion, namely, by learning to predict random masked words in natural language sentences over a gigantic amount of natural language text (typically scraped from all over the Internet). Despite its apparent simplicity, working in an autoregressive generative fashion,[4] such training endows the model with the general capacity to perform a large variety of natural language tasks in the form of a text to

[4] That is, iteratively generating text one word at a time from a sequence of words initially given, recursively augmented by the words produced by the model.

Table 2 Example texts of the three tasks examined in Shen et al. (2021)

Task	Text
Knowledge component prediction	Simplify the expression: (z2)2 Put parentheses around the power if next to coefficient, for example, $3x2=3(x^2)$,$x5=x^5$
Question answer scoring	Q: Explain your answer on the box below A: Because it is the same shape, just larger, making it similar
Knowledge tracing correctness prediction	Q: What is $2.6 + (-10.9)$? A: -8.3

be generated as the continuation of a given prompt. Once pretrained, the model can be further trained or "*fine-tuned*" on a significantly smaller domain-specific dataset, to perform tasks expressible in natural language and normally requiring domain-specific skills. A variant of this "transfer learning" strategy was introduced by the celebrated GPT-3 model (Brown et al. 2020), aiming to circumvent the need for fine-tuning by drastically scaling up both the model size and the training data.[5] This change in scale afforded generative pretrained transformer models a unique feature, known as "in context-learning," namely, the capacity to perform domain-specific tasks without any further training, just by prompting the model with a few examples or a short description of the intended task. Thus, once the model has been pretrained, one can input a short text with a few examples of, say, pairs of grammatically incorrect/correct English sentences before yet another incorrect sentence, after which the model will continue the text autoregressively, outputting the correct counterpart. Surprisingly, this highly unexpected behavior holds with reasonable accuracy for a remarkably wide range of tasks.[6]

Within this line of research, it became natural to prompt the generic model with tasks requiring mathematical skills, either after fine-tuning the model on mathematical data or in an in-context fashion. Shen et al. (2021), for instance, evaluate the performance of the original pretrained BERT model when fine-tuned for three general tasks associated with mathematics education: large-scale knowledge component prediction, open-ended question answer scoring or autograding, and knowledge tracing correctness prediction (see Table 2 for examples). Their work shows that such a model achieves a performance of almost 92%, 89%, and 87% for the three tasks, respectively (the first and third measured as accuracy, the second as area under the curve). Moreover, the authors could improve this baseline by adding a pretraining step on a dedicated mathematical corpus between the original pretraining and the fine-tuning. The mathematical corpus included paper abstracts from arXiv,

[5] Whereas BERT contained a maximum of 340 million parameters in its original version, and at the time of GPT-3's release, the largest model contained 17 billion, GPT-3 was composed of more than ten times this number: 175 billion parameters. As for the data, GPT-3 was trained on 500 billion words (tokens) compared to 3300 million for BERT.

[6] For a comprehensive account of LLMs, see Bommasani et al. (2021). For a precise yet accessible presentation of the mechanisms behind GPT, see, for instance, Wolfram (2023).

college MOOC syllabus, and textbooks and curricula ranging from prekindergarten to college graduate level.

As for in-context learning, the original GPT-3 paper by Brown et al. (2020) already showed the arithmetical skills of such a generic model, in particular, by trying to perform up to five-digit elementary arithmetic. The model is thus prompted with a few cases (typically a dozen) of arithmetic operations expressed in natural language, such as:

```
Q: What is 24 times 42?
A: 1008
```

ending with a line that stops at `A:`, after which the model is expected to fill in the subsequent text, hopefully with the correct answer to the last question. GPT-3 exhibited an accuracy of almost 100% on two-digit addition and subtraction and over 94% and 80% for three-digit subtraction and addition, respectively. These results are certainly surprising considering the model was never trained to perform such a task, but only to predict the next token given previous tokens. In addition, the authors provided evidence that only a negligible number of arithmetic problems tested could be found in the training data, suggesting that the model's performance cannot be attributed to simple data memorization. Nogueira et al. (2020) later showed that the capacity of LLMs to perform elementary arithmetical operations was highly dependent on the textual representation of numbers. By fine-tuning a pretrained T5 model (Raffel et al. 2019) on textual expressions like the ones used in GPT-3, the authors demonstrated that, while single-token decimal notation performed very poorly, representing numbers as digits separated by powers of 10, either using scientific notation or not (e.g., `3 10e1 2 10e0` or `3 10 2` for 32), could afford the model almost perfect accuracy for the addition of numbers up to 15 digits. Their study also confirmed the importance of pretraining on generic masked language modeling: A transformer trained from scratch needs ten times more training examples to reach the same performance on addition as a pretrained model.

A noteworthy characteristic of this approach is that *any mathematical problem is treated by expressing it in natural language* (see, for instance, Griffith and Kalita 2021; Meng and Rumshisky 2019; Cobbe et al. 2021). Yet, as surprising as those elementary results may be from a conceptual standpoint, tasks requiring mathematical skills have proved challenging for LLMs generically trained on natural language data when compared to other (mostly linguistic) tasks, such as machine translation, summarization, or sentiment analysis (see, for instance, Hendrycks et al. 2021a; Davis 2023). As suggested above, a possible strategy for the skill-oriented line of research to remain relevant despite this difficulty is to further train pretrained LLMs on large amounts of mathematical (or mathematically related) texts. This further training remains generic, in the sense of not being oriented toward any specific task: The training continues to take place as language modeling. A good example of this approach is provided by the Minerva model (Lewkowycz et al. 2022), where the PaLM LLM (Chowdhery et al. 2022) is further trained on a vast

mathematical and scientific dataset built from the arXiv preprint server and mathematical webpages scraped from the Internet. The objective is to be able to perform both numerical calculations and symbolic manipulation without training on specific tasks or relying on principles foreign to the neural architecture (like a calculator or a compiler). To improve the performance, the model also implements a series of techniques, including prompting methods that encourage detailed answers and majority voting on samples of possible results to a question. A distinctive feature of Minerva is that, unlike typical language modeling training, mathematical expressions are not normalized to keep only the natural language text but include the syntax of mathematical typesetting systems such as LaTeX and MathJax. Thus, an expression like $E = mc^2$ is represented as the string `$E=mc^2$` instead of `Emc2`. In this way, the model input and output can include a more precise representation of mathematical expressions. With all these tweaks and tricks, Minerva was able to significantly outperform previous models on different mathematical benchmarks, including high school, college, and graduate math problems and STEM-focused language understanding problems, with gains of up to 30% in some cases. Figure 3 shows an example from the MATH dataset correctly solved by Minerva. The model exhibited an accuracy of over 50% on this dataset, compared to less than 20% for existing neural models at the moment of publication.

The challenges faced by a skill-oriented approach are more than just technical. Among others, the notion of "mathematical skill" is difficult to characterize. The field has progressively converged to an implicit agreement assuming an institution-centered answer to this question: mathematical skills are the ones measured by formal education tests, exams, and competitions. This choice is reflected in the benchmarks established by the field, which are essentially composed of textbooks and curricula from different educational levels, national (which often means: American) admission tests, like the Scholastic Assessment Test (SAT), and institutional competitions such as the International Mathematics Olympiad (IMO). But such a choice is as uncritical as it is unreflective. Historical, geographical, and social biases

Question: A line parallel to $y = 4x + 6$ passes through $(5, 10)$. What is the y-coordinate of the point where this line crosses the y-axis?

Target: Since the line is parallel to $y = 4x + 6$, we know that its slope is 4. Thus the equation of the line is $y = 4x + b$ where b is the y-intercept. Plugging $(5, 10)$ into this gives $10 = 4 \cdot 5 + b \Rightarrow b = \boxed{-10}$ which is what we wanted.

Model output: The line is parallel to $y = 4x + 6$, which means that it has the same slope as $y = 4x + 6$. Since the line passes through $(5, 10)$, we can use the point-slope form of a line to find the equation of the line:

$$\begin{aligned} y - 10 &= 4(x - 5) \\ y - 10 &= 4x - 20 \\ y &= 4x - 10 \end{aligned}$$

Now that we have the equation of the line, we can find the y-coordinate of the point where the line crosses the y-axis by substituting $x = 0$ into the equation:

$$y = 4 \cdot 0 - 10 = \boxed{-10}.$$

remain unassessed. Also, the field's research habits leave no room to address the consequences of reinforcing a school-like conception of mathematics, which is fundamentally focused on performance due in part to the uninterpretable characteristics of the proposed models. Let alone the encouragement of an anthropomorphic image of neural models resulting from the idea that they can acquire skills and "beat" humans on tests designed for specific human purposes. Yet, if we refrain from taking these models at their face value and admit from a critical stance that the notion of mathematical skill is not independent of how educational institutions measure it at a given space and time, the performance exhibited by these models appears no less surprising. Compared to the previous orientations, the lack of dedicated model architectures (like in proof-oriented cases) or datasets (as in object-oriented approaches), as well as the highly unstructured and underspecified goals and means characterizing the skill-oriented perspective, endows those results with enough room for philosophical inquiry.

3.4 Heuristic-Oriented

The fourth and final research orientation differs from the previous ones in that neural models are not conceived as generic devices performing multiple tasks in a way supposedly akin to human agents. Instead, the idea is to use neural nets as *tools* addressing specific aspects of advanced open problems in mathematics in order to guide the intuition of mathematicians at work. From a philosophical perspective, this approach can be deemed one of the most sensible and fruitful, if only because it grants a central place to working mathematicians, whose judgment is arguably indispensable when mathematical practice is not reduced to reproducing existing mathematical knowledge. However, this orientation is the most underdeveloped in the current state of the field. Many factors may explain this situation, starting with ideological reasons, related to a widespread belief in the field viewing AI systems as agents imitating, competing with, and ultimately replacing human agents. Such a position is not independent of economic conditions in a field that is largely driven by corporations. In its current state, AI research is not separable from profit-seeking through the development of market products, and the market size of advanced mathematical research is negligible compared to the one defined by the automation of known mathematical tasks in business and education. Finally, from a sociological perspective, the development of this orientation requires the close collaboration of two very different research communities, namely, professional mathematicians (often in the area of pure mathematics) and applied computer scientists and engineers, which represents an additional challenge to the success of the attempts in this direction.

As a result of their heuristic nature, works belonging to this category are less characterized by unified methods, frameworks, and goals than by the individual adaptation of new machine learning tools to specific and highly technical mathematical problems. Accordingly, this orientation might be better presented through concrete cases rather than general trends. We will present two such cases, which

represent two important aspects of mathematical heuristics: forming *conjectures* and searching for *counterexamples*.

Early uses of deep learning for conjecture generation can be found in Hughes (2020); Carifio et al. (2017); Levitt et al. (2019); Jejjala et al. (2019); and Heal et al. (2020). Most of this work concerned combinatorial properties in knot theory. But it was undoubtedly the paper by Davies et al. (2021) that attracted renewed attention to this line of research by presenting the use of machine learning in mathematical practice as a general framework for working mathematicians. The authors present deep neural methods as a tool "to guide [the mathematicians'] intuitions concerning complex mathematical objects, verifying their hypotheses about the existence of relationships and helping them understand those relationships" (p. 70). In their view, deep learning techniques can contribute to understanding the relation between two objects $X(z)$ and $Y(z)$ by helping to identify a function $\hat{f}$ such that $\hat{f}(X(z)) \approx Y(z)$ for some well-specified domain of z. Such a function can then be used to verify the existence of structural features in objects and understand them through attribution techniques. Accordingly, the proposed method consists in starting with a hypothesis for a function f, generating synthetic data, training a supervised model, and finding patterns through attribution techniques. The whole procedure can help mathematicians formulate conjecture candidates, informing, in turn, new hypotheses and data generation in an iterative and interactive process.

The authors of this work demonstrated the fruitfulness of their approach in the case of two open problems concerning the structure of knots and the combinatorial invariance of symmetric groups in representation theory. To better understand how neural techniques interact with mathematical objects and practices in this case, it may be helpful to examine certain aspects of this work. The result obtained concerns the connection between two distinct branches of knot theory, which could be addressed by finding relations between their respective characteristic invariants. In particular, the goal was to obtain a connection between the *signature* of a knot (a classical algebraic invariant in gauge theory), and typical geometric invariants in hyperbolic knot theory. Such a connection was not yet known in the field. The strategy was, then, to predict the signature of a knot from its hyperbolic invariants.

Using existing libraries in knot theory, the authors produced a sample set of 2,7 million knots with their corresponding invariants, divided into a train and a test set, which served to train a very classic fully connected feed-forward neural net to predict the signature from a list of hyperbolic invariants. Somewhat surprisingly, the model was able to predict the signature over the test set with very high accuracy, indicating that a connection does indeed exist between both kinds of properties of the knots. However, the high predictive accuracy can only do so much as verify that a structural connection exists. To obtain further insight into the structure of such a connection, the authors made use of gradient-based attribution techniques (saliency maps). The main idea is to measure the sensitivity of the prediction accuracy to small changes in the different dimensions of the input, which correspond, in this case, to the different hyperbolic invariants. In this way, the authors could determine that the prediction of the signature relied primarily on 3 out of 12 invariants, all 3 related to a geometric structural feature of the knot called "cusp." This observation allowed them to define

a new quantity attached to a knot, which they termed "natural slope" and used to state the conjecture that the signature was equal to the natural slope multiplied by some error. Interestingly, this first conjecture turned out to be false. Further investigation resulted in a refined version of the conjecture, including a fourth invariant also identified by the attribution analysis. This eventually led the authors to prove two theorems connecting the two kinds of invariants.

Our first example shows that the success of neural nets in targeting functions predicting some mathematical features from others can contribute to verifying and understanding structural properties of mathematical objects and formulating and refining conjectures. On the other hand, their capacity to find arguments in the domain for which the prediction fails can provide a powerful tool to discover counterexamples of existing conjectures. Such a practice can be no less informative of the objects' structure. Wagner (2021) provides a notable example of this approach. This paper uses neural models to find counterexamples and constructions to open problems in combinatorics and graph theory. The strategy adopted shows some originality compared to previous approaches. The idea is to train a neural model to find a mathematical object through *reinforcement learning*, following the success of this technique in training automatic systems to play games, such as Go. From this perspective, mathematics appears as a game where counterexample candidates are akin to possible winning moves. The model is highly general in that it requires only minimal prior knowledge, namely, the encoding of legitimate moves (i.e., the sort of mathematical construction expected) and a reward function providing a score to be used as feedback for how close the construction is from a winning move. Thus, by trying to maximize the score without knowing anything about the structure of the problem, the learning algorithm will improve the model's performance toward a winning move determined by the conjecture to be refuted.

Wagner (2021) applied this general strategy to a series of conjectures in extremal combinatorics, an area of mathematics interested in the maximum or minimum sizes of collections of finite objects (e.g., graphs) subject to some restriction. Significantly, within this framework, the general way to encode mathematic constructions is as *words*, in such a way that the combinatorial problem is translated into "a problem about generating a word of certain length from a finite alphabet" (p. 3). For instance, n-vertex graphs are represented as 0–1 sequences of length $\frac{n(n-1)}{2}$, which, as we have seen, can be generated by neural language models in an autoregressive fashion. The reward function computes a score once the entire word has been produced. The function typically includes a positive and a negative component reflecting desired and undesired properties given the problem studied. Using the reward function, the model is trained through gradient descent to minimize the cross-entropy loss.

A concrete example among the ones addressed by Wagner (2021) is a conjecture in spectral graph theory stating that for a connected graph of $n \geq 3$ vertices, with largest eigenvalue λ_1 and matching number μ, we have $\lambda_1 + \mu \geq \sqrt{n-1} + 1$. Although a counterexample to this conjecture already existed for $n = 600$, the method proposed was able to find a counterexample for $n = 19$ by setting n as a hyperparameter and training a neural model to minimize $\lambda_1 + \mu$ (set as the reward or loss function) hoping the loss would drop below $\sqrt{n-1} + 1$ for some construction

after enough training. Figure 4 shows a sample of the best construction at different moments of the training process. The last graph constitutes a counterexample for the targeted conjecture. Interestingly, while the trained model remains uninterpretable, the analysis of the evolution of the model's output during training provides some insight into the structural properties of the problem. We can see that the model first restricts the outputs to sparse graphs and then converges to a "balanced double star" structure. As exemplified in the paper, this kind of structural insight can be obtained even in the case where the model fails to provide an explicit counterexample for the problem in question, either indicating how a counterexample could be eventually obtained or providing hints as to why the conjecture holds and how it could be proved.

The relevance of neural methods for heuristic purposes in mathematical research has been called into question, for instance, by Davis' (2021) critique of Davies et al. (2021), for it is not clear what the specific value added by DNNs is compared to more classic statistical methods already in use by mathematicians in their own practice. Moreover, as pointed out by Wagner (2021), methods like the ones used in this paper are not adequate to address all problems and, as the author acknowledges, they "did not succeed in refuting any of the most famous conjectures in the field" (p. 1). Nevertheless, the renewed strengths and capabilities of statistical methods brought about by deep learning techniques are such that their most elementary application to the treatment of open problems in advanced mathematics is far from trivial, neither regarding the means deployed nor the kind of results obtained. In particular, neural methods seem to force the development of statistical approaches in fields classically considered foreign to them. Even though a heuristic use of DNNs relies more on a case-by-case approach rather than a solid general framework, it seems that the near future will show a fruitful development of works like the ones presented in this

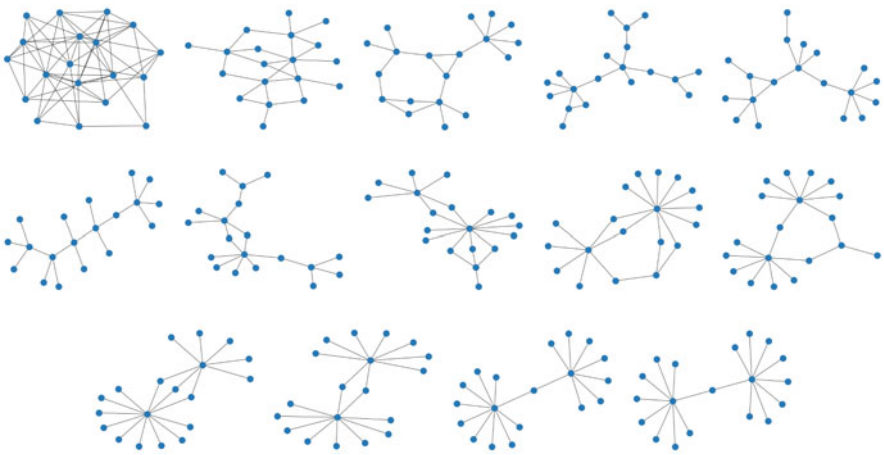

Fig. 4 Sample of the best construction over the training progress (from left to right, and from top to bottom) in Wagner (2021). The last graph (bottom right) constitutes a counterexample for the targeted conjecture

section. Consequently, this line of work could pave the way to more fundamental research on the statistical aspects of various fields in pure mathematics.

4 Philosophical Significance

Given the state of the field at the moment of writing these lines, the survey presented in the previous section is certainly fragmentary, partial, and guaranteed to be outdated by the time the reader encounters these pages. The four categories proposed to understand existing research orientations should be taken as temporary markers on moving soil rather than well-defined boundaries on a stable domain. Many of the papers presented lie at the crossroad of multiple research lines, and one can expect numerous blends of the four orientations in the near evolution of the field. It is nonetheless revealing that, faced with the renewed question of how to apply novel machine learning techniques to mathematics, instead of resorting to well-established distinctions, the research orientations tend to be spontaneously organized according to the AI researchers' implicit assumptions as to *what it is that we do when we do mathematics*. Indeed, as far as lines of research can be identified in this rapidly evolving field, they resist any traditional disciplinary (e.g., algebra, calculus, etc.), epistemological (e.g., pure, applied), or foundational (e.g., logic, set theory, category theory, etc.) categorization. Instead, they consistently explore specific *practices* assumed to characterize what mathematics is about: proving theorems, manipulating objects, acquiring skills, or addressing open problems.

The results in each identified direction exhibit countless limitations, many of which are already revealed in the literature, others yet to discover. We have referred to some of them in our account, including brittleness, poor generalization, restriction to elementary cases, lack of interpretability, absence of conceptual and theoretical foundations, and uncritical attitude toward mathematical corpora (see also Davis 2019; Welleck et al. 2022). All these limitations are real and could not be stressed enough if neural methods are to become a significant component of future mathematical practices. However, the simple fact that those mathematical practices can be addressed, if only with relative success, from the radically empirical perspective assumed by current machine learning approaches should be enough to arouse the interest of philosophers and historians of mathematics.

There are many reasons for the philosophy of mathematics, and the history and philosophy of mathematical practices in particular, to turn its attention to the recent mathematical applications of machine learning, even if, or precisely because, those reasons do not coincide with the ones advanced by the researchers in the field. Starting with the fact that, were these approaches to succeed to the point of becoming widely adopted as mathematical tools, the image of mathematics as we know it would certainly change in ways that are far from trivial, neither from a philosophical nor from a historical standpoint. Such a modification of mathematical practices would significantly impact the many dimensions philosophers and historians have become used to identifying in them, such as the role of proofs (Chemla 2012), the meaning of or even the need for foundations (Wagner 2019), the nature of

explanations (Mancosu 2008), or the role of experimental procedures (Borwein and Bailey 2003; Avigad 2008).

However, in the remaining pages, we would like to focus on a general feature underlying what, in our view, constitutes the philosophical novelty of neural models across their different applications to mathematical practices: *the renewed role of language in our understanding of mathematics*.

4.1 The Return of Language

If there is something our survey of neural applications to mathematics brings to light, it is at least the following: The success – actual or promised – of those methods in all their areas of application is inseparable from a whole new perspective on mathematical language, which goes far beyond the traditional understanding of mathematical expressions as simple notations for preexisting mathematical contents or a more or less arbitrary syntax for an independently determined semantics. The reason is that language, and more precisely, *writing*, including the wide variety of *textual forms* (statements, expressions, symbols, characters, etc.), *is all these models can rely on* to perform the mathematical tasks they are required to address. Whatever happens within the black box of a neural net happens on the basis of the processing of syntax and *syntax alone*. Granted, DNNs are not, as such, purely syntactic entities but the implementation of a relatively well-specified semantic procedure. However, such a procedure is highly generic, to the point that it can be successfully applied to very different kinds of data (images, language, sound, etc.) to perform significantly different kinds of tasks. The rapid convergence in recent years toward a single architecture (i.e., transformers) for all tasks confirms the resolve to rely on an unspecific analytic procedure. Given their generic character, it follows that if neural models can deal with mathematical content to any extent, such content is nowhere else to be found than in the corpus of (eventually supervised) textual expressions fed as inputs.

It is essential to understand that *this is not a bug but a feature* of this approach. Indeed, multiple ways exist to enhance neural models with hand-made rules and mathematical principles to increase their performance over specific tasks. As soon as accuracy becomes the primary concern, researchers do not hesitate to use all sorts of tweaks and tricks, introducing semantic features by other means. The resulting models progressively become, then, the object of an engineering practice, thus losing much of the philosophical interest concerning their relation to language. Nevertheless, the connectionist credo behind DNNs exhorts to develop learning models as generic concerning tasks as sparing regarding assumptions about the data. Consequently, whether openly acknowledged or unwittingly, current DNN applications to mathematical knowledge grant a critical place to mathematical language and textuality, providing the conditions for an original reflection on its role in the production and circulation of mathematical content.

Two primary aspects stand out when assessing the originality of the role played by language in this setting. The first is the effect of the fact that bare syntactic objects are

all these models can resort to for processing mathematical knowledge. Without dedicated axiom systems, deductive rules, logical operations, symbolic reasoning, material manipulation, or access to any other kind of context than textual, most of the conceptual focus within this line of research is put on mathematical *representations*. Be it logical statements, formulas, equations, expressions, or symbols,[7] researchers in machine learning have been led to raise the question of mathematical representations in ways that can communicate with current research interests in the philosophy of mathematics. Take, for instance, the proof-oriented approach and its reliance on multiple proof assistants' syntax to represent logical statements. The numerous strategies to process that syntax to improve the neural models' performance on inferential tasks (e.g., character- vs. token-based processing, explicit definition replacement, variable renaming, etc.) could provide novel perspectives for the design of mathematical languages, as addressed, for instance, by Avigad (2015) and "Mathematics as a Semiformal Language" (in this section). Furthermore, the various methods to encode mathematical objects in the object-oriented approaches (sequentialized binary trees for formulas, lists of numbers for matrices, different positional encodings for numbers, etc.) provide the elements for a fruitful dialogue with current investigations on the role of representations in the philosophy and history of mathematical practices, such as Schlimm (2018); Waszek (2018); and Kohlhase et al. (2018). In any case, practically no study across the different orientations fails to underline the critical character of the corpus and its representation for the success or failure of neural methods in mathematics. Yet, this centrality of representational aspects is not without novelty compared to existing philosophical perspectives on this problem. For the goal here is not to find the best representation for a given content (a suitable "notation") but the best representation for given texts so that tasks assumed to rely on their unknown content can be correctly performed by a statistical learning model such as neural nets. The careful investigation of this original question may bring unprecedented perspectives and insights into the classical problem of the relation between syntax and semantics, in mathematics as well as in language in general.

The second remarkable consequence concerning mathematical language is related to the connection between mathematics and *natural language*. Indeed, addressed as an artificial language from a modern logical perspective, most philosophical traditions have kept mathematical language apart from natural language for almost one and a half centuries. Moving away from this standard position, neural machine learning models are led to operate novel articulations between both, which are far from philosophically trivial. On a superficial level, one can find that, since many of the corpora used are composed of existing published papers (especially since the emergence of LLMs), the natural language necessarily present in those papers is usually leveraged to contribute to determining the content of mathematical expressions. A conceptual investigation on this topic is likely to provide compelling insight into the interaction between both

[7] To the best of our knowledge, there has been no work within this area of research involving the content of mathematical diagrams yet. From a different perspective, Sørensen and Johansen (2020) have used neural techniques to identify diagrams in mathematical texts.

natural and mathematical expressions in different corpora, be it from a historical perspective, in line with works such as those of Netz (1999) or Herreman (2000), or from a more cognitive viewpoint (Giaquinto 2008; Toffoli and Giardino 2013; Kohlhase et al. 2018). However, deep learning approaches bring natural language to the forefront of mathematical practice and knowledge in a more fundamental fashion. For the vast majority of the learning models and techniques used for processing mathematical expressions are none other than those specifically developed for the processing of natural language. The recent convergence toward transformer architectures also confirms this circumstance. This means that, within this setting, *mathematical expressions are treated as being themselves a sort of natural language*. This idea is not only implicit in all uses of neural language modeling architectures in mathematical applications but, as we have seen, is also repeatedly advanced by the researchers themselves across all research orientations. At odds with a view making a clear-cut distinction between natural and artificial languages or resolved to reduce the former to the latter through logical means, the success of neural methods in mathematics is inextricably tied to an essential yet unexplored link between mathematical contents and the mechanisms governing the ordinary practice of natural language. It could be, for instance, that mathematical and natural language share specific properties, or that the treatment of natural language constitutes a general framework for studying all kinds of languages, or yet that deep neural models constitute a general framework for the analysis of any type of data, including both natural language and mathematics. Whatever the case, the feats of neural models' applications to mathematics mark the return of natural language to the center of the reflection about what it means to do mathematics, in a philosophically original and compelling way.

4.2 New Challenges for a Linguistic Approach to Mathematical Practice

Despite the assumed divide between artificial and natural languages in modern philosophies of science, linguistic approaches to mathematics have not been altogether absent from the historical and philosophical scene, particularly since the emergence of the philosophy of mathematical practices. The chapters included in the current section of this Handbook provide an excellent account of much of that work. However, the many uses of neural models call for an original linguistic approach to mathematics, presenting new challenges to a language-driven philosophy of mathematics.

As already advanced, the originality lies in that *mathematical content is derived from expressions alone, semantics from syntax, meaning from pure text*. Yet, in modern mathematics, access to content is supposed to be provided through explicit and rigorous symbolic mechanisms, such as definitions within a formal language, logical operations, deductive rules, systems of axioms, or formal models. Those symbolic principles are assumed not only to determine what those expressions mean but also to control how expressions interact and what results from those interactions. Without direct access to explicit symbolic means – let alone cognitive faculties or

social conditions – it is difficult to know how the semantics or the content of expressions can be determined.

The difficulty is even greater if one considers the mathematical content DNNs manipulate is not limited to *referential* aspects of expressions. Indeed, the solution of mathematical tasks requires much more than associating, for instance, the expression `406` to a particular number or quantity, or to the same entity as the expression `four hundred and six`; it goes beyond referring the expression `A∧B` to a logical conjunction or $y''-y=0$ to a differential equation of second order. The tasks in question require, in addition, that enough *operational* content is involved when determining that `406` added to `326` equals `732`, that `A∧B` is likely or unlikely to be a premise in the proof of some given logical statement, or that $y(x)=c_1e^{x}+c_2e^{-x}$ is the solution to that differential equation.

Resorting to how content is dealt with in natural language, as most models do, might sound promising because the range of expressions does not depend, in this case, on explicit rules and other artificial procedures – typically absent in neural models – but tends to rely on more "natural" mechanisms. The latter could be invoked as being also at work in the relation between mathematical expressions and their content to explain the surprising capabilities of neural nets. However, as natural as it may seem, if we restrict ourselves to pure expressions, the access to content in natural language is far from simple and direct. The meaning of words is usually given through other words, risking an infinite regression, and ostensive definitions are doomed to inescapable ambiguities unless considerable segments of content are already known, as the radical critiques of Wittgenstein (2009) and Quine (2013), among others, have sufficiently shown.

To make things worse, the recourse to natural language imposes significant constraints on the treatment of expressions. Indeed, DNNs can only achieve their results by addressing the problem as a predictive task. Thus, given the expressions `406` and `326` as inputs, the model is required to predict the expression `732`, after being trained over a massive quantity of similar cases (although not this specific one). Or more precisely, it is expected to predict the expression `732` from any expression containing `406`, `326` and some expression of the additive operation, as in `406 + 326=` or `what is 406 plus 326?` (or some sequential encoding thereof). Now, by approaching the task as if we were dealing with natural language, we force models to perform those predictions by the same means by which they can predict, say, `you` from `she asked` when generating the expression `she asked you`, or `Paris` from `The capital of France is`, however differently structured those expressions and contents may be.

Finally, analyzing those underlying means presents innumerable obstacles. As it is widely acknowledged, DNN models are practically uninterpretable (see, for instance, Lipton 2018). In particular, we have no access to formal representations of a model other than its internal state, which can go from hundreds of billions up to over a trillion parameters in the current state of the art. Several methods have been developed in recent years, providing tools for the analysis and principles of interpretability of NLP neural models (see Belinkov and Glass (2019) and Madsen et al. (2021) for a survey). Among them, the method known as *probing* (Conneau et al. 2018) enjoys some success. The idea is to use the encoded vector representations of a model to train a classifier over a

specific linguistic property considered relevant for performing linguistic tasks (e.g., grammatical dependencies). If the classifier achieves good performance, the properties in question can be regarded as somewhat encoded in the internal state of the original neural model. However, while several mechanisms have been proposed to show that the information corresponding to the probed property is legitimately attributable to and effectively employed by the model (Hewitt and Liang 2019; Ravfogel et al. 2021), a fundamental gap remains between neural models and the symbolic feature being assessed. In other words, high – and ultimately superhuman – performance on such predictive tasks, which can indeed be conceived to grasp significant aspects of the content of expressions, might not reach that accuracy through the same means as humans. Neural models might be able to write sensible natural language or solve natural language tasks without ever following grammatical rules for any acceptable sense of grammatical rule-following. Likewise, those models might be able to solve mathematical tasks with reasonable and even surprising accuracy without ever manipulating any of the symbolic procedures by which we have historically controlled our mathematical practices. Converging results do not imply identical theories, representations, knowledge, or capabilities, which, in turn, does not mean that content is not being grasped. Interpretability attempts like the one of Charton (2022) presented above are certainly remarkable and promising but still limited and, all in all, largely insufficient given the scope of the problem.

5 Conclusion: But How?

In the face of all these obstacles, which are by no means unknown to researchers in the field, why should we place any hope at all in contemporary machine learning approaches to mathematical knowledge? Why should we rely on the orientations that a critical assessment could derive from them for a linguistically driven philosophy of mathematical practice? Is not the entire enterprise simply ill-conceived?

If the proof of the pudding is in the eating, it seems fair to acknowledge that, while the results exhibited so far are certainly limited from a mathematical point of view, they are far from insignificant from a philosophical one. Given the scale of the challenges, the slightest evidence that a seemingly impossible task can be achieved deserves philosophical consideration. Moreover, the models in question have shown surprising capacities in the treatment of natural language, where the richness of content makes the task otherwise challenging. Indeed, despite these models' duly identified limitations, the results exhibited by the application of DNNs to natural language processing in the last decade have been enough to catalyze, if not altogether generate, a revolution in the field (cf. Manning 2015).

Due to the close relation between mathematical texts and natural language within this framework, it seems legitimate to assume that the hope placed in neural methods for treating mathematical language is grounded on the mechanisms underlying the success of neural language models, whatever they may be. In this sense, the symbolic character of mathematical practices cannot be an objection *a priori* to this approach. On the one hand, it is not excluded that neural models are implicitly manipulating some higher-order representation akin to symbolic properties or structures (cf., for instance, Manning

et al. 2020). On the other, symbolic practices in mathematics as we know them are a relatively recent phenomenon. Although mathematical practices across different historical periods and cultures have constantly used expressive means that are irreducible to those of natural language, the recourse to a foundational role of symbolic practices such as axiomatic methods, formal systems of inference, or model-theoretical semantics has only become standard in the course of the past century. Mathematical knowledge has very well been produced and evolved for millennia across different cultures without such foundations (cf. Wagner 2019) and would arguably continue to do so if alternative principles and practices came to fulfill better the tasks expected from it in existing cultures, even if that requires to reinspect our existing notion of semantics, content, or even understanding, both in natural language and in mathematics.

Accordingly, a philosophical investigation of this phenomenon should focus on the elementary mechanisms responsible for the success of generic learning algorithms in manipulating natural language content when applied to a practically raw corpus of texts, and on the reasons and conditions for those same mechanisms to apply to the treatment of mathematical content. To avoid resorting to dubious, or at any rate unverifiable, analogies between artificial neural models and human learning capacities, let alone biological characteristics of the human brain, it is imperative to turn our attention to what those models *actually do*. As we have seen, DNNs are statistical models resulting from a statistical learning procedure in the context of predictive tasks. If such models can grasp linguistic content when operating with pure text, it is natural to ask what the source of that content can be. Since the expressions fed into the model are nothing but a sequence of empty identifiers, and models are highly generic before training, the source of all content, be it linguistic or mathematical, can lie nowhere else but in the training corpus. Which is another way of saying: *in the series of collective and historically determined linguistic and mathematical practices, as they are recorded in the many forms textuality can take*.

That significant segments of such content can be drawn from the expression of those practices is something the limited yet startling results of mathematical applications of neural language models are displaying before our eyes. The task remains to understand *how* that is even possible and invest this feat with the philosophy it deserves. With it, a whole new program opens up before a philosophy of mathematical practices informed by a renewed theory of language and signs.

Acknowledgments The author wishes to thank Deniz Sarikaya, Bharath Sriraman, David Waszek, Roy Wagner, and John Terilla for their patient support, precious feedback, and constant encouragement.

Ultraproduct of first-order structures, 1994
Uncountable set, 1966
Understanding, 2140, 2142, 2146, 2148–2150, 2152, 2153, 2160, 2626, 3051
Undirected weighted networks, 2750
Unification, 432, 435, 439, 440
Unification-inducing proofs, 435
Uniform continuity, 1482
Union set axiom, 2371, 2380
Uniqueness problem, 2220
Univalence, 2353, 2354, 2356, 3169
Univalence axiom, 2353, 2354, 2356
Univalent foundations, 2357
Universal commensurability, 1475, 1477
Universal democracy, 2377, 2378
Universal domain, 740
Universal Turing machine, 1938
Universe of sets, 122
Universe of set theory, 2375
Unrestricted domain, 2378
Unsurveyable computer-assisted proofs, 2434
Unsurveyable proofs, 2467
Uptake, 3050
The Uses of Argument, 2673
Uses of writing, 3069
USSR, 870

V
Validity, 2145
Valid transformations, 2154
Value of firm, 1331
Value of recognisability, 126

Values of mathematical proofs
abstract value, 2083, 2108
beautiful proofs, 2108
explanatory proof, 2099
practical, 2083
practical value, 2099, 2108
Value-system, 1233
van der Waerden on the history of Pell problem, 992, 997, 1000
Van Hiele model of learning, 2583
Varese Lake, 2327–2329
Variation of Cantor normal form (VCNF), 455, 456, 458
The Variation of Plants and Animals Under Domestication, 1389
Varignon parallelogram, 2574
Vaulezard, Jean-Louis sieur de, 211, 221, 227
Veblen hierarchy, 455
Vedāṅga, 1025, 1029
Vedic people, 1026
Venn diagrams, 1322, 2984
Verheideggert phenomenology, 649
Veridical fictional imagination, 2542
Vershik, Anatoly, 872
Victorian mathematics, 911
Victorian Payment, 1248
Viète, François, 200, 202, 211, 222
Views from other domains, 4
Vinogradov, Aleksandr, 877
Virtue theory, 1242, 1243, 2141, 2146, 2155
Virtuosity, 1243
Visualization, 2245, 3056
Visual symmetry in graphs, 2527
Visual synopsis, 2538
Viviani's theorem, 2567
Vlady, M., 16
Vocabulary types, 2182
Von Neumann, John, 95, 105, 160, 163–165
von Neumann ordinals, 1685
Vuillemin's analysis, 716

W
Wästlund's proof, 2547
Ways of reading, 3052
Weak König's lemma, 1915
Weak Theaetetus' periodicity theorem, 937
Philebean finite *vs.* Pythagorean finite, 952
in Philebus, 946–948
philosophical imitation of, 946–951
Plato, 939–945
in Politicus, 949–951
reconstruction of proof of, 953–967
Weber, Leonhard, 1852
Web of mathematical practices, 2806–2810
Weierstrass, Karl, 1482
Weierstrass's new foundation of theory of functions, 1144
Weigel, E, 168, 170, 171
Weil on the history of Pell problem, 918, 920, 960, 961, 980, 998–1000, 1005, 1007, 1011, 1012, 1015
Weiss, Christian Samuel, 1832
Weldon, Walter, 1391
Well-ordered sets, 1956
Well-ordering of positive numerals, 449–450
Well-ordering principle, 1913
Western society, 1330
Wetonan cycle, 1105, 1109, 1112, 1113
Weyl, Hermann, 75, 76, 1467, 1515–1521, 1553
Wilf-Zeilberger theory (WZ), 2439
William Whewell, 2139
Windu, 1115
Wisdom, 689
Wittgenstein, Ludwig, 2602, 2603, 3017, 3018
WolframAlpha app, 2565, 2566
Woodin, W. Hugh, 115, 128
WordPress, 2728, 2734
Work, 3061
Working practices, 3056, 3057
Working procedure, 3060, 3061
Wright, Sewall, 1384, 1394
Writing act, 3049
Writing of speech, 3069
Writing of utterances, 3069
Writing practices, 3069
Writings on Mathematical Procedures, 3055
Written evidence, 3058, 3063, 3067
Wuku, 1109
Wulan, 1113

X
Xenocrates, 467, 607, 608, 611–613, 619
Xylander, 217, 219, 232

Y
Yajamāna, 1031
Yijing, 187–188
Fuxi sequence, 187
King Wen sequence, 188
Yogyakarta, Sultanate, 1104, 1111, 1113, 1116, 1120
