> [Das Eine ist die Ewigkeit, die sich allezeit allein hält und wandellos ist. Die Zwei aber, das ist die Zeit, die sich wandelt und vermannigfaltigt. (Eckhart 1934, p. 240)]

It may appear at first sight, perhaps even after reading Brouwer (1909), that Brouwer dropped the intuition of space, present in Kant's philosophy, given the discovery of non-Euclidean geometries and the untenability of an intuition of Euclidean space (there would still be a possibility to assume the existence of an intuition of absolute geometry, the common part of Euclidean and hyperbolic space). In his thesis, even though there is a unique "basic intuition of mathematics," there is

an acknowledgment of a distinction between the discrete and the continuous intuition of time which does not occur in his later writings:

> Since continuity and discreteness occur as inseparable complements, both having equal rights and being equally clear, it is impossible to avoid one of them as a primitive entity, trying to construe it from the other one, the latter being put forward as self-sufficient; in fact it is impossible to consider it as self-sufficient. Having recognised that the intuition of continuity, of 'fluidity', is as primitive as that of several things conceived as forming together a unit, he latter being at the basis of every mathematical construction, we are able to state properties of the continuum as a 'matrix of points to be thought of as a whole'. (Brouwer 1907, p. 17)

To justify the untenability of an intuition of space, Brouwer brings arguments taken from "mechanics," such as a reference to the "relativity postulate" due to Lorentz (Brouwer 1909, p. 115) (he was probably unaware of Einstein's work at that time) or the impossibility of separating time and space, against both Frege's and Russell's attempted defense of Euclidean geometry in the form that "our faculty of cognition can assimilate the world of experience only in the form of Euclidean geometry" (Brouwer 1909, p. 109). This is surprising, given that time and space are supposed to be those *of intuition*, not those of physics. He mentions this explicitly for time: "Of course we mean here *intuitive time* which must be distinguished from *scientific time*" (Brouwer 1907, p. 61).

It is apparent that he favored a view of geometry that is only about the continuum, and the continuum can be developed from the intuition of time. As he put it in Brouwer (1913, p. 128): "For since Descartes we have learned to reduce all these geometries to arithmetic by means of the calculus of coordinates."

Brouwer's insistence on a single basic intuition might also have been motivated by an aversion, felt by many of those whom Fromm calls Masters of Living, for dualism. We know he was not just in awe of the writings of Meister Eckhart and Jakob Böhme, of the Bhagavad-Gita (all of which he mentioned already in 1905 in Brouwer (1996)), but also of Spinoza, for he wrote, as a case in point for his "logic is not a reliable instrument to discover truths and cannot deduce truths which would not be accessible in another way as well" (Brouwer 1948, p. 488) that "we feel the wisdom that blooms in Spinoza's work as completely independent of his logical system" (Brouwer 1908, p. 107). We think it is the same "definite aversion to those pairs of opposites" found by Haas in "the world concept and philosophy of the East," that Nina Berberova confessed to, that made the mystically inclined Brouwer avoid treating time and space as generating distinct intuitions.

> All dualism is painful for me, all splitting or bisecting contrary to my nature. When Lenin speaks about matter in opposition to energy, when Berdyaev speaks about material principle (reaction) and spiritual principle (revolution), when idealist philosophers speak about spirit and flesh, I am jarred, as by a false note. My commandment was the truth that matter is energy. My whole life has been the reconciliation within myself of the old dichotomy. (Berberova 1992, pp. 23–24)

This monistic view is not generally accepted. It is clear that the intuition of time allows the creation of natural numbers and thus a foundation for number theory. While, in Atiyah's view, modern algebra is also dependent on time, he finds geometry to be distinctly *not* related to time.

> Algebra, on the other hand (and you may not have thought about it like this), is concerned essentially with time. Whatever kind of algebra you are doing, a sequence of operations is performed one after the other and 'one after the other' means you have got to have time. In a static universe you cannot imagine algebra, but geometry is essentially static. I can just sit here and see, and nothing may change, but I can still see. Algebra, however, is concerned with time, because you have operations which are performed sequentially and, when I say 'algebra', I do not just mean modem algebra. Any algorithm, any process for calculation, is a sequence of steps performed one after the other; the modern computer makes that quite clear. The modern computer takes its information in a stream of zeros and ones, and it gives the answer.
>
> Algebra is concerned with manipulation in time and geometry is concerned with space. These are two orthogonal aspects of the world, and they represent two different points of view in mathematics. (Atiyah 2002, p. 6f)

However, the state of mind Atiyah describes for geometry, "I can just sit here and see, and nothing may change, but I can still see," sounds awfully close to that undifferentiated state that one is graced with in meditation, not the kind called up by the I who has decided to "meditate," but the one that establishes its dominion by itself, reminds one of what Krishnamurti describes as "the state of experiencing."

> In the state of experiencing, there is neither the experiencer nor the experienced. The tree, the dog and the evening star are not to be experienced by the experiencer; they are the very movement of experiencing. There is no gap between the observer and the observed; there is no time, no spatial interval for thought to identify itself. Thought is utterly absent, but there is being. This state of being cannot be thought of or meditated upon, it is not a thing to be achieved. The experiencer must cease to experience, and only then is there being. In the tranquillity of its movement is the timeless. (Krishnamurti 1956, p. 32)

That is not the state in which geometry happens. In geometry itself, one has to separate two things "one of which gives way to the other, but is retained by memory," as Brouwer put it, to discover any geometric truth. The mind must still be traveling from one entity to the other, its stillness may give rise to awe, but will never generate an insight, languageless or not, about the *structure* of the observed.

We have here identified the intuition that allows to "mentally differentiate between objects" with the intuition of time. Placek is not sure whether that identification is allowed, as he finds no confirmation for it in Brouwer's writings:

> although one may introduce a number of other intuitions as well, say those allowing the subject to separate a mathematical entity, or mentally differentiate between objects, Brouwer does not identify the intuition of two-ity with any of them. Even more, he does not even mention any such faculty in his writings. Whether these faculties are needed in his doctrine is [a] separate question. (Placek 1999, p. 42)

Only if Brouwer understood geometry strictly as the science of the continuum could he have considered that the intuition of time can serve to construct space by means of the construction of the coordinate space. However, he was too well-informed about the axiomatic foundations of geometry and certainly knew that ordered geometry, as axiomatized by the axioms of incidence and order, in the two-dimensional case, without the addition of any configuration theorem, does not allow for an algebraization. He had read the entire relevant literature, had a regular course on the subject, and was the advisor of a thesis in classical axiomatic geometry.

There is a striking similarity with the confluence of time and space in Buddha's language, which was pointed out by Monier Williams.

> Another interesting feature of the Buddha's language of temporality is his use of the term for 'space' to refer to time as well. In the traditional literature, the term *adhvan* is used exclusively in the sense of road, way, orbit, journey or course. In fact, Monier Williams has noted that Buddhism and Jainism used it in the sense of time. The "Discourse on Convocation" (*Sangīti-suttanta*) enumerates the three *addhā* [paths] as past, present and future. Elsewhere it is said:
>
> A person, wandering for a long stretch of time with craving as companion, does not overcome the continued cycle of wandering *(saṁsāra)* in this or other modes of life. (Kalupahana 1999, p. 59)

Now, leaving aside the fact of a *single* origin, what about the fact that mathematics originates in an *intuition* at all? This is Brouwer's middle way between nominalism (for which mathematical objects, relations, and structures do not exist – as physical objects or as entities having causal powers) and Platonism (for which there are abstract mathematical objects whose existence is independent of human beings, of the language or thought processes of those beings – Plato was, incidentally, not a Platonist in this sense, as pointed out in Pritchard (2010, p. 111)), shying away from both extremes. One can also see it as a middle way between a naturalism that declares "all mathematics" to be "ultimately a product of the human nervous system, the best product produced at each stage of our development" (Korzybski 1931, p. 276), a position defended by the neurobiologist Jean-Pierre Changeux, and a Platonism, backed in conversations with Changeux (Changeux and Connes 1995) by Alain Connes. It is Brouwer's version of denying mathematics a *svabhāva*, a self-existence, it is his version of "dependent origination" (*paṭiccasamuppāda*), his insistence on the interrelatedness of all there is.

So how is this intrusion of *paṭiccasamuppāda* on the altar of Western philosophy, with its relentless search for the object, received? We present two quotes, from critics of intuitionism (which Hartmann calls "Intuitivismus") by Nicolai Hartmann and by Felix Kaufmann, that read as if the authors had read Haas's book, have internalized how Western philosophy has to proceed, and came up with the predictable answers.

> 'Intuition' is from the start a mode of cognition, i.e. a 'grasping', a transcendent act; in that it differs essentially from the 'setting', and it is just the theory that misjudges that. The truth of intuition is that it is not a giving act, but a receiving (receptive) act, and that the giving authority behind it ought to be searched for at the object. It is the one who determines the intuition to the extent that it 'presents' (appears) itself to it, and that happens as an object that

> is indifferent to the very act of intuition. It is thus already assumed as an existent-in-itself. In case such an object were not to present itself, in case no existent were available, that would have its particular suchness already as its own, then the act itself would not be a seeing apprehension either. (Trans. V. P.)
>
> [‚Intuition' ist nämlich von vornherein ein Modus des Erkennens, also ein‚Erfassen', ein transzendenter Akt; sie ist darin von Grund aus anders gestellt als die‚Setzung', und es ist nur die Theorie, die das verkennt. Die Wahrheit der Intuition ist, dass sie nicht gebender, sondern aufnehmender (rezeptiver) Akt ist, und dass die gebende Instanz hinter ihr beim Gegenstande zu suchen ist. Dieser bestimmt die Anschauung, insoweit er sich ihr‚darbietet' (erscheint), und zwar als ein gegen den Anschauungsakt selbst indifferenter. Er ist also schon als ansichseiender vorausgesetzt. Bietet sich ein solcher Gegenstand nicht dar, liegt also kein Seiendes vor, das sein bestimmtes Sosein schon an sich hätte, so ist auch der Akt kein schauendes Erfassen. (Hartmann 1965, p. 236)]
>
> For Brouwer's view that mathematical facts change with mathematical knowledge implies that there is something cognizable that is created only by being cognized, which runs counter to the nature of cognition. For [. . .] all cognition presupposes an object that must be thought of as existing independently of its being cognized. (Kaufmann 1978, p. 56f)
>
> [Denn Brouwers Auffassung, daß sich die mathematischen Tatsachen mit der mathematischen Erkenntnis wandeln, schließt ein, daß es ein zu Erkennendes gebe, welches erst durch die darauf bezogene Erkenntnis geschaffen wurde, was dem Wesen der Erkenntnis zuwiderläuft. Denn jede Erkenntnis setzt [. . .] einen unabhängig von seinem Erkanntwerden als bestehend zu denkenden Gegenstand voraus.]. (Kaufmann 1930, p. 65)

Here is what the theoretical physicist David Bohm had to say about this objectifying tendency of Western philosophy:

> The weakness of thought is that thought inevitably separates itself from what it thinks about. It creates an imaginary other, which it calls the object – which is still really thought. Let's say I'm thinking about the image of a tree. Now that which I am thinking about seems to be separated from me. It seems the image is over there somewhere and I am here. Therefore it seems that I have created two images, one is the tree and the other is me. (Krishnamurti and Bohm 1999, p. 49)

Going even deeper into the process of object-creation, as well as into the phenomenon of *tṛ́ṣṇa*, we find in Brouwer (1948, p. 480) that

> As mind it [consciousness] takes the function of a subject experiencing the present as well as the past sensation as object. And by reiteration of this two-ity-phenomenon, the object can extend to a world of sensations of motley plurality.
>
> In measure of the irreversibility with which the subject has receded from an element of the object, this element loses its egoicity, i.e. gets estranged from the subject, and in measure of this estrangement, mind becomes disposed to desire and apprehension, and consequently to positive or negative conative activity with respect to the element in question.

There is a striking emphasis on the *yang*, on the object, on the external, the visible, which goes hand in hand with a de-emphasis of the *yin*, the internal, the invisible in these critiques of Brouwer's intuitionism. The same emphasis on external features is prominent in formalism, in which the origin of the strings of meaningless symbols, that are its subject matter, is irrelevant. Formalism is not specific to mathematics as a modernist doctrine. Its counterpart in philosophy is analytic

philosophy, which focuses on the language of philosophy, given that, what is philosophy other than a philosophical text, and what other purpose could philosophy serve than producing exact sequences of words? Its counterpart in psychology is behaviorism, which ignores the inner life of a human being and focuses on the observable part, namely, behavior. To put in in Hannah Arendt's terms, "behavior has replaced action as the foremost mode of human relationship" (Arendt 1998, p. 41). In legal theory, the modernist approach is that of the "Pure Theory of Law" (*Reine Rechtslehre*) of Hans Kelsen, against the counter-modernist legal theory of Natural Law (*Naturrecht*), with Leo Strauss as its prominent twentieth-century proponent.

This rejection of mathematics' dependency on intuition, of its birth from intuition, the preference for thinking of mathematics as of a thing – for in its formalist understanding it is a thing, namely, the system consisting of strings of meaningless symbols, together with the formal rules that allow for the generation of other strings of meaningless symbols – is another case of what Günther Anders called "the shame of not being a thing," in which he sees "a second level of alienation," that on which "man has recognized the superiority of things, brings himself in conformity with them, approves of his own having-become-a-thing, respectively condemns his not-having-become-a-thing as a shortcoming" (Anders 1980, p. 30) (Trans. V. P.). The shame of being born – an unavoidable fact in any philosophy of complete interdependency – has been already noticed by Schelling (as mentioned in Anders 1980, p. 325), who writes that "Der Eigendünkel des Menschen sträubt sich gegen diesen Ursprung aus dem Grunde [. . .]" (Schelling 1809, p. 360) ["The self-conceitedness of man rejects this deep origin [. . .]" (Trans. V. P.)].

How does formalism avoid having to admit that time is playing a decisive role? Having created a "material instrument" (Brouwer 1929, p. 422), namely, the strings of meaningless symbols, that one can imagine as being written on paper or stone, it has transformed mathematics into the physical object that is represented by the strings of symbols. The deceptive part in this procedure is that one cannot thus consider that this spatial artifact is free of time, for the strings of symbols are concatenations, so time in the sense of *this after that* and a direction of reading are required. Without a direction of reading and the notion of a successor, the notion of string itself falls apart.

On a very concrete level, philosophically inclined mathematicians fear that, if one were to accept Brouwer's origin story, mathematics would – from being capable of bringing forth the envy of a Christian theologian (who is afraid that a Platonic understanding "precludes God's being the sole ultimate reality," the existence of "uncreatable" abstract objects being "incompatible" with God's aseity (Craig 2017, p. 13)) – become part of psychology. This fear is unjustified (and has been dealt with in both Placek (1999) and Van Atten (2004)) and has been addressed in a very condensed form by Largeault:

> intuitionism has something *aristocratic* about it which is connected with the exceptional nature of intuition. (Despite this fact, intuition, pure and disinterested knowledge that it is, is

> *universal* rather than individual, which refutes the legend of solipsism which has been attributed to the Dutch geometer.) (Trans. V. P.)
>
> [l'intuitionisme a quelque chose d'*aristocratique* qui tient au caractère exceptionnel de l'intuition. (Malgré cela, l'intuition, connaissance pure et désintéressée, est *universelle* plutôt qu'individuelle, ce qui réfute la légende du solipsisme attribué au géomètre hollandais.). (Largeault 1993, p. 224)]

This universal nature of mind, as well as the rejection of what Brouwer refers to as "the plurality of mind," is emphasized by Krishnamurti in many of his talks. One of these is a talk with David Bohm:

DB: You are using the word mind, it means it is not my mind.
JK: Oh, mind, mind, it is not mine.
DB: Universal or general.
JK: Yes. It is not my brain either.
DB: No, but there is a particular brain, this brain or that brain. Would you say there is a particular mind?
JK: No.
DB: Now, you see that is an important difference. You are saying mind is really universal.
JK: Mind is universal – if you can use that word, ugly word.
DB: Unlimited and undivided.
JK: It is unpolluted, not polluted by thought.
DB: But I think for most people there will be a difficulty in saying how do we know anything about this mind. I only know of my mind is the first feeling – right?
JK: You cannot call it your mind. You only have your brain which is conditioned. You can't say, 'It is my mind'.
DB: Yes, well whatever is going on inside I feel is mine and it is very different from what is going on inside somebody else.
JK: No, I question whether it is different.
DB: At least it seems different.
JK: Yes. I question whether it is different, what is going on inside me as a human being and you as another human being, we both go through all kinds of problems, suffering, fear, anxiety, loneliness, suffer, and so on and so on. We have our dogmas, beliefs, superstitions, and everybody has this.
DB: Well we'll say it is all very similar but still it seems each one of us is isolated from the other.
JK: By thought. My thought has created that I am different from you, because my body is different from you, my face is different from you, so we carry that same – we extend that same thing into the psychological area. (Krishnamurti and Bohm 1983)

That universal nature of introspectively discovered truth is also stated in the following "reflection" of Goethe, which appeared posthumously in 1833 (Goethe 1953; Maximen und Reflexionen 1060, p. 514):

> In case I know my relation to myself and to the outside world, I call it truth. And in that way everyone can have their own truth, and it is nevertheless always the same. (Trans. V. P.)
>
> [Kenne ich mein Verhältnis zu mir selbst und zur Außenwelt, so heiß ich's Wahrheit. Und so kann jeder seine eigene Wahrheit haben, und es ist doch immer dieselbige.]

Brouwer himself wrote to Van Dantzig on August 24, 1949, that he sees a psychological interpretation of intuitionism as a misunderstanding:

> I am glad to see that these developments make the essentially negative properties meaningful also to those who do not recognize the intuitionistic creating subject, because with respect to mathematics they hold either a psychologistic point of view, or in any case stick to the 'plurality of mind'.
>
> As I told you in conversation, my example in question is for fundamental intuitionism so much more unassailable than for those of a different persuasion, because the intuitionistic creating subject can certainly, and from the outset put restrictions (or prohibitions of restrictions) on a specific growing mathematical entity, but not on his own possibilities of creation.
>
> My belief that psychological pictures of intuitionistic mathematics, however interesting they may be, never can be adequate, has, if possible, been even strengthened by your comment. (Van Dalen 2011a, p. 439)

Now why and how does this philosophical stance of Brouwer alter concrete mathematics? Why is his own fixed-point theorem becoming false under this understanding? Brouwer had proved that the assumption of a continuous self-map of the closed disc without a fixed point leads to a contradiction. So, if we denote by A the fixed-point theorem, then Brouwer proved the truth of $\neg\neg A$, or, put differently, "the absurdity of the absurdity of A." In classical logic, the double negation of a sentence is equivalent to it. Intuitionistically, that is not valid. Why? In classical mathematics, one thinks of the closed disk as a set of points, so if a continuous self-map f without a fixed point is an absurdity, then there must exist a point in that closed disk that is not moved by f. We might never be able to find that point for a specific f, but its existence is assured. This thinking – even if only encoded in the axiom system chosen, and thus purely formal and not making any overt claim of existence – is a tributary to Platonism, to the belief that the points of the closed disk exist independently of our ability to construct them. However, already in his doctoral dissertation, Brouwer has a section heading that reads "Mathematics can deal with no other matter than that which it has itself constructed" (Brouwer 1907, p. 51) and we find out that "to exist in mathematics means: to be constructed by intuition; and the question whether a corresponding language is consistent, is not only unimportant in itself, it is also not a test for mathematical existence" (Brouwer 1907, p. 96). In short, there are no "non-experienced truths" (Brouwer 1948, p. 488) in mathematics.

This is best illustrated by Brouwer's account of the intuitionistic continuum, whose very nature is that of an unfinished entity, one that is *becoming*. Brouwer found the need to introduce a new language to deal with intuitionistic entities. For example, he does not use the word "set." This has similarities with the Buddha's tendencies in matters of language.

> The Buddha needed a language that avoided [. . .] substantialist and nihilist implications. This was the language of becoming *(bhava)* that more accurately reflected his experience of change and continuity. It is the language of 'dependent arising' *(paṭiccasamuppàda)* that steered clear of the extremes of permanent existence and nihilistic non-existence. Thus the Buddha can be credited with revolution in linguistic philosophy when he consistently utilized the 'language of becoming' to take the venom off the 'language of existence.' (Kalupahana 1999, pp. ii–iii)

Again, Largeault, with his keen sensitivity for the cultural aspect of philosophy, had noticed this fact, for he writes that

> Does this mean that our mathematics is based on a substance-attribute ontology, reflected in our language (subject-copula-attribute sentences), inherited from the ancient Greeks, while intuitionist mathematics presupposes an ontology of processes, which is repelled by our thinking habits? (Trans. V. P.)
>
> [Cela signifie-t-il que nos mathématiques reposent sur une ontologie substance-attribut, reflétée dans notre langue (phrases suject-copule-attribut), héritée des Grecs anciens, tandis que les mathématiques intuitionistes supposent une ontologie de processus, qui répugne à nos habitudes de pensée? (Largeault 1993, p. 175, footnote 1)]

One could wonder why it was and still is so hard for mathematicians and philosophers of mathematics to allow the observer inside the halls of mathematics. Did not physicists do just that? True, they did, but they were forced to do so by the very nature of experiments, not out of an abundance of interest in the Eastern approach. And even physics tends to exclude those who overstep the boundaries of what is, due to experimental outcomes, strictly necessary to accept, such as David Bohm, with his Spinoza-like embrace of the interconnectedness of mind and matter (see also Espinosa Rubio 2000), and his statement, reminiscent of Teilhard de Chardin's "within of things" that

> Mind and matter are inseparable, in the sense that everything is permeated with meaning. The whole idea of the somasignificant or signasomatic is that at no stage are mind and matter ever separated. There are different levels of mind. Even the electron is informed with a certain level of mind. (Bohm and Weber 1987, p. 443)

But, one might ask, what is the value of the fact that Brouwer's philosophy displays characteristics similar to that of an Indian who lived more than 2500 years ago, when science or mathematics were as good as non-existent? And how is the thesis of Brouwer's Eastern disposition helped by having the support of Krishnamurti, to whom Walpola Rahula said in Rahula et al. (1996, p. 19) "there is hardly any difference between your teaching and the Buddha's"? Is that same Eastern mind still present in the twentieth century, in Indians who had extensive contact with the Western mind, and who did not discover "the liberation of insight" (Krishnamurti and Bohm 1999, p. 101)? Pupul Jayakar, in conversation with Krishnamurti, referred to an Indian tendency of "delving into the self, delving into the within, insights into things" (Jayakar and Krishnamurti 1996, p. 154). And then there is Rabindranath Tagore – who, just like Krishnamurti, whose talks Brouwer

frequented (see Van Dalen (2013, p. 364) and (van Atten 2015, p. 179), where we find out that "When visiting Krishnamurti, Brouwer said to a friend: 'Oh my, this is the baby room of philosophy'"), played a role in Brouwer's life – in conversation with Einstein "in the afternoon of July 14, 1930, at the latter's residence in Kaputh":

E.: There are two different conceptions about the nature of the universe: (1) The world as a unity dependent on humanity. (2) The world as a reality independent of the human factor.
T.: When our universe is in harmony with Man, the eternal, we know it as truth, we feel it as beauty.
E.: This is a purely human conception of the universe.
T.: There can be no other conception. This world is a human world – the scientific view of it is also that of the scientific man. There is some standard of reason and enjoyment which gives it truth, the standard of the Eternal Man whose experiences are through our experiences.
E.: This is a realization of the human entity.
T.: Yes, one eternal entity. We have to realize it through our emotions and activities. We realize the Supreme Man who has no individual limitations through our limitations. Science is concerned with that which is not confined to individuals; it is the impersonal human world of truths. Religion realizes these truths and links them up with our deeper needs; our individual consciousness of truth gains universal significance. Religion applies values to truth, and we know truth as good through our own harmony with it.
E: Truth, then, or Beauty, is not independent of Man?
T: No.
E: If there would be no human beings any more, the Apollo of Belvedere would no longer be beautiful?
T: No.
E: I agree with regard to this conception of Beauty, but not with regard to Truth.
T: Why not? Truth is realized through man.
E: I cannot prove that my conception is right, but that is my religion.
T: Beauty is in the ideal of perfect harmony which is in the Universal Being; truth the perfect comprehension of the Universal Mind. We individuals approach it through our own mistakes and blunders, through our accumulated experience, through our illumined consciousness – how, otherwise, can we know Truth?
E: I cannot prove scientifically that truth must be conceived as a truth that is valid independent of humanity; but I believe it firmly. I believe, for instance that the Pythagorean theorem in geometry states something that is approximately true, independent of the existence of man. Anyway, if there is a reality independent of man there is also a truth relative to this reality; and in the same way the negation of the first engenders a negation of the existence of the latter.
T: Truth, which is one with the Universal Being, must essentially be human, otherwise whatever we individuals realize as true can never be called truth – at least the truth which is described as scientific and can only be reached through the process of logic, in other words, by an organ of thoughts which is human.

According to Indian Philosophy there is Brahman the absolute Truth, which cannot be conceived by the isolation of the individual mind or described by words, but can only be realized by completely merging the individual in its infinity. But such a truth cannot belong to Science. The nature of truth which we are discussing is an appearance – that is to say what appears to be true to the human mind and therefore is human, and may be called māyā or illusion.

E: So according to your conception, which may be the Indian conception, it is not the illusion of the individual, but of humanity as a whole.

T: In science we go through the discipline of eliminating the personal limitations of our individual minds and thus reach that comprehension of truth which is in the mind of the Universal Man.

E: The problem begins whether Truth is independent of our consciousness.

T: What we call truth lies in the rational harmony between the subjective and objective aspects of reality, both of which belong to the super-personal man.

E: Even in our everyday life we feel compelled to ascribe a reality independent of man to the objects we use. We do this to connect the experiences of our senses in a reasonable way. For instance, if nobody is in this house, yet that table remains where it is.

T: Yes, it remains outside the individual mind, but not outside the universal mind. The table which I perceive is perceptible by the same kind of consciousness which I possess.

E: Our natural point of view in regard to the existence of truth apart from humanity cannot be explained or proved, but it is a belief which nobody can lack – no primitive beings even. We attribute to Truth a super-human objectivity; it is indispensable for us, the reality which is independent of our existence and our experience and our mind though we cannot say what it means.

T: Science has proved that the table as a solid object is an appearance, and therefore that which the human mind perceives as a table would not exist if that mind were naught. At the same time it must be admitted that the fact, that the ultimate physical reality of the table is nothing but a multitude of separate revolving centres of electric forces, also belongs to the human mind. In the apprehension of truth there is an eternal conflict between the universal human mind and the same mind confined in the individual. The perpetual process of reconciliation is being carried on in our science and philosophy, and in our ethics. In any case, if there be any truth absolutely unrelated to humanity then for us it is absolutely non-existing. It is not difficult to imagine a mind to which the sequence of things happens not in space, but only in time like the sequence of notes in music. For such a mind its conception of reality is akin to the musical reality in which Pythagorean geometry can have no meaning. There is the reality of paper, infinitely different from the reality of literature. For the kind of mind possessed by the moth, which eats that paper, literature is absolutely non-existent, yet for Man's mind literature has a greater value of truth than the paper itself. In a similar manner, if there be some truth which has no sensuous or rational relation to the human mind it will ever remain as nothing so long as we remain human beings.

E: Then I am more religious than you are!

T: My religion is in the reconciliation of the Super-personal Man, the Universal human spirit, in my own individual being. This has been the subject of my Hibbert Lectures, which I have called 'The Religion of Man'. (Gosling 2007, p. 161f)

For the mathematician who is not philosophically inclined, and who could not care less about East or West, the rejection of intuitionistic mathematics is connected with the fact that it is considered to be a mutilation of classical mathematics, given that many of the results of classical mathematics become false in intuitionistic mathematics. The fact that, on the other hand, there are results in intuitionistic mathematics that are flatly wrong in classical mathematics, such as the theorem proved by Brouwer in 1924 that "every full function is uniformly continuous" does not endear it to mathematicians either, given that such results remove from the body of mathematics all results about discontinuous functions. Brouwer's answer to this criticism was:

> In general intuitionism brings about a complete recasting of mathematics, with the result, to our regret, that in many places its supple and elegant character is lost, and it has to assume much harsher, more tortuous and more complicated forms. Alas, the spheres of truth are less transparent than those of illusion. (Brouwer 1933, p. 444)

This displeasure with "fewer" results is indicative of the approach to knowledge in the having mode of existence. *More knowledge* is preferred to knowing *more deeply*, which is what Brouwer proposes as "optimum knowledge in the being mode." As Meister Eckhart put it:

> That one is much more blessed, who can dispense with all things and does not need them, then he, who has taken possession of all things, because he needs them. (Trans. V. P.)
>
> [Der ist viel seliger, der alle Dinge entbehren kann und ihrer nicht bedarf, als der, welcher alle Dinge in Besitz genommen hat, weil er sie braucht. (Eckhart 1934, p. 109)]

Brouwer never claimed that classical mathematics or formalistic mathematics is *false.* He just claimed that just the fact that something is free of error does not make it worthwhile pursuing, that in a finite life, one should pursue "the structured elements of our thinking" (Brouwer 1946b, p. 475), the structures that arise from some lived intuition, not just any possible game of symbols. It is, after all, a *moral* argument for intuitionistic mathematics. He was opposed, also on moral grounds, to the cooperation of mathematicians with society:

> Of course art and philosophy continually illustrating such wisdom cannot participate in cooperation, in particular should not communicate with the state. Supported by the state, they will lose their independence and degenerate. (Brouwer 1948, p. 487)
>
> The two games [logic and mathematics], by dint of their origin, influence each other. By their very nature, they should not interfere with social life. Since the latter has nevertheless claimed them, they undergo the influence of the pragmatic sciences by cooperating, against their nature, to the transformations of social life that are called progress. Luckily, their most

> beautiful developments will probably never have any connection with technological, economical, or political matters.
>
> [Les deux jeux [logique et mathématique], en vertu de leur origine, s'influencent mutuellement. De par leur nature, ils ne devraient pas s'immiscer dans la vie sociale. Celle-ci les ayant néanmoins réclamés, ils subissent l'influence des sciences pragmatiques tout en coopérant, contre leur nature, aux transformations de la vie sociale qu'on appelle le progrès. Heureusement, leurs plus beaux développements n'auront probablement jamais aucun rapport avec les questions techniques, économiques ou politiques. (Brouwer 1950)

The same disdain for applications and the corrupting influence of money was present in René Thom's thinking (Papadopoulos 2018) and is certainly more widespread than meets the eye, given that many mathematicians will likely keep such thoughts private or never get the opportunity to make them public.

7 Wisdom and Mysticism: Beyond Mathematics and Time

While mathematics originates in the intuition of time, Meister Eckhart tells us that

> No thing is as despised by God as time. Not only time, the clinging to time as well. And not only the clinging, already the touch of time. And not only the touch, already the simple smell or taste of time. (Trans. V. P.)
>
> [Gott ist kein Ding so sehr zu wider als die Zeit. Nicht allein die Zeit, auch das Haften an Zeit. Und nicht allein das Haften, schon das Berühren von Zeit. Und nicht allein das Berühren: schon der bloße Geruch und Geschmack von Zeit. (Pfeiffer 1857, 308, 5)]
>
> If you are neither this nor that, then you are all things. – What has number or is number, from that he is far. (Trans. V. P.)
>
> [Bistu weder dies noch das, so bistu alle Dinge. – Was Zahl hat oder Zahl ist, von dem ist er fern.] (Pfeiffer 1857, 162, 7)

And Krishnamurti tells us that "a human being can see for himself that compassion is out of time, truth is out of time, and the depth from which that compassion comes is out of time. And therefore it is not cultivable" (Krishnamurti and Bohm 1999, p. 97).

Brouwer writes already in his dissertation (although his doctoral advisor crosses it out, as not relevant for mathematics):

> Mathematics is a free creation; it exists in developing a primordial intuition which can be called 'permanence in change' or 'the discrete in the continuous'.
>
> Applying it to the exterior world is creating the objective world; this is characteristic of the human strategy in the general struggle for life. As such it is clearly inferior and has nothing to do with religion or with wisdom. (Van Stigt 1990, p. 414f, The Rejected Parts of Brouwer's Dissertation)
>
> Perhaps the greatest merit of *mysticism* is its use of language independent of mathematical systems of human collusion, independent also of the direct animal emotions of fear and desire. If it expresses itself in such a way that these two kinds of representations cannot be detected, then the contemplative thoughts – whose mathematical restriction appears as the only live element in the mathematical system – may perhaps again come through without obscurity, since there is no mathematical system that can replace them. When the mystical

> author joins representations of this kind into more central affections, of which they were one-sided restrictions, he can, with the most ordinary words, gradually break down the barriers round the contemplative sphere and guide us back to the 'all-embracing' which every poet seeks to approach. His language will therefore appear as meaningless to those who expect to find in words only the communication of mathematical systems or a stimulus to mathematical activity. (Van Stigt 1990, p. 409, The Rejected Parts of Brouwer's Dissertation)
>
> In religious truth, i.e. in wisdom, which abolishes the discernment between the subject and something different, and where the perception of time is no longer admitted, there is no mathematical understanding, let alone reliability of logic. (L. E. J. Brouwer, 1908, p. 108)
>
> Searching for wisdom, we may find it in knowing that causal thinking and acting is non-beautiful and hard to justify, and that in the long run it brings disappointment.
>
> And in knowing that the exterior world with its innumerable individuals and with its hypertrophied cooperation is wedded to mind, its disharmonies reflecting mind's free-will-guilt.
>
> As a consequence of this knowing the exterior world and one's own position in it are accepted as they are, so that towards the exterior world generally only acts as reversible as possible aiming at maintenance, but no acts let alone causal acts aiming at change, are undertaken of one's free will. Repair of disadjustments, averting of danger and relief of need, all this negative intervening in human society is justified in itself and sometimes prescribed. But positive activity to change the structure of human society governed by so many unknown forces, will always be checked by the self-admonition: 'not to improve her works has Providence placed thee in this world', and only vocation and inspiartion tested in detachment-concentration will be stronger than this admonition. (Brouwer 1948, p. 485f)

This understanding leads to a "sceptical prognosis" for humanity, one that was the central concern of Fromm or Krishnamurti as well. In times past, this would have been dismissed as "pessimism," perhaps no longer as out of hand. Brouwer had expressed concerns regarding the equilibrium-upsetting interventions of humans in nature, already in 1905, in the opening lines of Brouwer (1996). It is important to notice that Brouwer offers not only a somber prognosis but also the means to escape it by abandoning the delusion of being able to steer and control life in desired directions by means of "causal acts," by "cunning."

> The categorical imperative prescribing the aforesaid attitude towards life has its counterpart in a sceptical prognosis that mankind, possessed by the delusion of causality, will slide away in a deteriorative process of overpopulation, industrialization, serfdom, and devastation of nature, and that when hereby first its spiritual and then its physiological conditions of life will have been destroyed, it will come to its end like a colony of bacteria in the earth crust having fulfilled its task.
>
> All this though timeless art and perennial philosophy continually suggest that the unknown forces governing the destiny of individual and community, are not subject to causality; that in particular the ways of fate cannot be paved with causality, and that security is as unattainable as it is unworthy; that intensification of organization increases vulnerability, that new vulnerability asks for protection through new organization, and that thus for organization which is believed in, there is no end of growth; finally that if the delusion of causality could be thrown off, nature, gradually resuming her rights, would be (except for her bondage to destiny) generous and forgiving to a mankind decausalized and subsiding to more modest and more harmonious proportions. (Brouwer 1948, p. 487)

And we can find already in 1905, in its last sentence, his categorical rejection of the having mode of existence:

> Only he who recognizes that he has nothing, that he cannot possess anything, that absolute certainty is unattainable, who completely resigns himself and sacrifices all, who gives everything, who does not know anything, does not want anything and does not want to know anything, who abandons and neglects everything, he will receive all; to him the world of freedom opens, the world of painless contemplation and of – nothing. (Brouwer 1996, p. 429)

While it might seem strange that Brouwer searches the ultimate answers whether for the source of mathematical intuition or for the source of "wisdom" in himself, in introspection, he is, again, in good company in doing so: Albert Schweitzer and Salman Baruch Rabinkow – a Chassidic Jew of the Chabad Chassidism branch, which originated in Lithuania, and Talmud teacher – with whom Fromm studied for 6 years the Talmud, and about whom he writes (Fromm 1987, p. 103) that he 'influenced my life more than any other man."

> The great secret is to go through life as an unconsumed person. Such an outcome is possible to the one who, instead of reckoning with people and facts, is thrown back on oneself and seeks the ultimate reason for things in oneself. (Trans. V. P.)
>
> [Das große Geheimnis ist, als unverbrauchter Mensch durchs Leben zu gehen. Solches vermag, wer nicht mit den Menschen und Tatsachen rechnet, sondern in allen Erlebnissen auf sich selbst zurückgeworfen wird und den letzten Grund der Dinge in sich sucht. (Schweitzer 1974, p. 312)]
>
> Judaism ascribes absolute value in its teaching only to this autonomous human being, who connects nature and spirit in a continuous synthesis. To the extent that the condition of autonomy is satisfied, Jewish doctrine does not recognize any difference in rank between humans. Everyone is entitled and obliged to say "The world was created for my own sake" (Sanhedrin, Mishnah, chap. 4), because every human being is an end in itself and is, as it were, burdened with the responsibility for the whole of Creation. (Trans. V. P.)
>
> [Allein diesem autonomen, Natur und Geist zur durchgängigen Synthese verbindenden Menschen spricht das Judentum in seiner Lehre absoluten Wert zu. Soweit aber die Voraussetzungen der Autonomie gegeben sind, kennt die jüdische Lehre keinerlei Rangunterschiede zwischen Mensch und Mensch. Jedermann ist berechtigt und verpflichtet zu sagen „Meinetwegen ist die Welt erschaffen" (Sanhedrin, Mischna, Kap. 4), denn jedes menschliche Wesen ist Selbstzweck und ist gleichsam mit der Verantwortung für die gesamte Schöpfung belastet. (Rabinkow 1929, p. 808f)]

Brouwer's emphasis on the inadequacy of language for communication and the overcoming of even the languageless activity that is mathematics with mysticism is not shared by all mystics. While mystics of the negative theological persuasion, such as Meister Eckhart, agree with Brouwer's take on the ineffability of the mystical experience, not all mystics regard language as inadequate. As Rudolf Otto pointed out, mysticism "preserves its special character, which explains itself clearly from the ground over which it domes up" ["wahrt ihren Sondercharakter, der sich deutlich aus dem Grunde erklärt, über dem sie sich wölbt"] (Otto 1926, p. 231). Given the high regard for language in Judaism ("Thy word (or: essence) is true from the beginning" (Psalm 119: 160)), Jewish mysticism highly values and is heavily reliant on

language, as pointed out in Scholem (1972), Ben-Sasson (2018), and Kilcher (1998, pp. 31–94).

> The point of departure of all mystical linguistic theories, among which we should also number those of the Kabbalists, is constituted by the conviction that the language – the medium – in which the spiritual life of man is accomplished, or consummated, includes an inner property, an aspect which does not altogether merge or disappear in the relationships of communication between men. (Scholem 1972, p. 60)

None of this diminished in any way the deep friendship, based to a great extent on a common interest for the mystic experience, between Brouwer and Erich Gutkind.

Questions regarding "the common core thesis on mysticism" (which "holds that all forms are in the end different ways to express the same thing" (Barendregt 2008, p. 131)) were addressed in Van Atten and Tragesser (2015) and in Barendregt (2008).

8 Conclusions

What we have attempted to show in this study is the fact that Brouwer's philosophy of mathematics is coherent and does not stand alone in the arena of philosophies. It is perceived as a foreign body by philosophers trained in the Western tradition, who usually do not even confer the title "philosophy" to its Eastern branch, let alone allow it to have anything to say about Western philosophy's oldest and most valued possession: mathematics.

We have seen that Brouwer's philosophy converses well with that of the Buddha, Erich Fromm, Krishnamurti, Meister Eckhart, Albert Schweitzer, David Bohm, Humberto Maturana, Francisco Varela, or Spinoza. Critics will say, fine, all you have shown is that he hung out with the wrong crowd, with the wrong side of C. P. Snow's "two cultures." What is a modern mind to do with the Buddha, Krishnamurti, Bohm, and Spinoza, who maintain that, although the world is highly causal and thus that there is a great amount of determinism, *insight liberates* (see (Bittner 1994) for the train of thought that led Spinoza to this conclusion)? All of them defend counter-modernist positions (certainly an anachronistic statement in the case of the Buddha, Spinoza, or Meister Eckhart); no contemporary ethics study in the English language, written by an analytic philosopher, even mentions Schweitzer's name. Both the being mode of existence and the Eastern approach are considered to be outside of the area of acceptable academic discourse. Incidentally, whoever thinks that counter-moderns must lie politically on the right spectrum should consider that Bohm was a communist until the Hungarian Revolution of 1956. This is also not the first instance in which Brouwer and Bohm have been brought together in an essay: a proposal for a model of indeterminism in physics (Gisin 2021) has called for the intuitionistic continuum as "an alternative mathematical language that is both powerful enough to

allow scientists to compute predictions and compatible with indeterminism and the passage of time" and mentions Bohmian mechanics.

What we have *not* attempted to do is to take sides. It is clear to us that Platonism, intuitionism, and formalism are all coherently expressed philosophies, and we are not at all interested in poking holes in one of them, with the aim of demolishing it or finding out inner contradictions. The conversation between Jean-Pierre Changeux and Alain Connes, in which none is able to convince the other of the wrong nature of one's own position, shows that such conversations make sense as exercises in informing the other, not in convincing the other of some mistake in one's own thinking (Changeux and Connes 1995).

Although we clearly stated this in a previous, much shorter essay on this topic (Pambuccian 1992), every attempt to defend Brouwer's position as coherent will likely bring on the same reaction that Brouwer's philosophy elicits, as can be read from the following review:

> This essay exhibits the efforts of a mathematician to articulate a philosophy justifying doing mathematics under the constraints of the outlook of the intuitionist L. E. J. Brouwer. But the philosophy does not concern having the proper concept of mathematical reality and, then, having the proper techniques for having truths about it. The word "having" is repeated in the preceding sentence to emphasize that a more fundamental philosophy, based on insights from (Fromm 1976), is pursuit of detachment from the way of existing which is dependent upon having things: the having mode of existence. This includes detachment from having the proper metaphysics and epistemology. The fruit of such detachment is an independent way of being: the being mode of existence. Presumably, those who are seeking this detached way of existing will do mathematics in Brouwer's way because they are detached from having access to a mathematical reality. (Kielkopf 1993)

The writer never attempted to justify his own activity, as he has written all his papers in a strict formalistic tradition and has used a (formal) intuitionistic result only once. The result used was arrived at by Michael Beeson in Beeson (2018). The writer's own use of it in solving an open problem going back to 1852 was straightforward (Pambuccian 2018). This essay is also not written to justify the writer's own or anyone else's activity. That would be pathetic, for, as Schweitzer put it:

> We are in truth when we experience conflicts increasingly deeper. The good conscience is an invention of the devil. (Trans. V. P.)
>
> [In der Wahrheit sind wir, wenn wir die Konflikte immer tiefer erleben. Das gute Gewissen ist eine Erfindung des Teufels.] (Schweitzer 1923, p. 249)

What we hope to have shown is that, if a formalist, whose papers are – unlike those of the majority of mathematicians, who are formalists only on Sundays – filled with actual strings of meaningless symbols, can understand what Brouwer was intending and why, then anyone can. There is no expectation that anyone will change their mind on the validity of Brouwer's philosophy after having read this essay.

Abstract

The primary aim of this chapter is to consider mathematicians' *working* philosophy of mathematics as emerging in and defining actual mathematical thinking and practice, as exemplified in three cases stated in my subtitle: Niels Henrik Abel and Évariste Galois, Nikolai Lobachevsky and Bernhard Riemann, and André Weil and Alexander Grothendieck. I speak of "and" and hence "conjunction," rather than the disjunctive "or," in all three paired cases considered in this chapter because, while my primary concern is on the (historically) second figure – Galois, Riemann, and Grothendieck – in each case, my aim is not merely to juxtapose these figures, especially given the significance of their thinking for transforming mathematics. The accomplishments of Abel, Lobachevsky, and Weil were revolutionary events as well. Instead, while granting the differences between their thinking, my aim is to explore the shared grounding that gives rise to these differences, defining, and defined by, their mathematical practice as philosophy. The chapter's approach to their mathematical practice and to creative mathematical practice in general is parallel to that of Deleuze and Guattari to creative philosophical practice, which or even true philosophy itself is defined by them as

1 Introduction

It is not uncommon in the historical and philosophical studies of mathematics to discuss mathematicians' own philosophical reflections on mathematics. While such reflections will also be addressed in this chapter, its primary aim is different. It is to consider mathematicians' *working* philosophy of mathematics as emerging in and defining actual mathematical thinking and practice, as exemplified in the three cases stated in my subtitle: Niels Henrik Abel and Évariste Galois, Nikolai Lobachevsky and Bernhard Riemann, and André Weil and Alexander Grothendieck. The chapter's approach to their mathematical practice and to creative mathematical practice in general is parallel to that of Gilles Deleuze and Félix Guattari to creative philosophical practice, as defined by the invention of new concepts, with philosophical concepts given by them a particular definition, in part in juxtaposition to mathematical and scientific concepts (Deleuze and Guattari 1996). The working philosophy of mathematics this chapter considers, under the heading of "mathematical practice as philosophy," is, analogously, that of the invention of new mathematical concepts. Against the grain of Deleuze and Guattari's argument, mathematical concepts will be understood here in affinity with rather than in juxtaposition to philosophical concepts, as the latter are defined by Deleuze and Guattari. This invention can sometimes be collective, either as a product of collaboration, more common in twentieth and twenty-first century mathematics, or of independent work by different mathematicians resulting in the same concepts. Both situations have been less common in philosophy, where the invention of new concepts is rarely collective. No such invention is ever entirely individual, because every concept, no matter how innovative, has a history defined by other concepts from which a new concept emerges and without which it would not be possible. A new concept is always a product of an interplay of continuities with and breaks from preceding concepts, although the balance of continuities and breaks can be different. Galois's and Riemann's concepts, such as that of a group by Galois and that of a manifold [*Manningfaltigkeit*] by Riemann, both especially central to this chapter, were more radically innovative, but still not completely, because they had continuities with earlier concepts, such as

(among others) those of Adrien-Marie Legendre in the case of Galois and those of Karl Friedrich Gauss in the case of Riemann.

This form of mathematical practice becomes especially important at a time when one or another part of mathematics and mathematical practice needs to be transformed, often in response to a crisis on one or another scale, from that defined by a single problem to that affecting a large area of mathematics. Such transformative events, leading to practice as philosophy, are also found in science, such as physics or biology, or of course in philosophy. One might argue that philosophy, especially as enacted in the work of creators of original and powerful concepts, such figures as Plato (ideas), René Descartes (cogito), Gottfried Leibniz (monads), or Immanuel Kant (things-in-themselves), is always practiced at the time of crisis, because each such philosopher always sees philosophy in crisis, to which such a concept responds. Or, to adopt Thomas Kuhn's language (without fully subscribing to his argument, which is difficult to apply in philosophy and which requires qualifications in mathematics and science), philosophy as a creation of concepts only admits a "revolutionary" practice, with a "normal" practice having at most only auxiliary importance for the advancement of philosophy, say, by exploring or applying new concepts (Kuhn 2012). In mathematics or science, both revolutionary and normal practices appear to be equally important for its advancement, as Kuhn recognizes, although they tend to be in a more complex interplay than was argued for by Kuhn. Thus, overtly normal, in *technical* terms, mathematical practice can, by reinterpreting the concepts used, adopt a different form of this practice from that of the revolutionary mathematics it follows and thus introduce a new, "revolutionary," form of mathematical practice.

Things are of course not so straightforward. There is more to a normal practice in philosophy than meets the eye. Institutional philosophical fields, such as analytic philosophy, are based on normal practice, which made important contributions to our understanding of philosophical concepts or theories, and, it might be added, of mathematical and scientific concepts in the analytic philosophy of mathematics or science. The distinction between the normal and the revolutionary, or the importance of each, is not unconditional and requires caution in any domain. There tends to be more continuity than the appearance of a break might suggest, or across a longer history with many revolutions. Thus are the relationships between Cantor's set theory and category theory, especially in Grothendieck's hands, those of a revolutionary break (a more common view) or that of continuity, a view advocated, for example, by Yu. I. Manin, who prefers to see the history of mathematics, as against, that of physics, in terms of continuity (Manin 2002, p. 8, 2019, pp. 129–130)? Perhaps they are equally both, in a complex interplay, in either field. The cases considered here, including that of Grothendieck, could be seen in terms of this interplay. They were revolutionary *events* insofar as they radically transformed the mathematical situation in relation to which they emerged. It may not always be possible, and perhaps is never ultimately possible, to *fully* track how new trajectories emerge from and against previous trajectories of thought. This limitation, however, leaves room for meaningful assessments of this emergence in terms of both continuities and breaks, in the case of breaks, I argue, in particular by virtue of the

invention of new concepts or conglomerates of concepts, some new and some already in place, for example, conglomerates comprising and defining new theories, such as algebraic geometry, as transformed by Grothendieck.

There are other cases that would illustrate my argument in this chapter, for example, that of Richard Dedekind and Leopold Kronecker, a famous example of two opposing (mathematical) philosophical positions. The main reasons for considering the cases selected here is that the first two stand at the origin of what we now see as *modern* mathematics, respectively, modern algebra and geometry – two ways of mathematical thinking (broadly conceived, so as to include arithmetic in the first and topology in the second) and the relationships between them that governed the history of mathematics since Pythagorean mathematics to our own time. Both and their relationships were transformed by modern mathematics that emerged roughly around 1800, although some of its trends can be traced to the mathematics, such as analytic geometry and calculus, contemporaneous with the rise of modernity itself as a cultural formation, defined by a series of transformations – scientific, technological, economic, political, and philosophical – from, roughly, the sixteenth century on. Of course, when it comes to modern mathematics, too, the thinking and work of other figures, such as Gauss in the case of algebra (his geometrical ideas will be considered in conjunction with Riemann's work), was important and some of this thinking and work will be noted as this chapter proceeds. As I argue here, however, two concepts, defining respectively Galois's algebraic and Riemann's geometrical thinking, that of a group and that of a manifold [*Manningfaltigkeit*] respectively, had an unmatched shaping influence on the subsequent developments of algebra and geometry, and in the case of a group, on both, and much of modern mathematics, as well as physics and other sciences, where, especially in physics, the concept of a manifold had played a role as well. Galois also introduced a related concept, that of a group action on another mathematical entity, such as a manifold in geometry or a Hilbert space in quantum physics, a concept that has been important in mathematics and science. Another concept invented by Riemann, that of a Riemann surface, has played a role in the development considered in this chapter, beginning with Riemann's own work, including his invention of the concept of manifold.

While one of the most important and remarkable examples of bringing algebra and geometry together in algebraic geometry and, as such, the main reason for being considered here, the case of Weil and Grothendieck is different. It belongs to twentieth-century mathematics, with the work of Grothendieck having a unique impact on subsequent mathematics, rather than to the rise of modern algebraic geometry in the nineteenth century. This rise followed non-Euclidean geometry (and its effects on the development of projective geometry), on the one hand, and, and on the other, the theory of Abelian integrals, which led Riemann to his concept of a Riemann surface (mathematically, a complex manifold), thus making Riemann a key figure in this development as well. As will be seen, his ideas also had a more direct impact on both Weil's and Grothendieck's work, as did Galois's theory.

I speak of "and" and hence "conjunction," rather than the disjunctive "or," in all three cases considered because, while my primary concern is on the (historically) second figure – Galois, Riemann, and Grothendieck – in each case, I am not merely

juxtaposing, let alone opposing, these figures to each other, especially given the significance of their thinking for transforming mathematics. The accomplishments of Abel, Lobachevsky, and Weil were revolutionary events as well. Instead, while granting the differences between their thinking, my aim is to explore the shared grounding that gives rise to these differences, defining, and defined by, their mathematical practice.

Realizing that mathematics itself or its basic fields cannot be given a single definition, I shall state a general understanding of these fields which is sufficient for my purposes and is, I would contend, in accord with how they are generally viewed. I understand algebra as the mathematical formalization of the relationships between symbols, arithmetic as dealing specifically with numbers, geometry as the mathematical formalization of spatiality, especially in terms of measurement, and topology as the mathematization of the structure of spatial-like objects apart from measurements, through their continuity or discontinuity. The corresponding mathematical fields are algebra, number theory, geometry, and topology. Analysis deals with questions of limit and related concepts, such as continuity, differentiation, and so forth. There are multiple intersections between these fields, and fields that branch off them.

On the other hand, defining algebra as the mathematical formalization of the relationships between symbols makes it part of all modern mathematics. Geometrical and topological mathematical objects always have algebraic components, while algebraic objects may, but need not, have geometrical or topological components. The term algebra has other meanings, such as that (standing at the origins of algebra as a mathematical discipline) of the study of algebraic equations, or that of algebraic structures, such as groups. These forms of algebra are important to both algebra itself and other mathematical disciplines, such as geometry, topology, or analysis. In defining algebra as the mathematical formalization of the relationships between symbols, however, it is not only a matter of having an algebraic component as part of the mathematical structure of geometrical, topological, or analytical objects, but also and especially of defining these objects themselves algebraically.

My argument, then, gives preference to the role of conceptual thinking in mathematics rather than to logical propositions or calculations. Both logic and calculations are essential to mathematics, including conceptual thinking there, because the structure of mathematical concepts is logical, and because calculations require concepts and can lead to new concepts. While, however, fully respecting these features, this chapter views creative mathematical thinking as most essentially defined by the invention of new concepts, a view based on a specific definition or *concept* of concept and of a mathematical theory as an organized assemblage of concepts, as considered in Sect. 2. Mathematics, I argue, advances most by the inventions of new concepts, which defines what I call "mathematical practice as philosophy," a *mathematical* philosophy. For this mathematical philosophy, especially in its emergence, could be analyzed in terms of a more general *philosophy of mathematics*, in part by means of nonmathematical concepts, as it is in this chapter.

The next section outlines a philosophical grounding of this chapter's argument. The subsequent sections are devoted to the three case studies – Abel and Galois,

Lobachevsky and Riemann, and Weil and Grothendieck – as concrete instantiations of this architecture as mathematical practice.

2 Philosophy: The Architecture of Concepts and Mathematical Practice as Philosophy

The concept of a *mathematical concept* to be proposed here is homomorphic to Deleuze and Guattari's concept of a *philosophical concept* proposed in *What is Philosophy?* (Deleuze and Guattari 1996). This homomorphism is not an isomorphism. It preserves the differences (which would be difficult to avoid) between philosophical and mathematical or scientific concepts, and thus the disciplinary specificity of each field, in particular a greater role of logical propositions or formal and quantitative elements in mathematical and scientific concepts vis-à-vis philosophical ones. This role was emphasized by Deleuze and Guattari in their argumentation concerning the difference between and even juxtaposition of philosophical and mathematical or scientific concepts. As discussed below, in the present view (if not strictly in that of Deleuze and Guattari), this difference is also related to the sharpness of the definition of a concept. Deleuze and Guattari's argumentation goes beyond arguing for the difference between philosophical and mathematical or scientific concepts. They see their concept of a philosophical concept as belonging only to philosophy in its *defining* features, while denying these features to mathematics and science, defined by logical propositions and formal mathematical or scientific elements, such as functions. "The concept," they say, "belongs to philosophy and only to philosophy" (Deleuze and Guattari 1996, pp. 11–12, 33–34). They might have argued that the homomorphism proposed here is either too limited or locates (strictly) philosophical subconcepts within mathematical or scientific concepts, something to which they refer as an "interference" (Deleuze and Guattari 1996, pp. 217–218). I argue that this homomorphism is sufficiently rich to be useful and goes beyond such interferences, although the latter are sometimes found in mathematical or scientific concepts. Ultimately, this type of objection would not matter for my argument, insofar as the present definition of a mathematical concept is workable, as I hope it is, for our understanding of what mathematical concepts are and how they work in mathematics. It is this understanding, rather than Deleuze and Guattari's philosophy, that is my concern, helped as my argument may be by theirs or those of other philosophical figures considered here, such as Kant.

In some respects, this chapter returns Deleuze and Guattari's view of concepts to its mathematical origin, given that their concept of a concept was in part modeled on a mathematical concept, that of Riemann's concept of manifold. In addition, as will be seen, part of the genealogy of their argument concerning philosophical concepts is in Abel's and Galois's, in my terms, mathematical practice as philosophy, considered in Deleuze's earlier analysis of "ideas," on which Deleuze and Guattari's argument builds (Deleuze 1995, pp. 180–181). Riemann's concept of manifold is, admittedly, not the only origin of their concept of a concept, which also has a philosophical genealogy. The mathematical genealogy of this concept is, however, important and

paradigmatic historically, beginning with Plato, who, too, both modelled his philosophical concepts on mathematical ones and yet claimed an essential distinction between them (Negrepontis 2019, p. 24, Plotnitsky 2021a, pp. 649–651). Riemann's ideas, as well as those of Galois and Abel, had a major impact on Deleuze and Guattari's philosophy in general, especially, again, Riemann's *concept* of manifold, beyond being a model for their concept of a concept. They saw this concept as heralding a revolutionary philosophical change. This view was helped by the French term "*multiplicité*" as a translation of Riemann's *Mannigfaltigkeit* (which the English translation of Deleuze and Guattari's works often renders, understandably but incorrectly, as "multiplicity"). They say: "It was a decisive event when the mathematician Riemann uprooted the manifold from its predicative state and made it a noun, manifold [*multiplicité*]. It marked the end of dialectics and the beginning of the typology and topology of manifolds" (Deleuze and Guattari 1987, p. 483; translation modified).

Of course, even if mathematical concepts were the only origins of new philosophical ideas or concepts (to the degree that such a single origin is ever possible), this would not challenge claims, such as those of Plato, Hegel, or Deleuze and Guattari, for the fundamental difference between mathematical and philosophical concepts, because these mathematical concepts could be transformed into philosophical concepts in this transition or translation. My argument, however, is that this difference may not be as fundamental as Deleuze and Guattari contend, insofar as arguably the most essential aspect in their definition of a concept, which makes it a composition of its components, a composition specific to each concept, equally defines a mathematical or scientific concept, in the present definition. As will be seen, another key feature, which makes a concept a problem, that they associate strictly with philosophical concepts, can be transferred, even if with qualifications, to mathematical and scientific concepts as well, at least to some of them, such as that of Galois's concept of a group or Riemann's concept of a manifold.

Riemann's thinking and practice provide, arguably, the most famous example of the expressly conceptual approach to mathematics, especially in geometry, where his thinking, leading him beyond all previous approaches to geometry, including those leading to non-Euclidean geometry, abandoned Euclid's axiomatic-theorematic method, previously dominant in foundational thinking concerning geometry. The axiomatic aspects of geometry were at most secondary for Riemann, as against Lobachevsky's and Jànos Bolyia's work, leading each to the discovery of non-Euclidean (hyperbolic) geometry. As I shall argue, however, conceptual thinking plays an essential role in the thinking of all figures considered in this chapter, although the relative balance between conceptual and other forms of mathematical thinking and practice, such as the axiomatic one, is different in each case. Lobachevsky in effect made axioms or postulates of geometry, ultimately all axioms and postulates (rather than only the fifth postulate of Euclid), hypotheses, based in conditional assumptions or conventions, and thus, in the first place, concepts. Intentionally or not, his discovery deprived these axioms and postulates of their status as self-evident or preexisting truths that needed to be assumed or discovered, rather than invented, as concepts and thus geometries always are in the present view.

Ultimately, all axioms, not the least those of Euclid, are conceptual inventions, even when their origins as such are lost. Moreover, as Gödel's theorems tell us, mathematical axioms, assumed to reduce the complex to the simple, are defined by the irreducible complexity that precedes the simple or what appears to be simple. Imre Lakatos, citing Hermann Weyl, referred to Cantor's set-theoretical paradise (as David Hilbert famously dubbed it), as "a bold theoretical construction, and as such the very opposite of analytical self-evidence" (Lakatos 1980, p. 31, n. 3, Weyl 2021, p. 64). This is no less true of Euclid's geometrical paradise.

It is, to reiterate, not my intention to diminish the role of logical or calculational aspects of mathematics or science, or to take anything away from the contribution of those philosophical investigations, such as those in the analytic philosophy of mathematics, that focus primarily on logical and propositional structures in mathematics or science (There are new powerful and rich approaches to logic in mathematics and beyond, such as homotopy type theory (Voevodsky et al. 2013; Corfield 2020). I would contend, however, that concepts still play an essential and unavoidable role in them). My aim instead is to place a proper emphasis on the role of concepts, especially in *creative* thinking in mathematics or science, but not only there, because working with already established concepts is indispensable in all mathematical or scientific practice. Besides, analytic philosophers, too, sometimes, give concepts their due, beginning with one of the founders of analytic philosophy, sometimes even seen as *the* founder of it, Gottlob Frege, who gave priority to the role of concepts in mathematics and philosophy. The unconditional opposition between the logical-propositional and conceptual structures, or between calculations and concepts, is not so easy to maintain, even in considering figures such as Galois and Riemann, or Dedekind. While their thinking was primarily governed by concepts vis-à-vis calculations, they were perfectly capable of and performed difficult calculations. And then, logic and calculations do involve concepts and lead to new concepts, as they did in the case of Abel, or more pointedly (as he insisted on their primacy) Kronecker. Calculations can also function as statements, sometimes even as philosophical statements, thus connected to concepts. (There are still other aspects of mathematical thinking, for example, a narrative one, the role of which, as constitutive rather than merely auxiliary, which has always been recognized, has received a considerable amount of attention during recent decades. For a representative collection of essays on the subject, see Doxiadis and Mazur (2012). For a full disclosure, the present author was among the contributors.) Calculations, too, involve narrative dimensions. My main emphasis in this article is, however, on concepts as, arguably, the primary creative vehicles of mathematics.

In the present understanding, then, extending that of Deleuze and Guattari beyond philosophy, concepts are essential and even primary vehicles of creative thinking in theoretical fields. What is a concept, then? First, a concept is not merely a generalization from particulars (which is commonly assumed to define concepts) or a general or abstract idea, although a concept may contain such generalizations or ideas, specifically abstract mathematical ideas in mathematics or physics, where these abstractions may also become concepts. A concept is a multicomponent structure, defined by the organization, *composition*, of its components, and some

of these components may be concepts in turn. This is, however, only a general, *abstract*, definition. What meaningfully defines a concept is the specific character of its compositional structure, defined by both the nature of each component and the character of their relations within this composition, by how these components relate to each other in the structure of this concept. Such components may be more general or particular, and some of them are concepts in turn. This composition is unique in a new concept, and make this concept unique. The creative essence of concepts is in their compositional individuality, which is only possible by virtue of their generally compositional nature, but is defined by the specificity of this composition. All musical works are compositions, but each gives us different music. A group is composed of its elements, but in accordance to very specific rules, which give it its structure and role in mathematics in group theory and beyond, and then it multiplies further to still more specific concepts of a group, a finite group, a Lie group, an algebraic group, and so forth, and then into further concepts within each of these.

A concept is a multicomponent conglomerate of concepts, figures, metaphors, and so forth, which are conjoint in a composition, a *relational organization* of the components. It is rare for a concept to have only one component, and ultimately impossible to do so. As Deleuze and Guattari say, "there are no simple concepts. Every concept has components and is defined by them. . . . There is no concept with only one component" (Deleuze and Guattari 1996, p. 16). A single-component concept, such as an element of a group, is a product of a provisional suspension or cut-off of its multicomponent organization, such as that defining the concept of an element, usually taken as a primitive concept as it may be. In fact, there are always cut-offs in delineating a concept, cut-offs that result from assuming some of the components of this concept to be primitive entities whose structure is not specified. These components could, however, be specified by alternative delineations, leading to a new concept, containing a new set of more primitive components.

Consider as an example the mathematical concept of space, discussed in detail in connection with Riemann's rethinking of the foundations of geometry in Sect. 4. Emerging historically at the intersection of mathematics, physics, philosophy, and general phenomenal intuition, and defined by such constitutive concept-components as point, line, plane, or distance, as philosophical, physical, and mathematical concepts, this concept and each of these components have a long history of definitions, modifications, transformations, and so forth. As a general phenomenal concept, it is arguably as old as is human consciousness (any concept requires consciousness to be defined as a concept). Kant did not see space and time as concepts, but rather as a priori forms of our phenomenal intuition. He had a point, even if one rejects (as many, including Riemann, have done) his a priori view of space and time, insofar as these phenomenal forms precede any concept of space and time our general phenomenal thinking can form, as Kant realized they can. As a geometrically representable physical concept, space is at least as old as ancient Greek geometry, well preceding Euclid, who does not define, although, arguably, implies space in the *Elements*. Its history as a mathematizable physical and eventually (that happened only in the nineteenth century) purely mathematical concept

extends, to mark some of its junctures, from Euclid to Descartes (a coordinate space) to Riemann (a space defined as a manifold) to Felix Hausdorff (topological space) to Grothendieck (topos). For the first three figures, the concept of space qua space was, while mathematizable, still physical. The concept also has its algebraic aspects and history. After each transformation, such as that of defining it as (representable by) a manifold by Riemann, the new concept of space, became, to stay with Kuhn's idiom, part of the *normal* practice in mathematics, or physics, during which it acquired further features and new definitions.

A concept, then, is an assemblage of its components connected by its composition, which define its specific individual nature. Some of its components may be unique as well but need not be. The components of a concept need not be new, but its composition must be new for a concept to be new. In this respect a concept is akin to a work of art, always defined by its composition, in accord with the ancient Greek meaning of *poiein* (to make), as making something new, in which the term poetry originates. A theory, then, or a disciplinary field, mathematical, scientific, or philosophical, such as geometry, classical physics, or Kant's philosophy (philosophy, again, tends to be more individualized), becomes an organized assemblage of concepts. It is a product of a broader *poiein*, in mathematics or science, more commonly collective, although it may be initiated by a single new concept, such as that of Galois's concept of a group or Riemann's concept of a manifold. In the present view, however, a *creative* conceptual *mimesis* (which may borrow elements of previous concepts but combines them in a new way) is a *technical* mimesis of previous concepts, rather than a Platonist mimesis of some preexisting independent reality, assumed to govern this mimesis.

I am not equating theoretical concepts (or theories) with works of art, either in their compositional nature or in their functioning. For one thing, a work of art, as a composition, may but need not contain concepts, although so-called conceptual art does. In functioning, a concept can be used directly or with minor modifications in, again, in Kuhn's terms, the normal practice in the corresponding theoretical field, especially mathematics and science. As noted, philosophy, at least a certain form of philosophy, may be associated, as it is in Deleuze and Guattari, with the invention of concepts as a revolutionary practice, which thus becomes its normal practice. In this respect, this practice is closer to that of art, which, while it may use a tradition, is compelled to be innovative in each work, but only in this respect, because the nature of the conceptual and artistic composition remains different. The relationships among mathematics, philosophy, and art have been an important and sometimes defining subject in the history of philosophy, from Plato on. It is, accordingly not surprising that art, as defined by artistic composition, versus philosophy, as defined by concepts, or versus mathematics and science, as defined by formal structure and logical propositions (and, in science the concept of reference), was an important part of Deleuze and Guattari's argument for defining philosophy. Art is beyond my scope here. On the other hand, it is difficult to bypass the fact that Deleuze and Guattari deny that concepts in their sense are found in mathematics or science, a denial that can be misleading for understanding the nature of conceptual thinking in either domain.

They even declare that "it is pointless to say that there are concepts in science [including mathematics]," adding that "even when science is concerned with the same 'objects' [as philosophy] it is not from the viewpoint of the concept; it is not by creating concepts" (Deleuze and Guattari 1996, p. 33). This, in my view problematic or at least insufficiently qualified, assessment also includes Riemann's thinking concerning manifolds and spatiality: "Riemannian functions of space [one presumes, those defining the mathematical structure of his manifolds], for example, tell us nothing about a Riemannian concept of space peculiar to philosophy: it is only to the extent that philosophy is able to create it we have a concept of a function" (Deleuze and Guattari 1996, p. 161). That may be true as concerns some philosophical "Riemannian" concepts of space, such as that of Henri Bergson (to whom Deleuze often refers in this connection). Perhaps this is what this statement primarily refers to, insofar as at stake in it is a Riemannian concept of space peculiar to philosophy and not Riemann's concept of space as a mathematical concept. Still, it would be difficult to agree that "it is only to the extent that philosophy is able to create it we have a concept of a function." The opposite appears to be the case: one can only have a function to the extent that mathematics was able to create its concept or the concept of function in the first place. This is certainly so in the case of those functions that appear in Riemann's concept of manifold or in his analysis of functions of a complex variable, which led him to his concept of a Riemann surface. Deleuze and Guattari add irrational numbers as another example, "the concept, on the other hand, refers not to series of [rational] numbers [series defining irrational numbers mathematically] but to a string of ideas that are reconnected over a lacuna (rather than linked by continuation)" (Deleuze and Guattari 1996, p. 161). Is not, however, a new mathematical concept, such as that of an irrational number (any such concept) equally defined by a string of new ideas reconnected over a lacuna left by earlier ideas? Was it not how Dedekind invented his concept of real numbers? One could in principle argue, as Deleuze and Guattari might have, that a mathematical definition of a concept by putting together its components, such as that of a group as a particular organization of its elements, represents a philosophical, rather than mathematical, thinking within mathematics, and as such defines a philosophical concept that underlies this mathematical concept. As noted, Deleuze and Guattari see this situation, or more generally, the relationships between philosophical and mathematical or scientific thinking, or between either thinking and art, in terms of "interference" with each other (Deleuze and Guattari 1996, pp. 217–218). There may be philosophical or, again, artistic dimensions to mathematical or scientific thinking, especially in its intuitive part, involved, for example, in plausible reasoning (Polya 1990; Corfield 2006). It would, however, be difficult to limit this type of creation in this way, even given the *exact* nature of mathematical or scientific concepts and thinking, which distinguishes them from *inexact* but (philosophically) rigorous philosophical concepts and thinking. This difference between the exact and the inexact is invoked by Deleuze and Guattari, in part, it is worth noting, via Edmund Husserl's analysis of the origin of geometry as an exact science vs. inexact, but, again, rigorous, philosophical thinking (Deleuze and Guattari 1987, pp. 407, 483; Husserl 1970). It may ultimately be impossible to strictly maintain this difference, as the exact and inexact

can coexist and invade each other, but it is not possible to disregard it either, these gray areas notwithstanding. One might take advantage here of an astute and far-reaching remark of Heisenberg, aimed especially against Kant, in view of quantum physics, but leading Heisenberg to a broader point, which equally and even more directly applies in mathematics:

> Any concepts or words which have been formed in the past through the interplay between the world and ourselves are not really sharply defined with respect to their meaning; that is to say, we do not know exactly how far they will help us in finding our way in the world. We often know that they can be applied to a wide range of inner or outer experiences, but we practically never know precisely the limits of their applicability. This is true even of the simplest and most general concepts like "existence" and "space and time." Therefore, it will never be possible by pure reason to arrive at some absolute truth [in physics or even mathematics as Kant thought it might be].
>
> The concepts may, however, be sharply defined with regard to their connections. This is actually the fact when the concepts become a part of a system of axioms and definitions which can be expressed consistently by a mathematical scheme. Such a group of connected concepts may be applicable to a wide field of experience and will help us to find our way in this field. But the limits of the applicability will in general not be known, at least not completely. (Heisenberg 1962, p. 92)

Kant is not as far from much of Heisenberg's argument as Heisenberg thinks, and if Kant could have benefited from modern physics, especially quantum theory, or mathematics, beginning with non-Euclidean geometry, he might have agreed with Heisenberg as concerning the role of causality, which he strictly maintained but which was challenged by quantum theory. I shall discuss the question of Kant's claim concerning our capacity to "arrive at absolute truth" in connection with Riemann's views of space (a physical concept for Riemann) and geometry in Sect. 4. Kant's analysis is also characterized by a search for a *sharper* definition and the limits of applicability of concepts, in part through establishing the connections between them, even if not as embedded in "a mathematical scheme." It may well be, however, that, although, by virtue of establishing more rigorous connections between concepts, a definition of an inexact philosophical concept is sharper than in the case of our daily concepts, this definition cannot be as sharp as that of a mathematical concept. Such a mathematical concept can also be used in physics, although a physical concept that uses this mathematical concept may not be defined as sharply as a mathematical concept either.

If one adopts this view, as I do here, the difference between *inexact philosophical* and *exact mathematical* concepts will be maintained as essential and as defining mathematical concepts, on this point in accord with Deleuze and Guattari's view. On the other hand, the compositional character, as equally defining both types of concepts, will be maintained, thus challenging Deleuze and Guattari's unequivocal claim that "the concept belongs to philosophy and only to philosophy," a claim that they appear to extend to the compositional character of concepts. It is conceivable that they would have accepted the view proposed here. Generally, however, they see the relationships between inexact philosophical and exact mathematical or scientific concepts or thinking as either operative alongside each other or in terms

"interference" (in the positive sense of interfering wave fronts rather than in the sense of inhibition), as when "a philosopher attempts to create the concept of . . . a function (for example, a concept peculiar to Riemannian space or to irrational number)" (Deleuze and Guattari 1996, p. 217). By contrast, in the present view, creative mathematical and scientific thinking is defined by the creation of multi-component mathematical or scientific concepts, compositionally, if not *functionally*, analogous or homomorphic to that of philosophical concepts in Deleuze and Guattari's sense, with each concept defined by the specificity of its composition. Just as there are Plato's ideas, Descartes's cogito, and Leibniz's monads, there are Gauss's curvature, Riemann's manifolds, Dedekind's ideals, and Grothendieck's topoi in mathematics. It may be that in mathematics and science such signatures below the concept are erased by history and the concepts themselves more commonly modified or translated by means of new concepts than in philosophy. But, apart from the fact that this is not always so, as in the case of Riemann surfaces or Hilbert spaces (redefined as each has been many times as a concept), this forgetting does not diminish the significance of the creation of concepts. These conceptual compositions are not *isomorphic* because of technical or, again, *exact* aspects of mathematical and scientific concepts, which enables a greater and perhaps maximal possible, even if, as Heisenberg says, never complete, sharpness of their definitions, which is demanded by and has defined the disciplinary nature of mathematics and science throughout their history.

Another difference, noted earlier, is, in Kuhn's terms, in the nature of *normal*, rather than *revolutionary*, practice in each domain. In philosophy, normal practice consists primarily in understanding, interpreting, and commenting on concepts, while in mathematics and science, the normal practice consists primarily (while still reflecting on and interpreting concepts) in working with frames of reference and other mathematical or scientific formations, propositions, and so forth. It is true that for Deleuze and Guattari revolutionary philosophical practice is the primary form of philosophy. This is, however, not in conflict with the view of creative practice in mathematics or science advocated here, insofar as this practice is equally defined by the invention of concepts.

In addition, according to Deleuze and Guattari, a philosophical concept in their sense is also defined as a problem, as positing a problem along with and even *as* this concept. This view has a mathematical genealogy, although the concept of a problem well preceded mathematics and was adopted by it and given a mathematical specificity by ancient Greek mathematics. A problem in this sense is not something that, like a theorem, is derived from assumed axioms by means of logical rules, but is something that is posed, created, along with and as a concept. A theorem could be a problem in this sense, when it arises, from a mathematical concept, such as that of Riemann's concept of manifold or Galois's concept of a group. In Deleuze and Guattari's understanding, however, insofar as it remains a philosophical concept, a problem persists rather than disappears in its solutions, which fact enables such a "concept-problem," as it may be called, to remain "always new," insofar as, as I understand it, its productive significance is retained in the history following its invention (Deleuze and Guattari 1996, p. 5). This is a complex conception, which

is not easy to interpret consistently, let alone definitively. The view of concepts as "concept-problems" that I adopt as applicable to mathematical concepts may only be a *version* or a variation on the theme, rather than an interpretation, of Deleuze and Guattari's understanding of concepts as problems. This view, however, appears to me to be workable in mathematics.

First of all, in this view, not all mathematical or scientific concepts as defined above are concept-problems, while all philosophical concepts in Deleuze and Guattari's sense appear to be for them, which is, however, a secondary matter here. My point here is that some mathematical or scientific concepts are in a way analogous to philosophical concept-problems in Deleuze and Guattari. A new concept-problem, such as that of a group by Galois or a manifold by Riemann, would be introduced, first, just as a concept in order to solve an already existing problem, which defied a solution by means of already existing concepts or perhaps offered such a solution that was unsatisfactory for one or another reason, conceptual, technical, or aesthetic. Finding the algebraic solution to a polynomial equation (or proving the impossibility of doing so) in Galois's case, or that of properly defining any possible geometry in Riemann's case, was such a problem. Their way of thinking already reflects two approaches (predictably with gray areas between them or sometimes combining both) to solving a problem, especially a difficult problem: the first is essentially logical, which aims to solve it by means of logical and technical manipulations of previously existing concepts, and the second is essentially conceptual, which uses a new concept or set of concepts, although technical and logical manipulations remain unavoidable of course. Such a concept may be relatively simple, which is not to say trivial, such as that of a group, or (still more nontrivially) of an action of a group, or it may be more complex, such as that of a manifold, or very complex, such as those of Grothendieck. But, even when relatively simple, such a concept usually arises in response to a complex problem, as in the case of the concept of a group, invented by Galois to find an algebraic solution to a polynomial equation (and proving the impossibility of doing so), a very complex problem at the time. By be means of his concept of a group, Galois redefined this problem by establishing that whether such a solution exists or not is related to the structure of a group of permutations associated with the roots of the polynomial, known as the Galois group of this polynomial. Abel's approach to this problem had elements of this thinking by posing the question whether a solution exists or not, given the structure of the equation, and finding that in general it does not, the finding now known as the Abel-Ruffini theorem or Abel's impossibility theorem. Paolo Ruffini gave an incomplete proof in 1799, and Abel was the first to prove it in 1824.

As a *concept-problem*, however, a new concept does more than merely solving a given initial problem. It defines a new problem-posing field in which new types of actual problems emerge and are being solved, while the concept-problem that initiated and governs this field is not something that is "solved" so as to no longer be necessary for this field to continue to develop, which it does by defining new concepts and concept-problems (some of which are new forms of the original concept-problem). Doing so is a far-reaching form of mathematical practice as

philosophy. Galois's concept of a group not only gave the Abel-Ruffini theorem a more general grounding but also, now as a concept-problem, gave algebra a new problem-posing field, Galois theory. This type of invention of a new concept in response to a concrete problem not only in solving this problem but also making this concept a concept-problem, which leads to a new problem-posing field, can happen as an outcome of a deliberate strategy, as it was arguably the case in Grothendieck or (although it is more difficult be certain) Galois and Riemann, or it might happen contingently, in a complex interplay between chance and necessity. In this sense, such concept-problems give rise to theories, such as Galois theory, Riemann geometry, or Grothendieck's topos theory.

Deleuze and Guattari would have probably seen such concept-problems as philosophical, even when they are operative in mathematics, while seeing mathematics as being about solutions of its problems, a relation that, as discussed in Sect. 3, Deleuze suggested earlier, via Albert Lautman and Jules Vuillemin, in speaking of ideas, rather than concepts, but conceived analogously, still using Abel's and Galois's thinking as a key model of this process (Deleuze 1995, pp. 163–164, 179–182). It is true that mathematics is commonly in pursuit of solutions of its problems, and there is often a philosophical dimension to defining such a new problem-posing field. However, in the present view, as just outlined (which I am, again, not attributing to Deleuze and Guattari), a concept-problem, such as a group, is *mathematical*. It still enables one to solve, or to advance the possibility of solving, concrete problems, beginning, in Galois's case, with a problem that gave rise to the concept of a group – the problem of finding the algebraic solution to a polynomial equation – but it does so by embedding this original problem in a new *mathematical* concept-problem, which defines a new problem-posing mathematical field, or even a new field of mathematics, such as Galois theory in algebra and in effect much more. This concept-problem is, accordingly, mathematical, including, again, by virtue of the sharpness of its formal definition, possible for all mathematical concepts, but difficult to achieve outside mathematics.

That need not and here does not mean that such a concept-problem contains or fully determines a problem-posing field it creates, even if only as a potentiality, in a Platonist fashion. This field emerges in a contingent development, as a complex interplay of causal chains and chance occurrences. In general, in adopting a problem-posing versus axiomatic-theorematic view of mathematics, one is more likely to reject a Euclidean, essentially Platonist, view in which axioms are assumed as pregiven truths rather than as created as concepts, as axioms are from the present perspective, a distinction that, as discussed below, was brought into the foreground by the discovery of non-Euclidean geometry. To sharpen this difference, I shall adopt Lakatos's distinction between a Euclidean theory (paradigmatically based on Euclidean geometry) and a quasi-empirical theory, which is how Lakatos sees mathematics. ("Quasi" reflects the fact that mathematics is "empirical" in dealing with mental rather than material phenomena.) The mathematical practice of figures considered here is quasi-empirical, in parallel with being problem-posing, rather than Euclidean and, hence, axiomatic-theorematic, although some of them, such as Abel, Weil, and Grothendieck might have adopted a more Euclidean ideology of mathematics. This

split is not uncommon; and one might even argue, as Lakatos does, that no Euclidean ideology can avoid quasi-empirical practice, thus making a purely Euclidean practice impossible. According to Lakatos:

> The methodology of a science is heavily dependent on whether it aims at a Euclidean or at a quasi-empirical ideal. The basic rule in a science which adopts the former aim is to search for self-evident axioms—Euclidean methodology is puritanical, antispeculative. The basic rule of the latter is to search for bold, imaginative hypotheses with high explanatory or 'heuristic' power, indeed, it advocates a proliferation of alternative hypothesis to be weeded out by severe criticism—quasi-empirical methodology is uninhibitively speculative.
>
> The development of Euclidean theory consists of three stages: first the naïve prescientific stage of trial and error which constitutes the prehistory of the subject; this is followed by the foundational period which reorganizes the discipline, trims the obscure border, establishes the deductive structure of the safe kernel; all that is then left is the solution of problems inside the systems, mainly constructing proofs or disproofs of interesting conjectures. ([The discovery of] a decision method for theoremhood may abolish this stage altogether and put an end to the development.)
>
> The development of a quasi-empirical theory is very different. It starts with problems followed by daring solutions, then by severe tests, refutations. The vehicle of progress is bold speculations, criticism, controversy between rival theories, problem shifts. Attention is always focused on the obscure border. The slogans are growth and permanent revolution, not foundations and accumulations of eternal truth.
>
> The main pattern of Euclidean criticism is suspicion: Do the proofs really prove? Are the methods used too strong and therefore fallible? The main pattern of quasi-empirical criticism is proliferation of theories and refutations. (Lakatos 1980, pp. 29–30)

Every new concept, especially a concept-problem, is taking a chance (possibly, sacrificing one's own interests to the rigor of thought) on the future of mathematics or science, or philosophy. The invention of new concepts, as "always new" concept-problems, has, according to Deleuze and Guattari, defined the creative practice in philosophy from the pre-Socratics on. Deleuze and Guattari may have been indebted most to Friedrich Nietzsche's view of all true philosophy as "a philosophy of the future," his subtitle to *Beyond Good and Evil: A Prelude to a Philosophy of the Future* (Nietzsche 1966). One can, I argue, take the same view of many new mathematical concepts, such as that of Galois's concept of a group or Riemann's concept of a manifold, although one cannot always know in advance which. Robert Langlands (of the Langlands program fame, a program in part grounded in Galois theory) compared Grothendieck to "Nietzsche's *Philosoph der Zukunft*" (Langlands and Shelstad 2007, p. 486). This is no less true about Galois and Riemann, or Abel, Lobachevsky, and Weil, or Langlands, as the Langlands program proved.

3 Algebra: Abel and Galois

My argument in this section is indebted to that of Jules Vuillemin's analysis, over half a century ago, of Abel and Galois, and their predecessors, such as Legendre and Gauss, and of algebra itself in *La philosophie de l'algèbre* (Vuillemin 1962) and that of Deleuze, building on Vuillemin's analysis (Deleuze 1995). This is not to say that

my argument *follows* that of Vuillemin, which has a strong structuralist orientation shaped by the Bourbaki program (the book is dedicated to, among others, Pierre Samuel, a member of Bourbaki), very different from the conceptual and quasi-empirical one of this chapter. Also, the project of Vuillemin's book is to transpose the methods of algebra, such as those of Abel and Galois, into philosophy, which is not my aim either. My argument absorbs some aspects of Vuillemin's argument within a conceptual orientation, as Deleuze does, inspired by Vuillemin and Lautman, again, in transposing the methods of Abel and Galois into his theory of ideas (a precursor of his and Guattari's theory of concepts) and thus into philosophy. Nor, for the reasons explained in the preceding section in considering concept-problems, does my argument quite follow that of Deleuze either, but instead builds on and yet transforms it. According to Deleuze:

> Abel elaborated a whole method according to which solvability must follow from the form of the problem. Instead of seeking to find out by trial and error whether a given equation is solvable [in radicals] in general, we must determine the conditions of the problem which progressively specify the fields of solvability in such a way that 'the statement contains the seeds of the solution'. This is a radical reversal in the problem-solution relation, a more considerable revolution than the Copernican. It has been said [by Vuillemin] that Abel thereby inaugurated a new Critique of Pure Reason, in particular going beyond Kantian 'extrinsicism'. This same judgement is confirmed in relation to the work of Galois: starting from a basic 'field' (R), successive adjunctions to this field (R', R", R"'...) allow a progressively more precise distinction of the roots of an equation, by the progressive limitation of possible substitutions. There is thus a succession of 'partial resolvents' or an embedding of 'groups' which make the solution follow from the very conditions of the problem: the fact that an equation cannot be solved algebraically, for example, is no longer discovered as a result of empirical research or by trial and error, but as a result of the characteristics of the groups and partial resolvents which constitute the synthesis of the problem and its conditions (an equation is solvable only by algebraic means—in other words, by radicals, when the partial resolvents are binomial equations and the indices of the groups are prime numbers). The theory of problems is completely transformed and at last grounded, since we are no longer in the classic master-pupil situation where the pupil understands and follows a problem only to the extent that the master already knows the solution and provides the necessary adjunctions. For, as Georges Verriest remarks, the group of an equation does not characterize at a given moment what we know about its roots, but the objectivity of what we do not know about them. Conversely, this non-knowledge is no longer a negative or an insufficiency but a rule or something to be learnt which corresponds to a fundamental dimension of the object. The whole pedagogical relation is transformed—a new *Meno*—but many other things along with it, including knowledge and sufficient reason. Galois's progressive discernibility unites in the same continuous movement the processes of reciprocal determination and complete determination (pairs of roots and the distinction between roots within a pair). It constitutes the total figure of sufficient reason. (Deleuze 1995, pp. 179–180)

This is a radical transformation of mathematical practice as philosophy and, on this pattern, of philosophy itself, including the pedagogy of ideas or concepts, which philosophy has always been. The argument also implies that the pedagogy of mathematics, at least as it implicitly functions in mathematical practice (and possibly even in the actual teaching of mathematics, which is, however, a separate subject).

Galois's thinking has a more revolutionary significance for both Vuillemin and Deleuze. Nevertheless, according to Vuillemin, Abel transforms algebra, as the inventor of "a general method":

> In the first place, we analyze, in its most general form, a mathematical relation or a defined set of such relations, which make it possible to determine a property, of which we do not yet know whether or not we can attribute it to a class of beings: by example the character of being algebraically solvable, of being convergent, of being expressible by a defined number of functions of a certain class. In the second place, one considers the class of beings to which it is a question of attributing this property [...]; we analyze these beings from a general point of view, we define the relationships to which their nature allows them to be subjected. Finally, this double examination reveals the cases of incompatibility (demonstrations of impossibility) and, possibly, indicates the way to find the new required relationships in cases of possibility. (Vuillemin 1962, pp. 214; translation mine)

Thus, rather than looking for the solution to the equations of the fifth degree, one asks whether such a solution is possible, in the first place, for any polynomial equation. Abel's new "idea of a general method consists in giving a problem a form such that it is always possible to solve it" (Vuillemin 1962, pp. 209; translation mine). What Abel then shows is that the conditions for any equation to be solvable are not, in general, fulfilled once the degree of the equation is more than four. In this way, by reversing the method of his predecessors, which proceeded from the particular to the general, by generalizing the particular, to proceeding from the general to the particular (the general conditions of solubility of algebraic equations are satisfied for any specific equations of any degree less than five), Abel becomes one of the creators of the modern algebraic method, which Vuillemin sees as, in effect, structuralist in Bourbaki's sense. Against Kant, who limited his construction of the proof of impossibility by positing the possibility of an experience as an exclusive criterion of knowledge, "general demonstrations, in the sense of Abel, change the modality of the proof. Particular demonstrations are actual [*réelles*]: they assume as their grounding principle the possibility of the experience given in the affect of sensation. The general proofs deal with the possible and start from the concept alone, disregarding the restrictive conditions of sensitivity" (Vuillemin 1962, p. 216; translation mine). This initiating concept is, thus, defined not by a generalization from particulars, but as a new structured entity. Mathematics needed Galois in algebra (a group) and then Riemann in geometry (a manifold) to be expressly rethought in this way. Abel thus introduced a new critique (in Kant's sense of an analysis of concepts) of pure reason, at least in mathematics, but, as both Vuillemin and Deleuze argue, extendable beyond mathematics.

While (independently) adopting the same "general method" as that of Abel, Galois brings a new, an even more revolutionary, dimension to this critique by his invention of the concept of a group. Some elements of group-theoretical thinking are found in Abel, or Legendre, earlier, but the concept carries Galois's signature, and it was conceived in accord with a concept of concept as defined here. It was, moreover, accompanied by another, equally innovative and important concept, that of an action

of a group on another structured entity, also defined as a concept, such as an algebraic field or vector space.

For Vuillemin, deeply steeped in Bourbaki's ideology, the emphasis is on the idea of structure, and he sees the concept of a group as the first algebraic structure, introduced and analyzed as such, in the history of mathematics. Galois's thinking, then, is both akin to that of Abel as concerns Abel's philosophy of solving problems, as just considered, and reaches beyond Abel by bringing in the role of a structure and the concept of a group as an entity (we would now say a set) with a structure, a relationally organized multiplicity. Galois, for Vuillemin, becomes the first modern algebraist, who associates with solving a problem the analysis of the structure from which this problem arises, and which makes it possible or not to solve it, such as the problem of finding algebraic solutions of polynomial equations. Vuillemin's structuralist perspective is not out of place. One cannot avoid structures, as all concepts are structures, compositions, and hence, merely dismiss structuralism (Corry 2003). My point here is the emergence of structures as concepts.

Indeed, as in the case of Abel's thinking, one of Vuillemin's main points is more about concepts than structures, keeping in mind that a concept is a structure, too, and conversely any given structure qua structure has to be defined and thus may be a concept, including in the present sense of problem-concepts, as it indeed was for Bourbaki. Vuillemin distinguishes two types of abstraction: the first is conventional, defined by an increasing generalization from the particular to the general, and the second, found in group theory, is conceptual in the present sense. It defines the differences between specific individual cases, because it constructs these cases, from the initial concept, such as that of a group. Vuillemin sees the second abstraction or, more precisely, "formalization" in terms of a double abstraction: the first is that of the formal presentation of the group, as a concept, in terms of algebraic symbols and their relations; the second is that defined by providing a method that makes it possible "to construct individuals, no longer in intuition according to imperfect [more arbitrary] schemes, but [determinately] in the concepts themselves" (Vuillemin 1962, pp. 288–289; translation mine).

Thus, one deals with an algebraically formalized conceptual practice, in accordance with the argument of this chapter, and redefines algebra accordingly, ushering in a new mathematical practice as philosophy. In Galois's and (more extensively) in Abel's case, one also deals with a parallel shift to the conceptual algebraization of analysis, as well as, in effect, geometry (where this shift was already initiated with the analytic geometry of Fermat and Descartes). The subsequent "returns" of geometry still use and are often based on this lateralization rather than dispensing with it (Plotnitsky 2021a). In noting that, in the wake of Galois, "modern mathematics is therefore regarded as based upon the theory of groups or set theory rather than upon differential calculus," Deleuze adds: "Nevertheless, it is no accident that Abel's method consisted in giving a problem a form such that it is always possible to solve it, concerned above all the integration of differential formulae" (Deleuze 1995, pp. 180–181).

Galois's contribution was ultimately more fundamental conceptually, as based in the concept of a group as a multiplicity, in effect as a set, with a structure, an entirely

new type of concept. As a concept-problem, this concept defines a new problem-posing field through the new mathematical formulations of existing problems (such as that of the solution of polynomial equations in radicals) and posing new problems, and the simultaneous establishing of their conditions of solvability. This new thinking changes the future of mathematics as a field of solving problems, because both these problems and the conditions of their solvability change, in particular, by asking under what conditions a given problem (such as that of finding the solution of polynomial equations in radicals) can be solved. Abel does something similar, but there is no concept of the type a group is. Galois, again, also creates the concept of an action of a group on another structural entity, such as a field or a manifold in geometry.

A momentous role of Galois's concept of a group for algebra has been akin to that of Riemann's concept of manifold for geometry. It may not, in retrospect, be surprising that, in the wake of both Galois and Riemann, with the work of, to mention some among the most prominent names, Felix Klein, Sophus Lie, Poincaré, Élie Cartan, and Weyl, the role of group theory – the action of a group on a manifold – became so crucial in geometry and elsewhere in mathematics or physics. Most elementary particle physics is now understood and practiced in terms of group representations and symmetries they define (irreducible representations correspond to elementary particles). The examples are numerous and will undoubtedly continue to accumulate. One of them is especially intriguing because, expectedly, it establishes remarkable connections between Galois theory and quantum field theory (QFT), specifically one of the most important and still controversial aspects of it, namely, the so-called renormalization. I would like, accordingly, to briefly comment on these connections in closing this section.

It was realized by the early 1930s that the computations provided by quantum electrodynamics (QED), the original form of QFT, were reliable only to a first order of perturbation theory. (Perturbation theory is a set of approximation methods using mathematical perturbation for describing a complex quantum system by using a simple one with a known solution and adding to it a "perturbing" Hamiltonian representing a small disturbance of that simple system.) These computations led to the appearance of infinities or divergences when one attempted to use the formalism for calculations that would provide closer approximations matching the experimental data. These difficulties were eventually handled through the renormalization procedure, which became and has remained a crucial part of QFT, because it still contains these divergencies, specifically certain divergent and, hence, mathematically illegitimate integrals. Roughly speaking, the renormalization procedure manipulates such infinite integrals by, at a certain stage of calculations, replacing them with finite integrals through artificial cut-offs. These cut-offs have no proper mathematical justification and are performed by putting in, by hand, experimentally obtained numbers that make these integrals finite, which removes the infinities (which happen to cancel each other) from the final results of calculations (e.g., Teller 1995, pp. 149–168.) At some point of the history of renormalization, a new concept (a concept-problem), that of the renormalization group, was introduced, with the work of Kenneth G. Wilson giving this concept its current form. The renormalization

group is a mathematical technique, part of the so-called effective QFTs, that enables one to properly investigate the changes of a quantum system as represented ("viewed") at different scales. It reflects the changes in the underlying force laws of QFT, changes due to the fact that the energy scale at which physical processes occur varies, with energy-momentum and resolution distance scales obeying the uncertainty relations. Actual computations are difficult and performed by means of various mathematical techniques, massively assisted by, and in fact impossible apart from, the use of very powerful computers. Conceptually, one evaluates the transformations in the formalism in accordance with Feynman's diagrams, which are, however, only heuristic guides to such calculations in most views, including Richard Feynman's own (e.g., Plotnitsky 2021b, pp. 300–302).

Quite unexpectedly, Galois theory can be brought up to recast the mathematics involved in a new and more rigorous form. The technical complexities are, again, formidable, even for most working in QFT, including among other stratospheric techniques, Grothendieck's theory of motives. These complexities may, however, be bypassed here. My point is a remarkable *fact* itself of the role of a Galois group in renormalization theory. The idea was initially suggested by Pierre Cartier, who designated the corresponding Galois group a "cosmic Galois group," in view, one suspects, of its potential significance in the ultimate QFT, possibly including gravity (Cartier 2001). It is sufficient to consider here the basic statement of how a specific ("motivic") Galois group enters, given by Alain Connes and Matilde Marcolli's article, which explains the essential point. The article and their related work also provide necessary formal definitions for a suitably informed reader, as the mathematics is formidable and requires advance levels of training. According to them:

> The divergences of quantum field theory are a highly structured phenomenon [even beyond the renormalization group, which already structures them]. More precisely, they provide data that define an action of a specific "*motivic Galois group*" U^* on the set of physical theories.
>
> In particular, this exhibits the renormalization group as the action of a one parameter subgroup $\mathbb{G}a \subset U^*$ of the above Galois group. . . .
>
> The natural appearance of the "motivic Galois group" U^* in the context of renormalization confirms a suggestion made by Cartier in [Cartier 2001], that in the Connes–Kreimer theory of perturbative renormalization one should find a hidden "cosmic Galois group" closely related in structure to the Grothendieck–Teichmüller group. The question of relations between the work of Connes–Kreimer, motivic Galois theory, and deformation quantization was further emphasized by Kontsevich in [Kontsevich 1999]. . . .
>
> The "motivic Galois group" U^* acts on the set of dimensionless coupling constants of physical theories, through the map of the corresponding group $\mathbb{G}$ to formal diffeomorphisms constructed in [Connes and Kreimer 2001].
>
> This also realizes the hope formulated in [Connes 2003] of relating concretely the renormalization group to a Galois group. . . .
>
> These facts altogether indicate that the divergences of Quantum Field Theory, far from just being an unwanted nuisance, are a clear sign of the presence of totally unexpected symmetries of geometric origin. (Connes and Marcolli 2004, pp. 4073–75) (See also Connes and Marcolli (2007, pp. 95–136) for a comprehensive exposition of these problematics).

The last conclusion is remarkable, because it counters the common sentiments (some of which have been more strongly negative) that have governed the attitude

toward the divergencies of QFT and renormalization from 1930 on. In addition, it brings in yet another, highly complex, instance of the interplay between algebra and geometry into quantum theory. The physical meaning and implications of this mathematics have hardly been explored as yet, even though there were some developments along these lines since. My main point is, however, an unexpected and potentially far reaching role of Galois's group, as a concept-problem in the present definition, in linking algebra, geometry ("symmetries of geometric origins" invoked by Connes and Marcolli), and fundamental physics. Moreover, this role changes our perspective on renormalization in QFT, which has appeared as inhibiting the relationships between mathematics and fundamental physics, but might reflect deeper aspects of these relationships, thanks to the concept-problem of a Galois group, which emerge along with the concept-problems of a group and an action of a group in the work of Galois.

I now move to Riemann and geometry. Galois, however, will make a return in the following section, via the role of Galois theory in algebraic geometry, specifically, Grothendieck's étale cohomologies, another momentous impact of Galois's way of thinking in mathematical practice as philosophy. Grothendieck's theory of étale cohomologies was, actually, one of the *motivations* for his concept, concept-problem, or a motive, and motive theory, which, among its numerous applications, eventually led to the role, just considered, of motivic Galois groups in renormalization in QFT, a theory, again, indebted, on several counts, to Riemann's concepts as well, as is in fact the concept of a cosmic Galois group. It might be added that the so-called anti-de-Sitter spaces, which are the Lorentzian analogies of Lobachevsky spaces, play an important role in developments of QFT theory and its extensions, such as string and brane theories – the holographic principle and Juan Maldacena's AdS/CFT (anti-de-Sitter/conformal field theory). There are also deep connections between these ideas and motivic Galois's groups, connections noted in (Kontsevich 1999), cited above, a key work on the role of motivic Galois theory in QFT.

4 Geometry: Lobachevsky and Riemann

My main focus in this section is Riemann's mathematical practice, as the most explicit exemplification of my main thesis concerning mathematical practice as philosophy, as defined by the invention of concepts. While characterizing all of Riemann's work, this philosophy is especially manifested in his rethinking of the foundations of geometry in his Habilitation lecture, "On the Hypotheses That Lie at the Foundations of Geometry" [*Ueber die Hypothesen, welche der Geometrie zu Grunde liegen*] (Riemann 1854). Lobachevsky's thinking and work, however, not only, obviously, have their own revolutionary place in the history of geometry, but are important in the present context as well. The differences in their thinking and mathematical practice remain important. It would be difficult to argue that, unlike Gauss (expressly mentioned by Riemann in the lecture), Lobachevsky was a precursor of Riemann, and as often noted, it is doubtful that Riemann was familiar with

Lobachevsky's work. On the other hand, it would be difficult to argue either that Riemann was unaware of Lobachevsky's discovery of non-Euclidean geometry (of the hyperbolic type), especially given that Gauss championed Lobachevsky's work, as against that of Bolyai.

Specifically, I shall argue that, while, unlike Riemann, expressly addressing Euclid's fifth postulate, Lobachevsky's thinking implicitly challenges the axiomatic approach, as developed from Euclid on, to geometry at its very core. While not, like Riemann, overtly grounding geometry in hypotheses and concepts, Lobachevsky's discovery in effect showed that the axioms of geometry in general, rather than only the fifth postulate, and, perhaps, all our axioms, including in physics, are hypotheses, based, however imperceptibly, in concepts, such as that of parallel lines in Euclidean geometry. The latter may be a notion arising from our general phenomenal intuition, which may still not be able to conceive how it is possible to have more than one parallel line in the same plane crossing a point outside this line. As a mathematical object, however, either is a concept, and the fact that there is one parallel line to a given one going through a point outside it is a hypothesis, either as concerns a physical space, with which the term geometry was associated at the time, or as concerns a possible mathematical geometry. Lobachevsky, thus, also (in accord with a key trend of modern mathematics), suggested a dissociation of geometry from physics, which is, arguably, one of the reasons why he, initially, referred to his hyperbolic geometry as imaginary geometry. Of course, he also thought that hyperbolic geometry may correspond to that of actual physical space on a broader scale, which, however, still allows for its mathematical independence. He gave his geometry or geometries other names, on which I shall comment below, merely noting now that his final name "pangeometry" may have been a reflection of the view, akin to that of Riemann, that what is mathematically shared is geometrical thinking. This thinking enables us to create new mathematical worlds, "out of the nothing," as Bolyai famously said about his invention of hyperbolic geometry (Stäckel 1913, p. 86). These worlds are creations of thought from its insubstantial *materials*, "such stuff/As dreams are made on," in William Shakespeare's even more famous phrase (*The Tempest*, IV, 1, ll. 156–157). This thinking, then, can lead to either Euclidean or hyperbolic geometry, and possibly still other geometries, eventually an uncontainable multitude of geometries with no connections to physics, although for Lobachevsky, Bolyai, and Riemann the terms space and geometry still referred to physical space and its geometry.

The landscape of geometrical thinking changed even more radically following Riemann's Habilitation lecture, given in 1854 but first published by Dedekind in 1868, 2 years after Riemann's death (On Riemann's subsequent developments of his geometrical ideas and their application to physics, see essays in Ji et al. (2017), where the earlier (longer) version of this discussion of Riemann was published (Plotnitsky 2017). The present version revises the argument offered there on several key points). The lecture offered a radical rethinking of space and geometry, as against the preceding history of both, from before Euclid to the discovery of non-Euclidean geometry. This rethinking was based on the concept of manifold or manifoldness [*Mannigfaltigkeit*], a major mathematical innovation. Establishing

the *possibility* of non-Euclidean geometry by Lobachevsky and Bolyai was a great discovery, with profound implications for mathematics, physics, and philosophy, and indeed culture. Riemann's thinking and argumentation departed even more radically from Euclidean geometrical thinking concerning space and geometry than those of his predecessors, including, Lobachevsky and Bolyai, or even Gauss, Riemann's teacher and, arguably, the main precursor as concerns his geometrical thinking. The question of the fifth postulate of Euclid played no role in Riemann's argument. Riemann pursued a different way of thinking, following Gauss's ideas concerning the curvature of two-dimensional surfaces (Riemann also mentions Johann F. Herbart as an influence or guidance, but, even leaving aside the fact that Riemann was ambivalent and sometimes critical of Herbart's philosophy, this influence does not appear to me ultimately that important, especially in the present context). Riemann's thinking was also, and correlatively, *problem-posing*, or quasi-empirical, rather than *axiomatic-theorematic*, as axioms of geometry were neither Riemann's starting point nor figured significantly, if at all, in his investigation, in the way they did in that of Lobachevsky or Bolyai. As I argue here, however, this juxtaposition is not unconditional. The proximities between their thinking is significant, and the fact that Riemann almost certainly knew about their findings is not insignificant either. Lobachevsky's thinking, I argue, had important conceptual and problem-posing aspects. Riemann's approach, however, through the invention of a new concept, concept-problem, that of manifold, establishing a new problem-posing field (extending beyond geometry), led him beyond a single alternative to Euclidean geometry to an uncontainable multiplicity of geometries and, in principle, to an even greater multiplicity of possible spaces, because some among them would not admit geometry. The latter circumstance, not considered by Riemann, became important for the development of topology, influenced by Riemann otherwise, beginning with his concept of Riemann surfaces, which played a major role in the emergence of topology, as well as algebraic geometry.

The implications for physics, extending those of the discovery of a single non-Euclidean geometry, were dramatic as well. Riemann's contribution to physics in the lecture was nearly as revolutionary as his contribution to mathematics, extending already major changes of thinking concerning space brought about by the discovery of non-Euclidean geometry. Before this discovery, one and only one geometry would be available for a geometrical description of physical space (which is, again, how the term space was understood at the time) – if one assumes that space or, in Riemann's astute phrase, "the reality underlying space" could be mathematically described geometrically (Riemann 1854, p. 33). This had been a grounding assumption of classical physics, from Galileo and Newton on, or of modern philosophy, from Descartes on. Kant's epistemology of phenomena (referring to appearances or representations constructed by our minds) versus noumena or things-in-themselves (referring to how things, material or mental, exist independently of how we perceive or represent them) qualified this assumption (Kant 1997). While important, this qualification did not change the essential import of this assumption for physics. Kant's epistemology does not affect measurements that allow us to ascertain the observable properties of space, specifically whether the observable

space is Euclidean (flat) or non-Euclidean (curved), or is three-dimensional (the only space we can phenomenally imagine) or not. Possible deviations from the flatness of physical space could be established indirectly by using measuring instruments, while our phenomenal experience of space could still be Euclidean. Riemann reflected on this situation in his lecture, leaving the question of the ultimate nature of physical space or of the reality underlying space to future physics. Kant, by contrast, assumed that physical space is Euclidean and three-dimensional, or at least that it was unlikely to be anything else. He allowed that such alternatives, specifically that space may have a dimension higher than three, are logically possible in his early (1747) work, but rejected the idea as improbable, on theological grounds (Kant 2012; de Bianchi and Wells 2015, Pesic 2007, pp. 3–4, 7).

Theological grounds would not have deterred Riemann, who was originally trained in theology, which might have even helped his thinking concerning space and geometry, including his concept of manifold. Although the term *Mannigfaltigkeit* was not uncommon in German philosophical literature, including in Leibniz and Kant, it is worth noting that the German word for the Trinity is "*Dreifaltigkeit*," thus, etymologically, suggesting a kind of "three-folded-ness," which could not have been missed by Riemann, or, for that matter, Leibniz and Kant. Nor would they have been likely to deter Lobachevsky, which is, however, a separate subject, except for the fact that he only considered mathematically two and three dimensional space. It was, however, mathematically crucial that his geometry was three-dimensional, as was that of Bolyai, but it appears not that of Gauss, who thus came short of this discovery, even if he ever reached the establishment of the two-dimensional hyperbolic plane. In Riemann's view, that space was a three-dimensional Euclidean manifold was a hypothesis, reasonably well confirmed by the measurements performed at the time, but a hypothesis nevertheless, the truth of which cannot be ascertained by reason alone, as Kant thought possible.

In any event, the situation dramatically changed, mathematically, physically, and philosophically, and even culturally, with the discovery of non-Euclidean geometry. That actual physical space *may not* be Euclidean (the three-dimensional nature of space was, again, rarely contested) made this discovery a major event, even though no measurements made at the time showed any deviation from Euclidean geometry. The possibility was momentous enough. In reality, this challenge was even more radical, including vis-à-vis Kant, because it went beyond questioning of the nature of physical space and geometry to that of our axiomatic presuppositions in general. Even if Lobachevsky himself only realized this radical nature and implications of this challenge to some degree (which was, I would surmise, likely), his discovery revealed that the fifth postulate and, by implication, all axioms or, in the first place, definitions are conceptual constructions based on our general phenomenal intuition but reaching beyond it as mathematical concepts. Axioms are not preexisting truths but are assumptions based in conceptual constructions. This difference became more radical and pronounced with Cantor's concept of the continuum. A given set of these constructions allows one to define a consistent geometrical system, that of Euclidean geometry. But an alternative set of axioms, such as that without any postulate concerning parallel lines (now known as "neutral geometry" or "absolute geometry")

or that in which the fifth postulate is replaced by the postulate that there are at least lines parallel to a given line crossing a point outside this line (hyperbolic geometry), implies another consistent geometry. Mathematically, it is a matter of decision (a preferable category to that of choice) in which of them or possibly in several one pursues one's mathematics, a decision the nature of which is ultimately not mathematical. Physically, any such geometry becomes a hypothesis concerning the nature of physical space, and as such is subject to testing, verification, qualification, refinement, and so forth. These considerations, although not all of them were pursued by Lobachevsky, give us an insight into his geometrical designations – imaginary geometry, as a construct of mathematical imagination, under the assumption that physical space and geometry are Euclidean, and then pangeometry, which, as Athanase Papadopoulus notes, refers to "general geometry," which included all geometries known at the time, including spherical geometry in two-dimensions (Papadopoulos 2010, pp. 229–231). (There were no known elliptical geometries in three dimensions before Riemann.) Pangeometry may, arguably, also be seen as referring to geometrical thinking itself.

Physically, there is yet another possibility inherent in Lobachevsky's discovery, which does not appear to have been entertained by Lobachevsky himself, but was expressly considered by Poincaré, who rediscovered one of Eugenio Beltrami's models for hyperbolic geometry, which helped to prove that it was equiconsistent with Euclidean geometry. (Lobachevsky might have had some intuitions concerning this equiconsistency as well [Papadopoulos 2010, p. 250].) The decision concerning the geometry of physical space may be arbitrary (not the same as random!), in other words, a convention. Whether it actually is, as Poincaré thought, is a matter of debate, which was given a new impetus with general relativity, discovered in 1915, after Poincaré's death (in 1913). Nevertheless, the possibility, which is inherent in Lobachevsky's discovery, is significant. His discovery might indeed be seen as more radical than that of Copernicus, insofar as it would be parallel to the assumption that the decision between the geocentric and heliocentric view of the solar system is a mathematical convention (something, ironically, the Church wanted Galileo to say, admittedly on different grounds). In view of general relativity, the heliocentric view is a convention, much more convenient mathematically as it is.

Of course, Lobachevsky's (or Bolyai's) decision to consider the fifth postulate as independent of, but consistent with, those of "general geometry" and to consider the hyperbolic alternative as an equiconsistent system, could not emerge without technical mathematical work. And yet, as in the case of Abel's and Galois's rethinking the problem of the solution of the polynomial equations in radicals, it was an entirely new way of posing the problem of geometry (as that of consistency of the set of axioms defining geometry, axioms that are mathematical concepts) and thus also a new concept of geometry. That of Riemann was still more radical, especially as concerns the multiplicity of possible geometries, which required an invention of a new concept-problem and new mathematics, those of manifolds. As a result, Riemann also gave a firmer conceptual grounding and more radical dimensions to the problem of geometry. Before I turn to Riemann, I would like to comment on the

following, in my view, misleading, assessment of Lobachevsky's and Bolyai's discovery by Jeremy Gray and José Ferreirós:

> The new geometry posed a radical challenge to Euclidean geometry, because it denied traditional geometry its best claim to certainty, to wit, that it was the *only* logical system for discussing geometry at all. It also exploited the tension known to experts between the concepts of straightest and shortest. But in other ways it was conventional. It offered no new definitions of familiar concepts such as straightness or distance, it agreed with Euclidean geometry over angles, it merely offered a different behaviour of parallel lines based on a difference in the distant behaviour of straight lines. Its proponents did not offer a skeptical conclusion. Bolyai and Lobachevsk[y] did not say: "See, there are two logical but incompatible geometries, so we can never know what is true." Instead, they held out the hope that experiments and observations would decide. The epistemological price people would have to pay if astronomical observations had come down in favour of the new geometry would, in a sense, have been slight: it would have been necessary to say that straight lines have an unexpected property after all, but one only detectable at very long distances. To be sure, many of the theorems of geometry would then have to be reworked, and their familiar Euclidean counterparts would appear only as very good approximations. But that is broadly comparable to the situation Newtonian mechanics found itself in after the advent of special relativity. (Gray and Ferreirós 2021)

That may be technically correct (although some qualifications would still be necessary), as is the claim that their view was that experiment and observation would decide which describes physical space, a view that Riemann held as well, with deep implications for physics. This assessment, however, misses the radical epistemological and ontological implications of the way of thinking thus brought about concerning our "basic" assumptions, axioms, postulates, and so forth, as no longer basic, but rather as constructions of thought the validity of which can be challenged in physics and in mathematics itself, as for example, when it comes to considering Newtonian physics, as axiomatic. It may be that hyperbolic geometry as such does not challenge physics in the way general relativity (which might have been the main example in this regard for Gray and Ferreirós) and quantum mechanics did as physical theories, but the way of thinking in which hyperbolic geometry was discovered suggests the possibility of questioning the "axioms" of physics. Einstein would have agreed: he did so in questioning our basic assumptions concerning the kinematics of motion in special relativity, or the special status of inertial systems in general relativity. On the other hand, he was unwilling to give up causality and especially realism as basic philosophical "axioms," which led to his refusal to accept quantum theory as a fundamental theory (a theory describing the ultimate constitution of nature).

The boldness and radical nature of Lobachevsky's thinking, or that of Bolyai, and their implications for our thought in physics is missing in Gray and Ferreirós's assessment. If one can create a mathematical "universe out of nothing," it is no longer easy to assume for modern physics, as a mathematical-experimental science, which one of these mathematical worlds corresponds best to the physical world, and perhaps ultimately none does, as quantum mechanics may imply (Plotnitsky 2021b). It is this spirit that matters more than technicalities invoked by Gray and Ferreirós.

They give more credit to Riemann, while, however, still underappreciating the radical nature of his thinking, including as concerns the point of the possible (or impossible) relationships between a given mathematical world and the physical world. Riemann offers a much better way of looking at the connection between radical thinking in mathematics and physics: "Investigations like the one just made here [concerning foundations of geometry], which begin from general concepts, can only serve to insure that this work is not hindered by unduly restricted concepts and that progress in comprehending the connection of things is not obstructed by traditional prejudices" (Riemann 1854, p. 33). Riemann refers to his own mathematics as allowing physics to break with "unduly restricted practice" and "traditional prejudices," such as those of Euclidean geometry or Newtonian mechanics. But the point is more general and concerns all concepts that become "unduly restricted" unquestionable axioms by forgetting their human origins and history.

Riemann's argument, again, *implied* that an infinite number of possible geometries could be associated with physical space or "the reality underlying space." Any such association is a *hypothesis* (this is one, the most direct, of the meanings of the "hypotheses" of Riemann's title) and as such is subject to testing, verification, qualification, refinement, and so forth. These processes can rule out some among possible geometries or require different geometries at different scales, as indeed happens in modern physics. Thus, with the help of Einstein's general relativity, we know reasonably well certain local physical geometries, say, the one, curved, in the vicinity of the solar system, and even more global geometries, say, that (on average flat) in the Milky Way. Or, more rigorously, the corresponding argumentation works well in physics and astronomy as things stand now. It is, however, much more difficult to be sure concerning the ultimate geometry of the Universe, although the current data seems to suggest that it is, *on the average*, flat as far as we can observe it. Locally, space could be curved by gravity or contain a singularity, such as a black hole, in accordance with general relativity. It is also possible that there are other Universes with different geometries. Riemann did not envision this possibility, which arises from quantum considerations concerning the Big-Bang origin of the Universe that we observe. However, his discovery of the infinite number of possible geometries is in accord with this idea, the genealogy of which goes back to Leibniz's concept of compossible worlds, although for Leibniz there existed, created by God, only one world, the best one, in which we live.

The significance and impact of Riemann's lecture for mathematics, physics, and philosophy were immense. This impact was delayed until its publication, in 1868, 2 years after Riemann's death, and 14 years after it was presented in 1854, although some of Riemann's key ideas contained there became known and had their impact earlier. Riemann opens as follows:

> As is well known, geometry presupposes the concept of space, as well as assuming the basic principles for construction in space. It gives only nominal definitions of these things, while their essential specification appears in the form of axioms. The relationship between these presuppositions is left in the dark; we do not see whether, or to what extent, any connection

between them is necessary, or a priori whether any connection between them is even possible.

From Euclid to Legendre . . . this darkness has been dispelled neither by the mathematicians nor the philosophers who have concerned themselves with it. The reason [*Grund*] for this is undoubtedly because the general concept of multiply extended magnitudes [*Grösse*], which includes spatial magnitudes, remains completely unexplored. I have therefore first set myself the task of constructing the concept of a multiply extended magnitude from general notions of magnitude. It will be shown that a multiply extended magnitude is susceptible of various metric relations, so that space constitutes only a special case of a triply extended magnitude. From this, however, it is a necessary consequence that the theorems of geometry cannot be deduced from general notions of magnitude, but that those properties that distinguish space from other conceivable triply extended magnitudes can only be deduced from experience. Thus arises the problem of seeking out the simplest data from which the metric relations of space can be determined, a problem that by its very nature is not completely determined, for there may be several systems of simple data that suffice to determine the metric relations of space; for the present purposes, the most important system is that laid down as a foundation of geometry by Euclid. These data are—like all data—not logically necessary, but only of empirical certainty, they are hypotheses; one can therefore investigate their likelihood, which is certainly very great within the bounds of observation, and afterwards decide on the legitimacy of extending them beyond the bounds of observation, both in the direction of the immeasurably large [*Unmessbargrosse*] and in the direction of the immeasurably small [*Unmessbarkleinen*]. (Riemann 1854, p. 23; translation modified)

These introductory reflections are already profound and far-reaching, and Riemann develops them much further in the lecture. Riemann is, again, not interested in the axiomatic approach to geometry and appears to doubt its effectiveness. In contrast to most previous works on non-Euclidean geometry, the parallel postulate is not the starting point of his investigation. The reason for the ineffectiveness of the axiomatic approach is that the *concepts* of space and of measuring distances in space, necessary for geometry, are not adequately defined. This is what leaves "the relationships between [axioms] . . . in the dark. We do not see whether, or to what extent, any connection between them is necessary, or a priori whether any connection between them is even possible." This questioning of the axioms of geometry was unusual at Riemann's time, and it was much deeper than customary doubts concerning the parallel postulate, in any event no longer assumed as such by the time of Riemann's lecture in view the discovery of hyperbolic geometry by Lobachevsky and Bolyai, of which, if not of their actual work, Riemann, as I suggested, was likely to be aware. As discussed earlier, however, their argumentation was not restricted to merely axiomatic thinking and, in effect, questioned the latter. In any event, only Gauss, rather than either Lobachevsky or Bolyai, was expressly invoked in the lecture (There were other reasons, beginning with the fact that Gauss was Riemann's mentor and the chair of his Habilitation committee. Indeed, Gauss selected this topic among three proposed by Riemann (following the rules). The philosopher R. H. Lotze, a fervent opponent of non-Euclidean geometry, was a member of the philosophy faculty, to which Riemann's Habilitation was presented. Later, Lotze criticized Riemann's approach anyway, as part of his general critique of non-Euclidean geometry. See Laugwitz (1999, pp. 222–226) and Russell (1897, pp. 97–112)).

Gauss does not appear to have been able to establish a possible existence (in the sense of logical consistency) of non-Euclidean geometry, because, unlike Lobachevsky and Bolyai, he did not do this for the three-dimensional case. In spirit, however, Gauss's work on the geometry of two-dimensional surfaces and his *concept* of curvature as intrinsic to a given surface was closer to and must have influenced Riemann's thinking. For Riemann, Gauss was pursuing a trajectory of thought better suited for the foundations of geometry and more fruitful for its conceptual development. In his famous theorem (*theorema egregium*), Gauss proved that the curvature of a surface, which he defined as well, was intrinsic to the surface. More precisely, the theorem states that Gaussian curvature of a surface does not change if one only bends the surface but does not stretch it. This means that curvature can be fully determined by measuring angles and distances on the surface itself, without considering the way it is embedded in the ambient (three-dimensional) Euclidean space, which makes the Gaussian curvature an intrinsic invariant of a given surface. Gauss's theorem thus suggests a two-dimensional conceptual architecture of geometry akin to that of Riemann, who was able to give this architecture a great generality. It suggests that one could see the surface as an *independent* curved manifold, a new concept and a new philosophy emerging in mathematical practice, and then to generalize this concept to higher dimensions via "the concept of a multiply extended magnitude," mentioned in this passage and the concept of manifold, which is what Riemann did. These concepts also helped him to generalize to higher dimensions Gauss's concept of curvature. To do so required yet another new concept, that of the tensor of curvature, and a new form of differential calculus, tensor calculus on manifolds, a generalization of differential calculus, another great invention of Riemann. This calculus was fully developed later (sometimes under the name of absolute calculus), and it played a major role in Einstein's general relativity.

The independence of the curvature or of geometry of a given manifold of any dimension from its embedding also allows one to determine, at least in principle, intrinsically whether the space thus represented is flat or curved, which is crucial for determining the nature of the physical space we inhabit. For example, as noted, space is curved in the immediate vicinity of the solar system, because of the gravity of the Sun, planets, and other material entities there (or locally around other stars), but, given the current experimental data, appears to be on the overage flat on the scale of the observable Universe. It has never been established definitively or, in any event, agreed upon whether such a determination is rigorously possible, at any scale, as opposed to having a practically effective and possibly, within its proper scope, the best available theory or, as Poincaré would have it, convention, without making a truth-claim concerning "the reality underlying space" (Riemann 1854, p. 33).

Riemann's thinking was clearly conceptual and/as problem-posing rather than axiomatic-theorematic, quasi-empirical rather than Euclidean: he grounds mathematics, as well as physics, in hypotheses and concepts, concept-problems, such as the concept of manifold and its subconcepts, or associated concepts (such as distance, curvature, and tensor). The problem of space and geometry was seen by Riemann as that of finding concepts that are necessary to define space and to give it a geometry. A general concept of manifold is assumed to be applicable to any possible

space, while specific manifolds define different spaces or subspaces. Thus, as *foundational* thinking, that of Riemann is different from that conforming to Hilbert's concept of "foundations" [*Grundlagen*] in the sense of axiomatic foundations, an idea that Hilbert also tried to apply to physics. One of the problems of his famous 1900 list (Problem 6) was that of the development of (mathematized) axiomatic foundations, system(s) of axioms, for physics, on the model of his own *Foundations of Geometry* (Hilbert 1979). That such a system is possible is a hypothesis. It became clear subsequently that the existence of such a system is a hypothesis even in mathematics, and in view of Gödel's incompleteness theorems of 1931, any such system cannot be proven to be free of contradiction, once it is large enough to include arithmetic, as most geometries are. While Hilbert's foundational thinking aimed to bring physics closer to mathematics, by giving physics an axiomatic form, that of Riemann brings mathematics closer to physics by grounding it in hypotheses and concepts, rather than in axioms, by making it quasi-empirical.

The parallel postulate is, again, never mentioned in the lecture, although Euclidean geometry is invoked as the geometry of "flat space," merely a particular and very special case of geometry, where metrical relations take an especially simple form, defined by the Pythagorean theorem. Euclidean geometry is no longer the starting point of Riemann's thinking concerning foundations of geometry, which has been noted, although rarely appreciated as a consequence of Riemann's mathematical thinking as defined by concepts. The starting point of geometry is measurement: the concept of the metrical relation and its instantiations characterizing given spaces and their geometry. The character of this relation is a hypothesis on which a geometry could be based, a hypothesis to be tested physically to establish whether it is in accord with actual physical space. Non-Euclidean geometry (Riemann, again, does not use the term) is introduced as a possible case of geometry, that of a curved, rather than flat, space of either negative or positive curvature, defined by Riemann by the corresponding type of quadratic form determining the metric. Riemann, thus, introduced a more general *concept*, concept-problem, of geometry, which also allows for a rigorous conceptual grounding to non-Euclidean geometry of either negative or positive curvature. He also introduced non-Euclidean geometry of positive curvature, elliptical geometry. Eclipsed, as it may have been, by Riemann's overall achievement in the lecture, this was a major mathematical discovery with important cosmological implications, as in anticipating the idea, later considered by Einstein, that the universe may be unbounded and yet finite (As noted, the currently dominant view or hypothesis, which appears to be confirmed by cosmological measurements, is that the universe is on average flat and is expanding). Spherical geometry, known previously, was a two-dimensional example of geometry of positive curvature, and no three or higher dimensional ones were established before Riemann.

Riemann's thinking may, thus, be seen as returning to pre-Euclidean thinking and to the original meaning of the ancient Greek word geometry as geo-*metry* – the way of measuring distances and volumes of figures on the surface of the Earth and extending this measurement to volumes of three- or even higher dimensional figures. In order to do so and to have geometry, two concepts are necessary, that of space and that of measurement of space. Axioms, if one needs them, can come later. Besides, as

Riemann clearly implies from the outset of his lecture, the axioms of geometry require concepts first, an understanding that, as I said, was implicit in Lobachevsky's work. This does not mean that one cannot productively pursue an axiomatic approach to geometry, but only that one cannot do so without concepts. Hilbert, again, did so, and he used and invented concepts, but as part of an axiomatic program. This is, however, not how Riemann thought about geometry. The question for Riemann, as for Galois, is always how to define mathematical entities in terms of their conceptual architecture reflecting the problems they respond to, which led them to defining new problem-posing fields by the corresponding concept-problem, that of a manifold and a group, respectively. Besides mathematical axioms are, first, mathematical concepts, and sometimes concept-problems.

Riemann defined the concept of space, again, understood as physical space (as against the concept of manifold, which is mathematical), as a three-dimensional physical instantiation of the concept of continuous manifold, or as something that can be, in an idealized way, represented mathematically by this concept, in accordance with the hypotheses that he assumed as likely given the experimental data then available. While a manifold, as defined by Riemann, may be either discrete or continuous, the concept of continuous manifoldness has a richer and more complex mathematics, and most of Riemann's lecture is devoted to it. Technically, continuous manifolds considered by Riemann were differentiable manifolds, which means that one can define differential calculus on them. Indeed, they are metrical manifolds, now called Riemannian, which allow for the concept of distance between any two points and thus for geometry (there were no discrete geometries yet. As most of his contemporaries, Riemann did not distinguish continuous and differentiable manifolds. It became eventually clear, however, that not all continuous (also called topological) manifolds are differentiable. There are topological manifolds with no differentiable structure, and some with multiple nondiffeomorphic differentiable structures. Thus, there is a continuum of nondiffeomorphic differentiable structures of $\mathbb{R}^4$. I shall, however, speak of continuous manifolds, following Riemann and his juxtaposition between continuous and discrete manifoldness. In modern use, the term manifold more customarily refers to continuous (but not necessarily differentiable) manifolds, although one also refers to discrete manifolds, which have topological dimension zero. Discrete and continuous manifolds do not appear to have that much in common and may be seen as different concepts. These two concepts could, in modern understanding, be subsumed under the same concept. It is conceivable that Riemann thought along similar lines, which would explain his choice of the term manifold for both discrete and continuous manifolds. It is difficult to be certain on the basis of his lecture or his other writings, because the term had a more general use at the time. Thus, Cantor, initially referred to sets as *Mannigfaltigkeiten* but eventually switched to *Mengen*. In any event, the difference between these two types of manifolds is crucial, in general and for Riemann, especially for his analysis of physical space. Riemann stressed the significance of the relationships between continuity and discontinuity for mathematics, physics, and philosophy (e.g., [Riemann 1991, pp. 515–524; Ferreirós 2006, pp. 77–80]).

Riemann's concept of continuous manifoldness was a new concept of geometrical multiplicity. It is a multiplicity of local subspaces, most specifically those, "neighborhoods," associated with each point, out of which a given space is composed. Riemann defines first the concept of "n-dimensional magnitude," which allows one to determine a position in a manifold by n numerical determinations, in the same way a position is determined by coordinates in the Euclidean space of n dimensions. A crucial and even the single most defining feature of the concept of (continuous) manifold is that it is conceived as infinitesimally Euclidean. This makes a continuous manifold into a conglomerate of local, continuously connected, open neighborhoods around each point. The concept of neighborhood, assumed to be infinitesimally flat (Euclidean), is a component-concept of the concept of manifold. The concept of manifold as composed out of local neighborhoods is extendable to a more general concept of topological space, in which case local neighborhoods need no longer be Euclidean and can be defined with a great degree of generality. It is true that Riemann did not define a concept of topological space as such, although it is conceivable, especially given his concept of a Riemann surface, that he entertained this type of idea, just as he, expressly, entertained the idea that "the reality underlying space" may be discrete at a very small scale. In any event, the conceptual architecture defining topological spaces is a nearly inherent generalization of Riemann's conceptual architecture of a manifold as a "space" composed of neighborhoods. Riemann surfaces, too, were recast in terms of manifolds. Weyl, who clearly considered a Riemann surface to be a concept, was the first to define them as manifolds (Weyl 2013). Riemann, however, must have realized that they were manifolds, and the concept of a Riemann surface was part of the genealogy of the concept of manifold.

In the case of Riemannian manifolds, while each neighborhood is infinitesimally Euclidean, the manifold as a whole is, in general, not, except in the special case of Euclidean manifolds. A manifold may be negatively or positively curved, and, which is another major innovation of Riemann, this curvature can also be variable. Riemann defined the metric form as a quadratic differential function of coordinates

$$1/\left(1+\frac{\alpha}{4}\sqrt{\sum dx^2}\right)$$

which is the only real formula in his lecture (discounting the coordinate expression for the line element). Riemann also assumed that the transition from one local coordinate system to another was differentiable. Thus, he de facto considered differentiable manifolds with positive metrics, Riemannian manifolds. In modern terms, each such a manifold has a differentiable section of positive-definite quadratic forms on the tangent-bundle. While, however, modern technical language can bring out deeper mathematical aspects of Riemann's concepts, it can also obscure and displace how Riemann thought, a displacement sometimes found in twentieth-century English translations of Riemann, including his Habilitation lecture.

Although it was Riemann's theory of continuous or differentiable manifolds that had the greatest impact, the concept of discrete manifolds was important for Riemann's argument, and it is important for the modern understanding of both

spatiality and geometry in mathematics, physics, and philosophy. While a discrete manifold has topological dimension zero, it may still be seen as multiply extended, if defined as forming a very fine lattice with very small intervals between points, which can be "filled," as it were, to form a continuous space of the corresponding topological dimensions. It is also possible to introduce metrical relations for discrete manifolds. This concept is important in the context of the relationships between physical forces in nature and the nature of space or, to return to Riemann's terms, the physical "reality underlying space," although Riemann was cryptic on such metrical relations. Crucially, however, he allows for the possibility that the physical "reality underlying space" might be "a discrete manifold" (Riemann 1854, p. 33). This possibility had been entertained even before Riemann and has been often considered since. Also, mathematically, finite geometries were beginning to be developed, usually in more axiomatic ways, around Riemann's time as well, later on also under the impact of his geometrical thinking (For some of these developments, see Pambuccian et al. (2017) and other articles in Ji et al. (2017)). Riemann saw the relationships between continuity and discontinuity as foundationally central to mathematics, physics, and philosophy (e.g., [Riemann 1991, pp. 515–524; Ferreirós 2010, pp. 77–80]), a view confirmed by the subsequent developments in the foundations of mathematics, from Dedekind and Cantor on, and quantum physics. The latter uses continuous (technically, again, differentiable) mathematics, that of Hilbert spaces over $\mathbb{C}$, to predict, in probabilistic terms, irreducibly discrete phenomena, that is, phenomena that are not, and that possibly cannot be, assumed to be connected to each other by a continuous physical process. The genealogy of this mathematics is still Riemannian, given that Riemann has already envisioned, along with discrete manifolds, infinite-dimensional ones. Tensor calculus, too, is a key aspect of quantum mechanics, reflecting crucial features of quantum phenomena. In sum, beyond Riemann's contribution to physics in his lecture itself, which, as noted, was nearly as momentous as his contribution to mathematics, his mathematical concepts have immense impact on the subsequent development of physics.

The final implication of Riemann's approach I would like to mention, in part, again, as a bridge to the next section, is that it allows one to define a geometrical or topological space (in modern terminology) not as a set of points continuously connected to each other, but in terms of open neighborhoods around each point. As explained above, following this way of thinking, topology describes a given space not only in terms of its points, continuously connected to each other, but also and most essentially in terms of its *open neighborhoods* around each point. These neighborhoods are subspaces of this space, the idea that underlies Riemann's concept of manifold, in this case giving each neighborhood a Euclidean geometry. The approach enabled Riemann, again, following Gauss's theory of curvature of two-dimensional surfaces, to define manifolds of any dimension in terms of its inner properties rather than in relation to the ambient Euclidean space, where a manifold could be placed against the flat Euclidean background. It is true that, if one appeals, as is usual even in considering Riemann, to open sets, this concept retains the concept of a set (of points) as a primitive concept. Thus, Ferreirós's analysis displaces Riemann's thought into the axiomatic and set-theoretical register,

dominant in the wake of Cantor (Ferreirós 2006, pp. 39–80). This displacement reflects Ferreirós's insufficient attention to the structure of Riemann's mathematical concepts, or in the first place, to the *concept* of mathematical concept found in Riemann's practice. Riemann did not think either in terms of axioms or in terms of sets of points, as Ferreirós contends, although his concepts could be translated into these terms (e.g., [Pambuccian et al. 2017]). Riemann thinks in terms of spaces composed of spaces. Riemann's way of thinking concerning manifolds, however, also suggests a possibility of thinking of, and even defining, a space (as a mathematical concept) in terms of its relations to other spaces, in effect categorically, which allows one to use this structure as more primordial by replacing covering a space by *open sets (of points)* with covering it by open *spaces*. A topological space becomes a collection of open spaces as subspaces with algebraic rules for the relationships between them. This way of defining a space in its relation to other spaces (as opposed to their constitution as sets of points) extends to Grothendieck's topos theory, inspired, however, primarily by the idea of a "covering space," originating in Riemann's theory of Riemann surfaces.

5 Algebraic Geometry: Weil and Grothendieck

I begin with a brief summary of the concept of curve, discussed in detail in [Plotnitsky 2019], which this section partly follows within the context and argument defined by the present chapter. By expressly making geometry algebra, or just about (this claim needs qualifications, considered below), the analytic geometry of Fermat and Descartes *in effect* gave mathematics its independence from physics, thus, initiating modern mathematics as a project dealing with ideal objects independent from material objects in nature. I qualify by "in effect" because it took about two centuries for this independence to get its momentum around the time of Gauss, Abel, and Galois, as discussed in Sect. 3. Analytic geometry did so because the equation corresponding to a curve, say, $X^2 - 1 = 0$ for the corresponding parabola, could be studied as an algebraic object, independently of its geometrical representation or its connection to physics, which eventually enabled mathematics to define algebraic varieties over finite fields and thus as discrete objects. A curve becomes, in its composition, defined by its equation, divested from its representational geometrical counterpart. Nor does it any longer geometrically idealize the reality exterior to it. It only represents itself. The equation, as algebra, also defines a separation of a mathematical curve or surface from any curve or surface found in the world, thus also revealing a deeper essence of all mathematics. When one says in mathematics, "consider a curve X," one separates it from every curved object in the world. This separation of algebra from material reality and geometry (as ordinarily understood) also enables it to define a discrete curve, or can make a curve a surface, or a surface a curve, give it an even more complex spatial algebraic architecture, or a yet more complex conceptual composition, such as that of a moduli space, the Teichmüller space (also the Teichmüller *curve*), Grothendieck's scheme and representable-functors, and so forth. We are yet far from exhausting the problem-posing field defined by the concept-problem of a Riemann surface, which is also a curve over

$\mathbb{C}$ (e.g., A'Campo et al. 2016). This view also transforms our view of geometrical objects in the same way: modern geometry, too, separates or liberates its objects and itself from daily phenomenology, even if not as completely as algebra does.

The concept of a Riemann surface is one of Riemann's great contributions to modern mathematics, which shaped several of its areas, most especially here algebraic geometry. In Papadopoulos's account:

> In his doctoral dissertation, Riemann introduced Riemann surfaces as ramified coverings of the complex plane or of the Riemann sphere. He further developed his ideas on this topic in his paper on Abelian functions. This work was motivated in particular by problems posed by multi-valued functions *w(z)* of a complex variable *z* defined by algebraic equations of the form
>
> $$f(w, z) = 0,$$
>
> where *f* is a two-variable polynomial in *w* and *z*.
>
> Cauchy, long before Riemann, dealt with such functions by performing what he called "cuts" in the complex plane, in order to obtain surfaces (the complement of the cuts) on which the various determinations of the multi-valued functions are defined. Instead, Riemann assigned to a multi-valued function a surface which is a ramified covering of the plane and which becomes a domain of definition of the function such that this function, defined on this new domain, becomes single-valued (or "uniform"). Riemann's theory also applies to transcendental functions. He also considered ramified coverings of surfaces that are not the plane. (Papadopoulos 2017, p. 240)

The concept of a Riemann surface gains much additional depth and richness when considered in terms of his concept of a manifold. Riemann, as noted, did not do so himself, although he undoubtedly realized that Riemann surfaces were manifolds, and they have likely been part of the genealogy of the concept of manifold. Riemann's surfaces were first expressly defined as manifolds by Weyl in *The Concept of a Riemann Surface* (Weyl 2013). It is an intriguing question whether Riemann himself thought of Riemann surfaces as curves, but it would not be surprising if he had. Weyl undoubtedly did, although the point does not figure significantly in his book, focused, topologically, on the *surface* nature of Riemann surfaces. This may be surprising. But then, Weyl was not an algebraic geometer. The work of Émile Picard, a key figure in the history of algebraic geometry would be more exemplary in considering this point (Picard 1891–1896; Papadopoulos 2017).

Weyl's argumentation leading him to his definition is an application of a principle akin to Joseph Silverman and John Tate's principle, "Think Geometrically, Prove Algebraically":

> It is also possible to look at polynomial equations and their solutions in rings and fields other than $\mathbb{Z}$ or $\mathbb{Q}$ or $\mathbb{R}$ or $\mathbb{C}$. For example, one might look at polynomials with coefficients in the finite field $\mathbf{F}_p$ with p elements and ask for solutions whose coordinates are also in the field $\mathbf{F}_p$. You may worry about your geometric intuitions in situations like this. How can one visualize points and curves and directions in $\mathbf{A}^2$ when the points of $\mathbf{A}^2$ are pairs (x, y) with $x, y \in \mathbf{F}_p$? There are two answers to this question. The first and most reassuring is that you can continue to think of the usual Euclidean plane, i.e., $\mathbb{R}^2$, and most of your geometric intuitions

> concerning points and curves will still be true when you switch to coordinates in $\mathbf{F}_p$. The second and more practical answer is that the affine and projective planes and affine and projective curves are defined *algebraically* in terms of ordered pairs (r, s) or homogeneous triples $[a, b, c]$ without any reference to geometry. So, in proving things one can work algebraically using coordinates, without worrying at all about geometrical intuitions. We might summarize this general philosophy as: *Think Geometrically*, *Prove Algebraically.*" (Silverman and Tate 2015, p. 277)

Affine and projective planes and curves can be defined without any reference to our phenomenal intuition, which grounds the geometrical thinking Silverman and Tate refer to. Even in these more intuitively accessible cases, we think algebraically, too, by using what may be called "spatial algebra." "Spatial algebra" refers to algebraic structures that *mathematically* define geometrical or topological objects and reflect their proximity to $\mathbb{R}^3$ and mathematical spatial objects there that are close to our phenomenal intuition. This proximity may be, and commonly is, left behind in rigorous mathematical definitions and treatments of such objects, beginning with $\mathbb{R}^3$ itself. The same type of algebra may also be used to define mathematical objects that are not available to our phenomenal intuition at all. Among examples are a projective line (a set of lines through the origin of a vector space, such as $\mathbb{R}^2$, with projective curves defined algebraically, as algebraic varieties) and an infinite-dimensional Hilbert space (the points of which are typically square-integrable functions or infinite series, although a Euclidean space of any dimension is technically a Hilbert space, too). Spatial algebra is an algebraization of spatiality that makes it rigorously mathematical, as opposed to something that is phenomenally intuited spatially, even in the case of more conventional spatial objects in $\mathbb{R}^3$. In addition, as Silverman and Tate state, spatial algebra retains its connection to geometrical thinking because analogies with $\mathbb{R}^3$ continue to remain useful and even indispensable. Weyl's argument concerning "thinking geometrically" about analytic forms is also a manifestation of the spirit of Riemann's mathematical practice, in which geometry and algebra, indeed geometry, topology, algebra, and analysis, come together in a complex mixture of the rigorous and the intuitive, algebraic and spatial-algebraic, mathematical and physical, and mathematical and philosophical. Riemann's work on his ζ-function and number theory reflect this mix as well, as his greatest contribution to algebra, but still not without geometry to do it. According to Weyl:

> It was pointed out . . . that one's intuitive grasp of an analytic form [an analytic function to which a countable number of irregular elements have been added] is greatly enhanced if one represents each element of the form by a point on a surface $\mathcal{F}$ in space in such a way that the representative points cover $\mathcal{F}$ simply and so that every analytic chain of elements of the form becomes a continuous curve on $\mathcal{F}$. To be sure, from a purely objective point of view, the problem of finding a surface to represent the analytic form in this visual way may be rejected as nonpertinent; for in essence, three-dimensional space has nothing to do with analytic forms, and one appeals to it not on logical-mathematical grounds, but because it is closely associated with our sense perception. To satisfy our desire for pictures and analogies in this fashion by forcing inessential representation of objects instead of taking them as they are could be called an anthropomorphism contrary to scientific principles. (Weyl 2013, p. 16)

Weyl resolves this "problem" not only by suggesting, as did Silverman and Tate, that one might think geometrically, while proving algebraically, but also that one can think "spatial-algebraically" (along with intuitively geometrically), by joining Riemann's concepts of Riemann surface and manifolds. Weyl says:

> However, these reproaches of the pure logician are no longer pertinent if we pursue the other approach, already hinted at, in which the *analytic form is a two-dimensional manifold* to which all the ideas of continuity that we meet in ordinary geometry may be applied. To the contrary, not to use this approach is to overlook one of the most essential aspects of the topic. (Weyl 2013, p. 16)

Weyl will proceed, in the spirit of Gauss and Riemann, to his definition of a two-dimensional manifold and then Riemann's surface, *intrinsically*, rather than in relation to its ambient three-dimensional space. This concept enables one to define a Riemann surface as a curve over $\mathbb{C}$. This intrinsic and abstract view of a Riemann surface was often forgotten by Riemann's followers, especially at earlier stages of the history of the concept. According to Papadopoulos, who follows Klein's assessment:

> Riemann not only considered Riemann surfaces as associated with individual multi-valued functions or with meromorphic functions in general, but he also considered them as objects in themselves, on which function theory can be developed in the same way as the classical theory of functions is developed on the complex plane. Riemann's existence theorem for meromorphic functions with specified singularities on a Riemann surface is also an important factor in this setting of abstract Riemann surfaces. Riemann conceived the idea of an abstract Riemann surface, but his immediate followers did not. During several decades after Riemann, mathematicians (analysts and geometers) perceived Riemann surfaces as objects embedded in three-space, with self-intersections, instead of thinking of them abstractly. They tried to build branched covers by gluing together pieces of the complex plane cut along some families of curves, to obtain surfaces with self-intersections embedded in three-space. (Papadopoulos 2017, p. 242)

Hence, Weyl (whom Papadopoulos cites) contends: "Thus, the concept 'two-dimensional manifold' or 'surface' will not be associated with points in three-dimensional space; rather it will be a much more general abstract idea," in effect a spatial-algebraic one. Weyl's position concerning the nature of mathematical reality is a different matter. As is clear from his philosophical writings (e.g., Weyl 2021), Weyl was ultimately a realist in mathematics and physics alike, notwithstanding his major contribution to quantum mechanics (which radically challenged realism), not the least by making group and group representation theories central there. Weyl continues as follows:

> If any set of objects (which will play the role of points) is given and a continuous coherence between them, similar to that in the plane, is defined we shall speak of a two-dimensional manifold. Since all ideas of continuity may be reduced to the concept of neighborhood, two things are necessary to specify a two-dimensional manifold:
> 1. to state what entities are the "points" of the manifold;
> 2. to define the concept of "neighborhood." (Weyl 2013, pp. 16–17)

This means one should define entities, such as points, lines, neighborhoods, by using algebraic symbols and relationships among them, without referring to objects in the world represented by ordinary language, even if still using this language, as the concept of a Riemann surface as a curve and then its avatars such as Gromov's concept of pseudoholomorphic curve (a smooth map from a Riemann surface into an almost complex manifold) exemplify. Its connections to our phenomenal sense of surface are primarily intuitive, as when it comes to the idea of continuity, for example, as defined by Weyl here, in terms of the concept of neighborhood. In any event, a Riemann surface is not a curve in any phenomenal sense.

This multifaceted nature of Riemann surfaces equally and often jointly defined the history of complex analysis, the main initial motivation for Riemann's introduction of the concept of a Riemann surface, and the history of algebraic curves, both building on this concept, and other developments, for example, in abstract algebra and number theory, including Riemann's work on the ζ-function and the distribution of primes. All these developments were unfolding during the period between Riemann and Weyl, whose book initiated the treatment of the concept of Riemann surface that defines the present-day understanding of the concept. This history joins several "Riemanns" – the Riemann of the concept of manifold, the Riemann of the concept of Riemann surfaces, the Riemann of complex analysis. A few more Riemanns could be added. This multiple history shaped algebraic geometry, eventually leading to the work of Weil and Grothendieck, to which I now turn, although Weyl's analysis of the idea of a Riemann surface will make yet another important appearance, via, remarkably, Galois theory.

Weil's and Grothendieck's work on algebraic geometry are among their greatest contributions and are remarkable cases of mathematical practice as philosophy, as the extension of the concept of algebraic variety over a finite field and the study of such objects by the standard tools of algebraic topology, in particular homotopy and cohomology theories. These theories had been previously proven to be very effective for the study of complex algebraic varieties. The project of extending them to finite fields was initiated by Weil by bringing together algebra, geometry, and number theory, in which he was a true heir of Fermat (and he probably saw himself as one), as well as of Kronecker (in this case, Weil expressly saw himself as one). Riemann remains a key presence in the history leading to Weil's work in algebraic geometry, first of all, again, given his concepts of a Riemann surface and a covering space, but also by virtue of introducing the concept of a discrete manifold in his Habilitation lecture. Gino Fano, one of the founders of finite geometry, belonged to the Italian school of geometry (1880s–1930s), contemporary with and an important part of the history of mathematical modernism (Fano was a student of Federigo Enriques), strongly influenced by Riemann. Representatives of the Italian school (quite a few of them, even counting only major figures) made major contributions to many areas of geometry, especially algebraic geometry, which were an important part of a rich and complex history leading to Weil's work on algebraic geometry, culminating in his 1946 *Foundations of Algebraic Geometry*, with the second edition published in 1962 (Weil 1946, 1962). The book is distinguished by many important technical contributions, which would be difficult to properly consider here. My main focus, defined

by the relationships between Weil's and Grothendieck's philosophies of algebraic geometry, is Weil's concept of a "universal domain," assumed by him to be necessary. This concept distinguishes his approach and, thus, his mathematical practice as philosophy from the previous approaches by requiring that in addition to the base field of definition of the objects (algebraic varieties) considered, an assumption of an (algebraically closed) "universal domain" encompassing all fields that may appear in any constructions made over the base field. The Platonist implications of this claim are tempered by his view that such a domain need not be unique. Weil argued that the theorems of algebraic geometry will remain the same regardless of the choice of this domain if it has an infinite transcendence degree and is closed. Grothendieck will abolish this idea, without a return to any previous thinking, on his way to solving a problem posed by Weil, or rather making it a concept-problem. While suggesting a new problem-posing field, Weil did not define the corresponding concept as such, only suggested it as a possibility. Grothendieck's redefinition of this problem as a concept-problem was a result of his mathematical practice as philosophy as different from that of Weil, the difference, arguably, most essentially defined *philosophically* by abandoning Weil's assumption of a universal domain.

As one of his greatest and most visionary contributions, Weil eventually (in 1949) suggested that a cohomology theory for algebraic varieties over finite fields, now known as Weil cohomologies, could be developed by analogy with the corresponding theories for complex algebraic varieties or topological manifolds in general. Weil's motivation was a set of conjectures (these go back to Gauss), known as the Weil conjectures, concerning the so-called local ζ-functions, which are the generating functions derived from counting numbers of points on algebraic varieties over finite fields. These conjectures, Weil thought, could be attacked by means of a proper cohomology theory, although he did not propose such a theory, as a corresponding set of concepts, only posed it as a problem, without such a concept. It was not a concept-problem or set of concept-problems. But the idea led Grothendieck to such a concept-problem and indeed a set of such concept-problems, and a new mathematical philosophy entailed by mathematical practice, a philosophy different, on several counts, from that of Weil that led him to this problem.

To develop such a concept, one needed, first, a proper topology, finding which was nontrivial because the objects in question are topologically discrete. A "native" topology that could be algebraically defined by then, known as Zariski's topology, did not work, because it had too few open sets. The decisive ideas came from Grothendieck, helped by the sheaf-cohomology theory and category theory, known as "cohomological algebra," by then the standard tool of algebraic topology. Using these tools, a hallmark of Grothendieck's thinking throughout his career, and his previous concepts, such as that of "scheme," led him to topos theory and étale cohomology, as a viable candidate for Weil's cohomology, which it had proven to be. Soon thereafter, it also led him to a more general concept-problem of motivic cohomology, mentioned earlier in conjunction with motivic Galois groups, but the subject requires a separate discussion. By using étale cohomology, Grothendieck (with Michael Artin and Jean-Louis Verdier) and Pierre Deligne (Grothendieck's student) were able to prove Weil's conjectures, and then Deligne found and proved

their generalization. Grothendieck's key, extraordinary, insight, also extending what I call spatial algebra in a radically new direction, was to generalize, in terms of category theory, the concept of "open set," beyond a subset of the algebraic variety, which was possible because the concept of sheaf and of the cohomology of sheaves could be defined by any category, rather than only that of open sets of a given space. Étale cohomology is defined by this type of replacement, specifically by using the category of étale mappings of an algebraic variety, which become "open subsets" of the finite unbranched covering spaces of the variety, a vast generalization of Riemann's concept of a covering space (Grothendieck's initial primary area of mathematical research was topological vector spaces, which suggests yet another genealogical link to Riemann, in this case, again, to his concept of manifold). Grothendieck was also building on related ideas of Jean-Pierre Serre. Part of the origin of this generalization was the fact that the fundamental group of a topological space, say, again, a Riemann surface, could be defined in two ways: it can either be defined more geometrically, as a group of the sets of equivalence classes of the sets of all loops at a given point, with the equivalence relation given by homotopy, or it can be defined even more algebraically, as a group of transpositions of covering spaces. In this second, algebraic, definition, it is analogous to the Galois group of the algebraic closure of a field, as Serre was first to consider for finite fields, importantly for Grothendieck's work on étale cohomology, a concept that, thus, has its genealogy in both Galois's and Riemann's thought. The connection had been established in the case of Riemann surfaces long before then and found in Weyl's book on a Riemann surface:

> The group of cover transformations, regarded as an abstract group, expresses purely and completely everything in the relation between the normal covering surface $\overline{\mathcal{F}}$ and the base surface $\mathcal{F}$ which has the character of analysis situs [topology]. This group is also called the *Galois group* of $\overline{\mathcal{F}}$. It is in fact the analog of the Galois group of a normal algebraic field (of finite degree) over a base field. (Weyl 2013, p. 58)

In a way, this passage defines the trajectory of this paper by connecting the mathematical practice as philosophy of Galois, Riemann, and Grothendieck.

For the moment, Grothendieck's concept of étale mappings gives a sufficient number of additional open sets to define adequate cohomolgy groups for some coefficients, for algebraic varieties over finite fields. For complex varieties, one recovers the standard cohomology groups with coefficients in any constructible sheaf. The category of étale mapping is a topos, a concept that is, for now, the most abstract form of spatiality, at least as spatial algebra. As became apparent later, étale cohomologies could be defined for most practical uses in simpler settings. The concept of topos remains crucial, however, especially in the present context, because it can be seen as the concept of a covering space over a Riemann surface converted into the (spatial-algebraic) concept of topology of the surface itself, and then generalized to any algebraic variety. The concept of topos also came to play a major role in mathematical logic. The subject cannot, however, be addressed here, except by noting that mathematical logic has radical epistemological implications

concerning the nature of mathematical reality, to which the concept of topos, as a *logical* concept, may be connected. On the other hand, Grothendieck's use of topoi in algebraic geometry is *ontological* rather than logical. His philosophical position concerning the nature of mathematical reality remains somewhat unclear, for example, as concerns whether it conforms or not to mathematical Platonism. My focus for the moment are the mathematical technologies that the concept of topos, whatever its ontological status, enables, such as étale cohomology. Such technologies may suggest a possible break with the possibility of the ultimate ontological description of mathematical reality, again, assuming that any *ultimate* reality independent of human thought, say, again, of the type considered in physics, is even possible in mathematics, as opposed to what can be specified by one's thought, possibly in one's unconscious (Plotnitsky 2019, 2020). I shall return to this subject in closing.

It would not be possible to present topos theory here in its proper abstractness and rigor, sometimes prohibitive even for those who are trained in the field of contemporary algebraic geometry. The essential philosophical nature of the concept, may, however, be sketched. First, very informally, consider the following way of endowing a space with a structure, generalizing the definition of topological space in terms of open subsets, as mentioned above. One begins with an arbitrarily chosen space, X, potentially any given space, which may initially be left unspecified in terms of its properties and structure. What would be specified are the relationships between spaces applicable to X, such as mapping or covering one or a portion of one, by another. This structure is the arrow structure $Y \rightarrow X$ of category theory, where X is the space under consideration and the arrow designates the relationship(s) in question. One can also generalize the notion of neighborhood or of an open subspace of (the topology of) a topological space in this way, by defining it as a relation between a given point and space (a generalized neighborhood or open subspace) associated with it. This procedure enables one to specify a given space not in terms of its intrinsic structure (e.g., a set of points with relations among them) but "sociologically," throughout its relationships with other spaces of the same category, say, that of algebraic varieties over a finite field of characteristic p (Manin 2002, p. 7). Some among such spaces may play a special role in defining the initial space, X, and algebraic structures, such as homotopy and cohomology, as Riemann in effect realized in the case of covering spaces over Riemann surfaces, again, one of the inspirations for Grothendieck's concepts of a topos and more specifically étale topos.

To make this a bit more rigorous (albeit still informal), I shall briefly sketch the key ideas of category theory. It was introduced as part of cohomology theory in algebraic topology in 1940 and, as I said, later extensively used by Grothendieck in his approach to cohomological algebra and algebraic geometry, eventually leading him to the concept of topos. Category theory considers multiplicities (which need not be sets) of mathematical objects conforming to a given concept, such as the category of differential manifolds or that of algebraic varieties, and the arrows or morphisms, the mappings between these objects that preserve this structure. Studying morphisms allows one to learn about the individual objects involved, often to learn more than we would by considering them only or primarily individually.

Categories themselves may be viewed as similar objects, in relating which one speaks of "functors" rather than "morphisms." Topology relates topological or geometrical objects, such as manifolds, to algebraic ones, as in the case of homotopy and cohomology groups. Thus, in contrast to geometry, topology, almost by its nature, deals with functors from categories of topological objects, such as manifolds, to those of algebraic objects, such as groups. Mathematical practice (as philosophy) becomes that of functoriality: it no longer primarily concerns objects but categories of objects.

A topos in Grothendieck's sense is a category of spaces and arrows over a given space, used for the purpose of allowing one to define richer algebraic structures associated with this space, as explained above. There are additional conditions such categories must satisfy, but this is not essential at the moment. To give one of the simplest examples, for any topological space S, the category of sheaves on S is a topos. The concept of topos is, however, very general and extends far beyond spatial mathematical objects (thus, the category of finite sets is a topos); it replaces the latter with a more algebraic structure of categorical and topos-theoretical relationships between objects. On the other hand, it derives from the properties of and categorical relationships between properly topological objects. The conditions, mentioned above, that categories that form topoi must satisfy have to do with these connections.

Beyond enabling the establishing of a new cohomology theory for algebraic varieties, as considered above, topos theory allows for such esoteric constructions as nontrivial or nonpunctual single-point "spaces" or, conversely, spaces (topoi) without points (first constructed by Deligne), sometimes slyly referred to by mathematicians as "pointless topology." Philosophically, this notion is far from pointless, especially if considered within the overall topos-theoretical framework. In particular, it amplifies a Riemannian idea that "space," defined by its relation to other spaces, is a more primary object than a "point" or, again, a "set of points." Space becomes a Leibnizean, "monadological" concept, insofar as points in such a space (when it has points) may be seen as a kind of monad, thus also giving a nontrivial structure to single-point spaces. These monads are elemental but structured entities, "spaces," rather than structureless entities (classical points), or at least are defined by structures associated to them (Cartier 2001). Naturally, this appeal to monads is metaphorical. Leibniz's monads are elemental *souls*, the "atoms" of soul-ness. One might, however, say, getting more mileage out of the metaphor, that the space thus associated with a given point is the soul of this point. In other words, not all points are alike insofar as the mathematical nature of a given point may depend on the nature or structure of the space or topos to which it belongs or with which it is associated. This approach gives a much richer architecture to spaces with multiple points, and one might see (with caution) such spaces as analogous to Leibniz's universe composed by monads. It also allows for different (mathematical) universes associated with a given space, possibly a single-point one, in which case a monad and a universe would coincide. Grothendieck's topoi are possible universes, possible worlds, or compossible worlds in Leibniz's sense, without assuming, like Leibniz (in dealing with the actual world), the existence of only one of them, the best possible.

One might also think of this ontology as an assembly, a "democracy," of ontologies (Grothendieck's concept of topos is, again, ontological, rather than logical), in the absence of any encompassing ontology. Topoi are multiple universes, defined ontologically, in the absence of a single encompassing domain, such as that found in Weil's "imperial" approach. According to David Reed's summary:

> Grothendieck's constructions [beginning with schemes replacing the varieties of Weil] are far from the 'palaces' which Weil suggest belong to algebraic geometers by birthright. Rather than refurbishing and renewing the old constructions he has instead created an entirely new type of architecture and in the process is forced to make extensive use of the 'makeshift algebraic constructions' Weil carefully thought to avoid placing reliance upon. Both Weil and Grothendieck seek generality in order to be able to analyze rigorously geometric situations to which the older algebraic geometers paid little attention. This generality permits consideration of 'degenerate' cases, objects with singularities, 'non-reduced' objects and the like. Whereas Weil sought this generality through a large 'domain' in which the result of his constructions could be contained, Grothendieck seeks generality by expanding the category of objects under considerations until a certain 'self-sufficiency' is acquired, i.e. until a natural reflexivity can be found so that the objects in the category can be related to each other and operations on them can be undertaken without going outside the original category. Furthermore, the objects do not require a predetermined 'fixed point' outside of the category for their specification. . . . This relativity also extends to the set theoretical foundations of the theory. Grothendieck introduces a set theoretic 'universe' which provides the sets used in his constructions and then studies those properties which remain invariant under a change of universe! (Reed 1995, pp. 131, 177n.36)

One, thus, encounters two very different (mathematical) ontological philosophies and, hence, forms of mathematical practice as philosophy – that of unification or encompassment and that of multiplicity, relational, but without a single encompassing domain. Grothendieck's generality or, better (Reed is right to shift to this term), *relativity* of construction is a kind rigorous mathematical instantiation or model of the capacity of mathematics as a human endeavor, for which Riemann's work on foundations of geometry is, arguably, the main modern precursor. This model is that of the creation of mathematical realities (possibly as mental ontologies, of which Grothendieck's topoi are examples), on the basis of, but creatively transforming, previously established realities, in the absence of an ultimate underlying or encompassing Platonist reality. Phenomenally, it is indeed a kind of creation of universes (now plural!) out of nothing, as Bolyai said, insofar as it is a creation of new mathematical worlds out of elements of the stuff of thinking. It is the same "stuff as dreams are made on," the stuff of all our thinking, conscious and unconscious, given a rigorous mathematical structure, rather than the worlds created by matter from its "dark materials," as John Milton aptly described them, admittedly, referring to God's power to create "worlds" out of his dark materials (*Paradise Lost*, Book 2, l. 916).

On the other hand, our thought and thus these mathematical worlds are ultimately created from and by these dark materials, and thus, by *everything*: they are the creations of our bodies and brains, which are the products, creations, of evolutionary history of life, in turn made possible by the whole history of the universe, composed

of its dark materials, from the Big Bang on. It is true that our thought is likely to reach little of how all this was made possible. We certainly do not and possibly cannot know or even conceive of how, by means of what material processes, our bodies and brains make thinking and, hence, mathematics, or science, philosophy, and art, possible. That, however, still leaves us plenty to think about and create in these fields, including in dealing with the nature and practices of thinking. There is still so much in them to be invented and so much that we need from them in our life beyond them.

mathematics. Instead, it is a mathematics that, while still exterior to the major mathematics to which it juxtaposes, constructs itself within and even at the very core of this major mathematics. This may be seen as merely a special form of revolutionary vis-à-vis normal mathematical practice in T. Kuhn's sense. I shall argue, however, by using the work of N. H. Abel, É. Galois, E. Noether, and A. Grothendieck, as my main cases, that this "special" type of revolutionary practice is the primary and even the only form of revolutionary practice possible in mathematics. I designate this mathematics Abelian mathematics, the term commonly associated with formal mathematical properties (such as commutative group or abelian categories), because Abel's work was, arguably, the first manifested case of a minority mathematics in this sense in modern mathematics.

1 Introduction

This chapter considers the nature of radical transformations of mathematics, enabled by minority mathematics. It will be particularly concerned with modern mathematics, which emerged roughly around 1800, as abstract mathematics – abstracted from mathematics' relations to the natural world and physics, relations that previously dominated mathematics. As, however, defined here (transferring Gilles Deleuze and Félix Guattari's concept of a minor(ity) literature, as exemplified by Franz Kafka work) a minority mathematics is not something that exists entirely outside a *major* mathematics, to be distinguished here from a majority mathematics. Instead, it is a mathematics that, while still exterior to the major mathematics to which it juxtaposes itself, is created, constructed within and even at the very core of the major mathematics it transforms. This may be seen as merely a special form of revolutionary vis-à-vis normal mathematical practice in Thomas Kuhn's sense. I shall argue, however, by using the work of Niels Henrik Abel, Évariste Galois, Emmy Noether, and Alexandre Grothendieck, as my main cases, that this "special" type of a revolutionary practice is the primary and even the only form of revolutionary practice in mathematics. I designate this mathematics Abelian mathematics, the term commonly associated with formal mathematical properties (such as commutative group or abelian categories), because Abel was, arguably, the first manifested case of a minority mathematics in this sense in modern mathematics. (To highlight this difference, Abelian will be capitalized when designating a minority mathematics.)

I would like to stress from the outset that in the present view all such transformations of a major mathematics by a minority mathematics, and more generally all mathematical developments, continuous or discontinuous, are assumed to be local, even though they always have their (more or less) extended history. They are the product of a *technical* or *technological* mathematical practice: Each is a local invention of new mathematical technology or a local development of an already existing one, without having their origins in Platonist-like archetypal preexisting mathematical forms or any others preexisting mental reality, or being governed by a unique preordained form (however multifaceted) of mathematics in its historical developments. By the same token, the history of mathematics and its transformations becomes multiple. It is comprised of a manifold of histories proceeding along different trajectories, with multiple forms of interplay between continuities and discontinuities even within each such history, if one can ever rigorously, rather than provisionally, speak of a single history of any mathematical entity – a concept, a theory, or a field. In this chapter, I am specifically concerned with transformations enacted by means of what I define as minority mathematical practices. As I shall argue, however, such minority practices are always involved in and shape transformations, especially radical transformations, of mathematics.

In speaking of a minority mathematics, I adopt Deleuze and Guattari's concept of minor or, as I shall term it (for the reasons explained below) minority literature, introduced by them in their analysis of Kafka's work, and expand this concept to other creative endeavors, with mathematics as my main subject. This expansion is virtually inherent in their concept and transpires in their treatments of many figures in different fields, including mathematics, for example, Abel and Galois, or Bernhard Riemann.[1] Of course, a minority practice is specific to the nature of its field, such as literature and art, philosophy, or mathematics and science. Kafka's work exemplifies both the generality of the concept and the specificity of its application to literature, and further specificity that accompanies the work of each particular figure, in this case Kafka vis-à-vis other modernists, such as James Joyce or Virginia Woolf. To cite Deleuze and Guattari's definition of the concept, as applied to mathematics (which I substitute for literature in their formulation):

[1] Deleuze and Guattari saw Riemann's concept of a manifold (a form of minority mathematics, but its status as such would require a separate analysis) as heralding a revolutionary *philosophical* change, manifesting a minority philosophy, versus dialectic as a (post-Hegelian) major philosophy. This view is helped by the French term "*multiplicité*" as a translation of Riemann's *Mannigfaltigkeit* (which the English translation of Deleuze and Guattari's works often renders, understandably but incorrectly, as "multiplicity"). They say: "It was a decisive event when the mathematician Riemann uprooted the manifold from its predicative state and made it a noun, manifold [*multiplicité*]. It marked the end of dialectics and the beginning of the typology and topology of manifolds" (Deleuze and Guattari 1987, p. 483; translation modified). It could be shown, however, that to leave dialectics behind requires a traversal through dialectical thinking, which, or in any event, thinking in terms of unities (rather than multiplicities, even if unities that contain multiplicities within them) remains the dominant, *major*, philosophical thinking. Philosophically, this chapter advocates the philosophy of the multiple, ultimately uncontainable by a unity. For a discussion of Riemann's conceptual thinking, including as parallel to that of Galois, see Plotnitsky (2022), which also contains further references.

> A minor [*minorité*] [mathematics] doesn't come from a minor [mathematical discourse]; it is rather that which a minority constructs within a major [mathematical discourse]. But the first characteristic of minor [mathematics] in any case is that in it [mathematical discourse] is affected with a high coefficient of deterritorialization. . . . We might as well say that minor no longer designates specific [mathematics] but the revolutionary condition for every [mathematics] within the heart of what is called great (or established) [mathematics]. (Deleuze and Guattari 1989, pp. 18–19)

A minority is an exteriority: A minority thinking comes from the outside of the majority or (as explained below, they are not the same) major thinking to which it relates, even if its representative is an "insider," as, say, Riemann was at Göttingen in his time, rather than is an "outsider," as Abel or Galois was. But a minority mathematics (or a minority practice in any field in this definition) is an *exteriority from within a major mathematics*: It works *through* the interiority of a major mathematics, by interacting with a major mathematics and using it to create new mathematics. I do, thus, introduce a terminological asymmetry, which is, however, suitable and may be necessary here. The term "minority mathematics" is arguably more fitting. It is in effect suggested by Deleuze and Guattari by speaking of a minor literature as "that which a *minority construct* within a major (or established literature)" [emphasis on minority added]. Thus defined, a minority mathematics qua mathematics, such as that of Abel or other figures considered here, is not minor or marginal (any more than a minor literature qua literature is), quite the contrary, although it may be and may remain marginal for a while, even a long while. ("Minoritarian" has been used as a translation of the French "*minorité*," but the term has other meanings in English, such as related to a political power of a minority in a society, which can make it misleading.) Hence, the term "major mathematics" (or "major literature") is a more accurate reflection of the situation, insofar as a minority mathematics (or a minority literature, such as that of Kafka) transforms the central or the most advanced part of the existing mathematics, which may not necessarily be a majority mathematics. Accordingly, I shall adopt this asymmetrical terminology as more precise in reflecting what a minority or Abelian mathematics does. "Minor mathematics" is a linguistically more graceful term, but "minority mathematics," or "minority mathematical practice," is more precise in reflecting the role of a minority, sometimes consisting of a single person. A few immediate qualifications are in order, beginning with the concept of a single-person minority.

A minority thinking is never entirely individual, even if the corresponding practice is individual or nearly so, as it was in the case of Abel or Galois. Either case is probably as close to a single-person minority in mathematics as one can find. One's mathematical thinking, however, is always, to one degree or another, affected by the preceding history of mathematics, because even the most innovative concepts or theories have their history (which is always collective, however individualized it may become), and by extramathematical, such as cultural, factors, which give any individual thinking collective dimensions. Such exterior elements are manifested more in literature, especially, because of the role of ordinary language in shaping the difference between a major (or in this case, a majority) and minority literature (as German vs. Czech, or Hebrew, in Kafka). The role of extramathematical factors

impacting mathematical thinking and practice has been extensively considered in historical studies of mathematics. Indeed, the analysis of "exterior" personal and cultural, including political, factors in the workings and development of mathematics and science has been dominant in the historical scholarship of mathematics and science during the last half a century or so, especially in the so-called constructivist school or rather schools. There have been several such schools, sometimes different in their approach, and the number of works in these areas is massive by now, although most of these works are devoted to science, rather than mathematics.[2] These works challenge the uncritical separation (previous common in the history and philosophy of mathematics and science) of the "interior" and the "exterior" in mathematics and science. On the other hand, the role of (conventionally) "exterior" factors is often difficult definitively to justify as concerns their weight relative to the role of (conventionally) "interior" considerations, the role of mathematics itself. The latter can still be sufficiently demarcated as such, even if one adopts a more critical view of the exterior and the interior of mathematics as relative, case-dependent, rather than absolute. Was Galois' concept of group or Grothendieck's concept of topos impacted by extramathematical factors, for example, given that in both cases one deals with figures with strong political views, and in Galois' case with a political revolutionary? Perhaps, and even likely! The degree of this impact is, however, usually difficult to establish, in contrast to the interaction of either figure with the institutional mathematical establishment, although even this aspect of either case still poses complexities and has been debated, especially, in the case of Galois. In any event, the present chapter is not this kind of study. Mathematics itself, specifically as the interaction between a minority and a major mathematics, is my main concern, and it takes precedence throughout. While exterior elements will be brought up, for example, in commenting on the minority situation of the figures considered in relation to disciplinary or institutional mathematics, my main emphasis will be on mathematical thinking and primarily individual mathematical thinking. I will suggest certain political implications of my argument. This part of my argument is, however, very different from those of the works with the constructivist orientation just mentioned. It is not my aim to challenge this orientation and projects that it led to, some of which have been convincing and important. My aim is to offer a different type of view on the nature of the political in connection with mathematics.

It is essential that, as defined here, a minority mathematics as the transformative, revolutionary, force for mathematics always arises *within* a given major mathematics, rather than (by definition) only in interaction with the latter from its intellectual exterior, as it does in the case of Abel or Galois. It would, however, be difficult to

[2] I mention here some key precursors or founding figures, such as Imre Lakatos (one major philosopher in this field who was primarily concerned with mathematics), Thomas Kuhn, Paul Feyerabend, and a few key recent figures, such as Ian Hacking (who has also written on probability theory), Bruno Latour, Peter Galison, and the Edinburgh school, founded by David Bloor. While addressing minority figures or groups (in the conventional sense), none of these authors or, to my knowledge, any other authors in this field consider concepts similar to those of a minority mathematics (or science) in the present sense.

think of Karl Friedrich Gauss, Riemann, and David Hilbert, whose thinking led to revolutionary mathematical transformations, as minority figures in the way Galois and Abel were (for both mathematical and extramathematical reasons). Nevertheless, even in cases like those of Gauss, Riemann, or Hilbert, there must be (in their case was) some minority mathematics for a revolutionary transformation of mathematics to be possible, although Riemann was more a minority figure overtly. Such a transformation is only possible when a minority thinking restructures or reterritorializes major mathematics, whether this minority thinking is that of a manifested outsider or that of an "official" insider, who must move to a minority-type outside to change mathematics. Cases of the first type, however, such as those of Abel, Galois, Noether, and Grothendieck, allow one to see better how, to return to Deleuze and Guattari's formulation, "minor [is] no longer a specific [form of mathematics] but [is] the revolutionary condition for every [mathematics] within the heart of what is called great (or established) [mathematics]," all major mathematics. Conversely, no minority mathematics is possible without the major mathematics which it affects. A minority mathematics is a revolutionary condition for every mathematics, but by the same token, it can only be this condition *within* a major mathematics. The exteriority of a minority mathematics is an exteriority from within the major mathematics with which this minority mathematics interacts.

The term "deterritorialization," uncommon outside the context of Deleuze and Guattari's work, needs to be explained. While Deleuze and Guattari's *concept* so designated, used by them in a broader set of contexts, would require an extended treatment, its meaning in the present context is reasonably straightforward. It means expanding a given territory, while also reshaping, *reterritorializing*, this territory by means of new conceptions and practices, such as minority ones, although it can also be done otherwise. A clear example is the deterritorialization/reterritorialization of the part of algebra dealing with solving polynomial equations by radicals by making it the mathematics of group theory by Galois. In this respect, Galois' work went beyond Abel's already radical deterritorializing and then reterritorializing (restructuring) the field of mathematics in the context of this problem itself, although, as discussed below, Abel's overall thinking was reaching much further as well. In any event, Galois' group theory is one of the greatest mathematical deterritorializations and reterritorializations ever. The deterritorializations and reterritorializations enacted by Noether and Grothendieck's restructurings of, respectively, algebra and algebraic geometry are far reaching as well, although it is hard to match the concept of group in this respect.

While, however, arguing for the interaction and in this respect continuity between minority and major mathematics, I do maintain that the practice of mathematics contains both continuity and discontinuity, in a complex and (from case to case) varied interplay, including between minority and major mathematics. This interplay always, in each local case (in the present view all such cases are, again, local), contains both a continuity and a discontinuity, even a radical, revolutionary discontinuity, just as it does in other fields, such as literature. Modernism, such as that of Kafka (or James Joyce, Samuel Beckett, and others in literature, Pablo Picasso and Wassily Kandinsky in art, or Arnold Schoenberg in music), was a revolution that

transformed established major literature and art, while retaining continuity with it. Although certain key modernist trends were shared by these figures, the interplay between the major and minority art was also specific in each case, given the individual thinking of each figure and the particular cultural situation in which their minority practice took place. The same is true in mathematics, for example, in Abel and Galois' cases, which had both shared and strictly individual aspects in their thinking and their cultural situations. It may not always be possible, and arguably is never ultimately possible, to *fully* track how new trajectories emerge from and against previous trajectories of thought, including all elements of minority thinking involved in any revolutionary practice. This limitation, however, leaves room for meaningful assessments of this emergence in terms of both continuities and breaks. Algebraic geometry, as transformed by Grothendieck, is a case in point. Grothendieck took advantage of and, first, transformed, by a minority thinking, established concepts of category theory, cohomological algebra, and sheaf theory, already in interaction with each other, even before he transferred them into algebraic geometry, where his work was most transformative.

Continuities do not prevent new theories from breaking with old ones and changing the nature of mathematics in the process but instead help these breaks. Continuities with a major mathematics are, by definition, necessary for breaks enacted by a minority mathematics, although never sufficient for these breaks. Galois' invention of the concept of group was helped by the major algebra of polynomial equations, but as a minority concept a group comes from elsewhere in a broader landscape of Galois' thinking. It was a very complex landscape, far exceeding mathematics and shaping the "elsewhere" that gave rise to the idea of a group. Also, previous major practices may continue alongside revolutionary changes or may change more continuously with previous practices. Not all major literature was transformed into modernism by a minority literature, such as of Kafka or Joyce. In both cases the role of minority (they were not minor!) languages, Czech and and Irish, were crucial. Joyce expressly played with this linguistic multiplicity, by adding other languages into that of his novel, in his final masterpiece, *Finnegans Wake*. Realist literature and "milder" modernist, or mixed, literature, including in good and important works, have continued to remain prominent or even dominant, and they still do.

It may be that, as Yu. Manin contends, there is more continuity in mathematical practice than scientific ones, specifically in physics (Manin 2002, 2010, 2019).[3] It is

[3] As an illustration of his thesis concerning the continuity of mathematical practice (keeping in mind that his article accomplishes a great deal more), Manin offers an analysis of the history of the mathematical theory of time and periodicity, from Ptolemy's epicycles to Schrödinger's quantum amplitude interference and Feynman path integrals, with a few key junctures in between, such as Fourier sums and integrals, which are also central to quantum theory (Manin 2019). One cannot deny this overarching continuity and local continuities with it, elegantly traced by Manin. It is also true that the role of such continuities deserves more attention than it is commonly given, versus revolutionary breaks within this history, which tend to have attracted most commentaries. I would argue, however, that it is difficult to see this history apart from several breaks, sometimes radical

certainly true that major accomplishments are possible by means of primarily, even if not entirely (which, I would argue, may not be possible), continuities with preceding developments, for example, with a major mathematics. This can, however, happen in physics as well: There are cases when the continuity succeeded, at least more so than expected, while attempts at revolutions failed, which also may (but need not) mean that the failure was in not finding a right revolutionary path.[4] In general, it is not always clear, as Kuhn realized and has shown in the case of Max Planck's discovery of quantum theory (Kuhn 1987), and may be a matter of interpretation and debate where, or whether, a normal practice ends and a revolutionary practice begins. I would, accordingly, argue that the balance between them is contingent, shaped by the circumstances of a given case. Thus, while set theory and its concepts are part of the history of category theory and its concepts, as Manin contends, there is, I would argue (contesting Manin's view) just as much, if not more, discontinuity between them. Grothendieck's use of category theory in his work,

breaks, even as concerns the emergence of revolutionary mathematical concepts involved, such as those of Fourier's analysis or the calculus of variations, used by Schrödinger, or the role of complex variables. (Each of these concepts has its own history of continuities and breaks with their predecessors.) These mathematical concepts also reflect and have shaped an even more radical change in physics during this history brought in by quantum physics versus classical physics. Manin acknowledges that such developments and their use of mathematics are "more sensitive to respective 'revolutions' and 'paradigm shifts,' whereas those parts that are closer to 'pure mathematics' show rather a kind of continuous development, as [he] argue[s] in [his] paper" (Manin 2019, p. 130). It is, as I said, possible that there is more such continuity in mathematics overall. I would, nevertheless, argue that either history, that of pure mathematics and that of physics, including in its use of mathematics, shows the interplay between continuities and breaks (again, more complex than that between normal and revolutionary practices), different at different junctures. Some of them in mathematics exhibit changes, such as those defined by new concepts, that are as revolutionary as in physics. This is, again, not to say that such changes do not have history and, hence, continuities with preceding concepts or ways of thinking, including those defined by the interactions between major and minority mathematics found throughout this history. In physics, too, one can see quantum mechanics as, mathematically, a reconstruction (it was called quantum-theoretical reinterpretation at the time) of Hamiltonian and Lagrangian mechanics, the dominant formulation of classical mechanics then. Mathematically, quantum mechanics or, in high-energy regimes, quantum field theory is a major and a majority quantum theory now. Attempts at alternatives, however, never stopped, primarily in view of the epistemological discontent with the theory, most famously expressed by Albert Einstein, but they have not thus far achieved the transformative minority role that quantum mechanics had. See also Note 1 above.

[4] The history of renormalization in quantum electrodynamics (QED) offers an instructive example of this situation. It was believed by many, including Paul Dirac, the founder of the theory, that its problems, having to do with the appearance of infinities (divergent integrals) in QED, could only be resolved by means of an alternative theory, and hence by a revolutionary break, akin to that from classical to quantum theory. As it happened, the renormalization program was able by 1950 to handle these difficulties within QED itself, as it existed. In fact, QED is now the best confirmed physics theory ever, although the discontent with its nature, as requiring renormalization, has never entirely disappeared (Dirac never came to terms with it) and is still around. See Schweber (1984) for a helpful historical account of QED and Plotnitsky (2021, pp. 273–305) on the epistemological aspects of quantum field theory. See also Plotnitsky (2022, pp. 271–274) on recent approaches to the mathematics of renormalization via motivic Galois theory, bringing both Galois and Grothendieck's mathematics into it.

vis-à-vis previous history of algebraic geometry, as in part based on set theory, as in case of André Weil, who, as will be seen, disparaged category theory (Weil 1962, p. 358). Grothendieck's use of category theory or (and in) sheaf cohomology, by then part of a major mathematics in algebraic topology, was a minority mathematics there. (Admittedly, Jean-Pierre Serre already started to bridge both fields in terms of sheaf theory.) The same case can be made for Galois' use of group theory or Noether's rethinking of Dedekind's ideal theory, an established part of the major algebra then, or, more radically, Noether's algebraically defined minority ventures into topology. Her insights, with the help of her students and followers, such as Heinz Hopf and Pavel Alexandrov, had a crucial impact on algebraic topology.

Abel and Galois' mathematics might be seen as more radically *exterior* minority mathematics (still, again, inevitably related to the major mathematics of their time), while that of Noether and Grothencieck as being closer to the major mathematics on their respective situations, except for Noether's minority intervention (from the exterior territory of abstract algebra) into algebraic topology. Still, topology needed topologists, some of which were Noether's students or followers, to build on her ideas to make them part of major topology. A minority mathematics and the major mathematics (or whatever field where both types of thinking are at work) need and depend on each other. Only through a minority mathematics, however, can mathematics transform itself. To return to Deleuze and Guattari's expression of this relationship, minority mathematics is the revolutionary condition for every mathematics in the heart of great (or established) mathematics, in the heart of a major mathematics.[5]

In the remainder of this introduction, I outline a general philosophical view of mathematics, especially creative mathematics, as conceptual mathematics, following (Plotnitsky 2022). Focused (in addition to the role of concepts) on epistemological questions, that study did not consider, except by implication, the role of a minority mathematics, which is, as I argue here, essential to all creative mathematics, including the invention of concepts. This chapter primarily concerns modern mathematics, as abstract mathematics. This mathematics began to emerge around 1800, consolidated, as the dominant form of major mathematics, around 1900, and has continued as such to our own time. The abstraction in question is double: Modern mathematics is abstracted from (A) the physical world, mathematically representing which defined modern physics; and (B) from our daily phenomenal intuition. (A) and (B) are connected because our intuition also contains the phenomenal representation of the external world. It was in fact this representation that was mathematically idealized by classical physics, from which modern mathematics aimed to abstract

[5] Manin might have been more in agreement with the present view of the role a minority mathematics in transforming a major mathematics, which retains some interactive continuity between them or thus a general continuity of mathematical practice. While, however, admitting this element of continuity within the interaction between a minority and a major mathematics, I do maintain that the practice of mathematics contains both continuity and discontinuity, in a complex and varied interplay, including between minority and major mathematics.

itself as well. A phenomenal reality could of course be mathematically represented apart from physical reality, beginning with the reality of mathematics itself.

The term "concept" is often used uncritically, without being defined or by merely assuming some common understanding of it, in mathematical (or scientific) or even philosophical literature. There is no single definition or concept of a concept. The concept of a concept assumed here is parallel to and in part follows that of Deleuze and Guattari's definition of a philosophical concept as grounding a creative practice in mathematics (Deleuze and Guattari 1996). This practice is that of the invention of new philosophical concepts, in juxtaposition to mathematical and scientific concepts. The latter, while casually mentioned sometimes, are in fact not defined by Deleuze and Guattari. They even deny that mathematics or science have concepts in their sense and see them defined by logical propositions and formal mathematical or scientific elements, such as functions, a surprisingly conventional view for these unconventional philosophers, including in other aspects of their view of mathematics and science. "The concept," they say, "belongs to philosophy and only to philosophy" (Deleuze and Guattari 1996, pp. 11–12, 33–34). By contrast, I shall define mathematical or scientific concepts on the model of their concept of a philosophical concept, following the argument given in (Plotnitsky 2022, pp. 52–76), which also offers a critique of Deleuze and Guattari's view of the role of concepts in philosophy versus mathematics and science.

This chapter, accordingly, gives preference to the role of conceptual thinking rather than in logical propositions or calculations, which, however, could also be shaped by a minority mathematics, as were some of Abel's methods of calculations. Both logic and calculations are essential to mathematics, including conceptual thinking there, because the structure of mathematical concepts is logical, and because calculations require concepts and can lead to new concepts. Nevertheless, while respecting these features, this chapter views creative mathematical thinking as most essentially defined by the invention of new concepts, which, I further argue, is only possible by means of a minority mathematics.[6]

In the present *general* understanding, following, as a general understanding, that of Deleuze and Guattari, a concept is not merely a generalization from particulars (which commonly defines concepts in linguistics, analytic philosophy, or cognitive psychology) or a general or abstract idea, although a concept may contain such generalizations or ideas, specifically abstract mathematical ideas, where they may also be concepts in their own right. A concept is a multicomponent structure, defined

[6] There are still other aspects of mathematical thinking, for example, a narrative one, the role of which, as constitutive rather than merely auxiliary (which has always been recognized), has received a considerable amount of attention during recent decades. For a representative collection of essays on the subject, see Doxiadis and Mazur (2012). For a full disclosure, the present author was among the contributors, although his article questioned, on epistemological grounds, the degree of the efficacy of narratives in mathematical invention or argumentation, advocated by other contributors (Plotnitsky 2012). In any event, my emphasis in this chapter is on concepts as the primary creative vehicles of mathematics, and the role, and one indeed might say, the narrative of minority mathematics, a narrative not discussed by the contributors in (Doxiadis and Mazur 2012).

by the organization, *composition*, of its components, and some of these components may be concepts in turn. Of course, every concept, no matter how innovative, has a history defined by other concepts (or other forms of thought) from which this concept emerges and without which it would not be possible. Just as any theory (which, while it may have other components, is always a conglomerate of concepts), a new concept is a product of an interplay of continuities with and breaks from preceding concepts. Some concepts considered here, such as those of a group by Galois or a topos by Grothendieck, were more radically innovative. Still, however, they had connections with earlier concepts, such as (putting aside the earlier history of which) those of Adrien-Marie Legendre in the case of a group and those of category theory in the case of a topos.

Riemann's thinking and practice, discussed by this author on several previous occasions (e.g., Plotnitsky 2022, pp. 99–135), provide arguably the most prominent example of the conceptual approach to mathematics, especially in geometry, as based on the concept of a manifold [*Mannigfaltigkeit*]. This approach led him beyond all previous approaches to geometry, including those, axiomatic in nature, that led to non-Euclidean geometry. Riemann shunned axiomatic thinking in favor of conceptual thinking, in accord with the present general definition of a mathematical concept. Riemann himself did not offer such a general definition, but his concepts, such as and in particular that of manifold, fully conform to the definition adopted here and may, as indicated above (Note 1), be seen as a model for Deleuze and Guattari's concept of a (philosophical) concept. Conceptual thinking plays, however, an essential role in the thinking of all the main figures considered here, although the relative balance between conceptual thinking and other forms of mathematical thinking, such as an axiomatic one, is different in each case. For example, axiomatic thinking plays a greater role in Grothendieck's work, although the minority part of his thinking was essentially conceptual, also shaping his view of axiomatization. It is, again, not my intention to diminish the role of the logical or calculational aspects of mathematics or science, or to take anything away from the contribution of philosophical investigations, such as those in the analytic philosophy of mathematics, that focus primarily on logical and propositional structures of mathematics or science.[7] My aim is to give a proper emphasis to the role of concepts, especially in *creative* thinking in mathematics or science, but not only in creative thinking, because working with already established concepts is indispensable in all mathematical or scientific practice. The unconditional opposition between the logical-propositional and conceptual structures, or between calculations and concepts, is not so easy to maintain, even in considering figures, such as Galois, Riemann, or Dedekind, who gave concepts a dominant role in their work. While their thinking was primarily governed by concepts vis-à-vis calculations, they were perfectly capable of and did perform difficult calculations. Besides, calculations involve

[7] There are new powerful approaches to logic in mathematics, such as homotopy type theory (Voevodsky et al. 2013; Corfield 2020). Concepts, however, still play an essential and unavoidable role in them.

concepts and lead to new concepts, as they did in the case of Abel, or Leopold Kronecker, who insisted on their primary role in mathematics. I would still argue, however, that the invention of new concepts is the primary feature of creative mathematical practice, accompanied and defined (the degree may vary) by the role of a minority mathematics, again, in the present definition, working within a major mathematics.

The definition of a concept given above was only a general, *abstract*, definition. What meaningfully establishes a concept is the specific character of its compositional structure, defined by both the nature of each component and the character of their relations within this composition, by how these components relate to each other in the structure of the concept. This composition is unique in a new concept, and it makes this concept unique. The creative essence of concepts is in their compositional individuality, which is only possible by virtue of their general compositional nature but is defined by the specificity of this composition. All musical works are compositions, but each gives us a different music. A group is composed of its elements, but in accordance to very specific rules, which give it its structure and role in mathematics in group theory and beyond, and then it multiplies further to still more specific concepts of a group, a finite group, a Lie group, an algebraic group, and so forth, and then into further concepts within each of these. A single-component concept is a product of a provisional suspension or cutoff of its multicomponent organization. In fact, there are always cutoffs in delineating a concept, which result from assuming some of the components of this concept to be primitive entities whose structure is not specified. These components could, however, be specified by alternative delineations, leading to a new concept, containing a new set of primitive (unspecified) components.

Consider the mathematical concept of space. Emerging historically at the intersection of mathematics, physics, philosophy, and general phenomenal intuition, and defined by such constitutive concept-components as point, line, plane, or distance, this concept or each of these components has a long history of definitions, modification, and transformations. As a general phenomenal concept, it is arguably as old as human consciousness. Kant did not see space (or time) as a concept, but rather as an a priori form of phenomenal intuition. He had a point, even if one rejects (as many have done) Kant's a priori view of space and time: In his view, these phenomenal forms precede any concept of space and time. As a geometrically representable physical concept, space is at least as old as ancient Greek geometry, well preceding Euclid, who did not define, although, arguably, implied, the concept of space in the *Elements*. The history of the concept of space, as a mathematizable physical and eventually (in the nineteenth century) purely mathematical concept, extends from the Pythagoreans to Euclid to Descartes (a coordinate space) to Riemann (a space defined as a manifold) to Felix Hausdorff (topological space) to Grothendieck (topos), with further versions within each. In the first four cases, the concept of space qua space was, while mathematizable, still physical. After each transformation, which was a product of a minor mathematics, the resulting new concept of space became part of a major mathematics, or physics.

A concept, then, is an assemblage of its components connected by its composition, which define its specific individual and, at the time of its invention, unique

nature. Some of its components may be unique but need not be. The components of a concept need not be new, but its composition must be new for a concept to be new. In this respect, a concept is *akin* to a work of art, always defined by its composition, in accord with the ancient Greek meaning of *poiein* (a making of an entity), as making something new, in which the term poetry originates. A theory, or a disciplinary field, mathematical, scientific, or philosophical, such as geometry, classical physics, or Kant's philosophy (philosophy may be more individualized), becomes an organized assemblage of concepts. It is a product of a broader *poiein*, which in mathematics or science may be commonly collective, although a theory may be initiated, but never contained, by a single new concept, such as Galois theory, initiated by the concept of group. In the present view, however, a *creative* conceptual *mimesis* (which may borrow, "imitate," elements of previous concepts but combines them in a new way) is a partial *technical* mimesis of previous concepts, rather than a Platonist mimesis of something that belongs to a preexisting independent reality.

Of course, theoretical concepts (or theories) are, in their compositional nature and functioning, different from works of art. For one thing, a work of art need not contain concepts, although so-called conceptual art always does. In functioning, a concept can be used directly or with minor modifications in, again, Kuhn's terms, the normal practice in mathematics and science. Philosophy, at least a certain form of philosophy, for example, as defined by Deleuze and Guattari (1996), may be associated strictly with the invention of concepts as a revolutionary and hence a minority practice, which thus becomes its normal or major practice. In this respect, this practice is closer to that of art, which, while it may use a tradition, is compelled to be innovative and in this case a minority art, but only in this respect, because the nature of the conceptual and artistic composition remains different.

What is shared in the creative nature of art, philosophy, and mathematics and science is *poetically* (again, in the ancient Greek sense of *poiein*) the role of composition, and *politically* the minority nature of creative thought, the political essence of which is freedom. All these fields and all creative human endeavors first assume, as Deleuze and Guattari argue, the necessity of a war they, by their different means, wage against the dogmatism of opinion or any dogmatism, the greatest enemy of creative and, hence, free thought, which is always a minority thought (Deleuze and Guattari 1996, p. 202). Although Deleuze and Guattari did not expressly make this point, their argument concerning a minor (minority) literature, certainly in Kafka's case, clearly implied it. A minority literature is, by definition, a creative practice of literature, and as such is always at war with, and is a war against opinion, and it poses a great danger to opinion and majority thinking, or even major thinking, when the latter becomes governed by opinion. The dogmatism of opinion is, in the first place, dogmatism, to which Hegel juxtaposes true thinking, as defined by a free creative mediation. "*Dogmatism*," he says in the Preface to *The Phenomenology of Spirit*, "the way of thinking, in both knowing or in the study of philosophy, is nothing but the opinion that truth consists in a proposition which is a fixed result or else in a proposition which is immediately known [*der unmittelbar gewußt*]" (Hegel 2019, p. 31). In other words, dogmatism forgets or disregards the mediating and especially creative (all creation is mediation, but a special one) role of

thinking and makes one surrender one's capacity for true thinking. The dogmatism of opinion was an enemy of thought for all figures considered in this chapter. They had to confront and fight opinion, not the least by means of new concepts, as Riemann argued in closing his Habilitation lecture. New concepts, such as those his lecture introduced, are, he said, needed "to insure that [our] work is not hindered by unduly restricted concepts and that progress in comprehending the connection of things is not obstructed by traditional prejudices" (Riemann 1854, p. 33). Such restricted, and *restricting*, concepts are often part of a majority mathematics and sometimes even of a major mathematics. On the other hand, new concepts or all creative thought always require one or another degree of a minority thinking and hence a freedom in deciding to pursue a minority thinking rather than follow a majority thinking, even when it is a major thinking. A decision is, I would argue, a better category than choice, at least a free choice, because there may always be factors, psychological, social, or cultural, that shape our decisions, restricting and sometimes precluding their freedom. It does not follow, however, that there is no freedom in our decisions, although this type of argument is made sometimes (usually in the form of denying the existence of free will). The category of decision allows for the *possibility* of freedom, which, while always relative, is crucial. Also, in saying that the *essence* of minority thinking is freedom, the possibility of freedom, I *do* refer to its political *essence*. I am not saying that mathematics (or science) always involves politics, either within mathematics itself or in relation between mathematics and culture. This may be true, but it means little, without giving such claims due specificity. My point here is specific and different in nature: The *essence* of minority thinking in mathematics or elsewhere is the possibility of freedom, because a minority thinking and hence creative mathematics would not be possible otherwise. I shall return to this point in closing this chapter to argue that mathematics allows for an extraordinary and even unique degree of freedom, and that a minority mathematics, defining all creative mathematics, is *governed* by this freedom rather than by a majority mathematics, even when it is a major mathematics. Deleuze and Guattari, in this connection, also speak of a majority mathematics or science, governed by a major mathematics, as "royal" or "state" mathematics (or science), and a minority mathematics or science, as nomadic, specifically juxtaposing Gaspar Monge's (state) geometry to Girard Desargues' (nomadic) projective geometry (Deleuze and Guattari 1987, pp. 363–365). Creative mathematics is grounded in and is an affirmation of a minority thinking and of freedom in mathematics. There is no creative mathematics otherwise. Although creative mathematical decision-making may, as Georges Polya argued, be based on plausible reasoning (Polya 1990), we still have the possibility of freedom to decide on the line of thought to pursue. There is no possibility of new mathematics without a minority mathematics and without the possibility of freedom to pursue it.

Now, according to Deleuze and Guattari, a philosophical concept, as defined by them, is also a problem, a positing of a problem. This view has a mathematical genealogy, although the concept of a problem preceded mathematics and was adopted by it and given a mathematical specificity by ancient Greek mathematics. A problem in this sense is not something that, like a theorem, is derived from

assumed axioms by means of logical rules but is something that is posed, created, along with and as a concept. According to Deleuze and Guattari's definition of these connections, however, as applied to philosophical concepts, a concept as a problem persists and thus remains a problem, rather than disappears, or is *solved*, in its solutions (Deleuze and Guattari 1996, p. 5). This is a complex conception, which is not easy to interpret, especially given the paradoxical nature of this formulation, and I shall not attempt to do so. Nor shall I adopt this concept as such, in part, because this conception is applied by them to philosophical concepts as problems, rather than to mathematical problems, which, in their view, are always, in principle, soluble, rather than continue to remain problems in their solutions as philosophical concepts do. Instead, I shall use a different mathematical concept proposed in (Plotnitsky 2022), that of "a concept-form," without claiming that Deleuze and Guattari would have subscribed to this concept, either in relation to their concept of a philosophical concept or otherwise.

A (new) concept-form, such as that of a group by Galois or a topos by Grothendieck, would be *introduced*, just as any concept, in order to solve an existing problem, which defied a solution by means of already existing concepts or had a solution that was unsatisfactory, conceptually, technically, or even aesthetically. Finding the algebraic solution to a polynomial equation (or proving the impossibility of doing so) in Galois' case was such a problem, leading him to the concept of group. There are thus two approaches (with gray areas between them and sometimes combining both) to solving a problem, especially a difficult one: The first is essentially technical, which aims to solve it by means of logical and technical manipulations of previously existing concepts; and the second, adopted by Galois, is essentially conceptual, which uses a new concept or set of concepts, although technical and logical manipulations remain necessary, as they are in all mathematics. Such a concept may be relatively simple, such as that of a group, although this simplicity is retrospective. But, even if it is, such a concept usually arises in response to a complex problem. This was certainly so in the case of the concept of group, which was invented by Galois to find an algebraic solution to a polynomial equation (and, as it happened, proving the impossibility of doing so for the equations of degree five and higher). This was a very complex problem at the time. By means of this concept, Galois redefined this problem by establishing that whether such a solution exists or not is related to the structure of a group of permutations associated with the roots of the polynomial, known as the Galois group of this polynomial. Abel's approach had elements of this thinking by posing the question whether a solution exists or not, given the structure of the equation, and finding that in general it does not. This finding is now known as the Abel-Ruffini theorem or Abel's impossibility theorem. Paolo Ruffini gave an incomplete proof in 1799, and Abel was the first to prove it in 1824. Galois accomplished much more, by making a group a concept-form.

As a concept-form, however, a new concept does more than merely solve a given (initial) problem. It defines a new problem-posing field in which new types of actual problems emerge and are being solved, while the concept-problem that initiated and governs this field is not something that is "solved" in the sense of no longer being

necessary for this field to continue to develop, which it does by defining new concepts and concept-forms, some of which are new forms of the original concept-form. In this way, one can maintain a certain affinity with Deleuze and Guattari's understanding of a concept as a problem persisting in its solutions, rather than disappearing in them. I am, again, not claiming that the concept of a concept-form offers an interpretation of Deleuze and Guattari's concept of a concept-problem. In fact, it cannot be because the latter concept is philosophical, while the concept of a concept-form is mathematical. All that matters here is that the concept of a concept-form works, as I think it does, in mathematics and science. Galois' concept of group not only gave the Abel-Ruffini theorem a more general grounding but also gave algebra a new field, Galois theory, in which new problems were subsequently posed, as they still are, which give Galois theory its continuing life. The same is true about Grothendieck's topos theory. This type of invention of a new concept in response to a concrete problem not only in solving this problem but also making this concept a concept-form can happen as an outcome of a deliberate strategy or it might happen contingently, in a complex interplay between chance and necessity.

The concept of a concept-form is both a tribute to Plato's thinking and a critique and ultimately abandonment of all Platonism, including Plato's own, which is different from many other Platonisms, including mathematical Platonism, a twentieth-century conception, quite different from the way of Plato's thought, including about mathematics. It is a tribute insofar as it affirms a creation of new conceptual forms which then shape the subsequent development of thought in a given field and beyond it. Thus, the concept of group has shaped and continues to shape both mathematics and other fields, such as physics or other natural sciences, and even social sciences. On the other hand, against Platonism (now including Plato's own) a concept-form is not something that preexists the history of thinking related to it and is then discovered by human thought, which may only conceive of this something itself partially or approximated. It is still human thought that assumes the existence of this something as a real preexisting human thought. This assumption is Platonism in its ultimate form. By contrast, as explained, each concept-form emerges in and shapes this history in the complex interplay of chance and necessity in the work of individual figures and communities. It comes from, *emerges in*, a contingent history, even though it can shape the subsequent history in, one might say, quasi-Platonist fashion. I qualify by "quasi" because new concepts or concept-forms shaped by this concept-form are not mimetic shadow-images of preexisting (eternal) forms, as in Plato (Plotnitsky 2022).

By the same token, a concept-form need not be seen as containing or fully determining a problem-posing field it creates, even if only as a potentiality. This field emerges in a contingent development, as a complex interplay of causal chains and chance occurrences. In general, in adopting a problem-posing versus axiomatic-theorematic view of mathematics, one is more likely to reject a Euclidean, essentially Platonist, view in which axioms are assumed as pregiven truths rather than created as concepts first, as axioms are from the present perspective, a distinction that was brought into the foreground by the discovery of non-Euclidean geometry. The present view is close to Imre Lakatos' conception of a quasi-empirical theory versus

a Euclidean theory, modeled on Euclidean geometry. ("Quasi" reflects the fact that mathematics is "empirical" in dealing with mental rather than material phenomena.) Lakatos sees creative mathematics as quasi-empirical, consistently with or even implying the key role of a minority mathematics in it.

Reciprocally, the present view is quasi-empirical, even though some and even most of the figures considered here, such as Abel, Noether, or Grothendieck, might have adopted a more Euclidean philosophy of mathematics. Lakatos also argues that no Euclidean ideology can avoid quasi-empirical practice, especially as creative practice, any more than a creative major mathematics can avoid becoming a minority mathematics. According to Lakatos:

> The development of a quasi-empirical theory is very different. It starts with problems followed by daring solutions, then by severe tests, refutations. The vehicle of progress is bold speculations, criticism, controversy between rival theories, problem shifts. Attention is always focused on the obscure border. The slogans are growth and permanent revolution, not foundations and accumulations of eternal truths.
>
> The main pattern of Euclidean criticism is suspicion: Do the proofs really prove? Are the methods used too strong and therefore fallible? The main pattern of quasi-empirical criticism is proliferation of theories and refutations. (Lakatos 1980, pp. 29–30)

This proliferation invites and even gives a central role to a minority mathematics. As, correlatively, both quasi-empirical and grounded in the role of a minority mathematics, the present view of the history of mathematics is that of multiple trajectories, heterogeneous yet interactive, that is, trajectories with multiple connections between them, without assuming or even precluding unifying them in a single "grand" narrative, as Manin appears to see as at least possible to do (Manin 2010, p. 242).[8]

Every new mathematics, which, as new, is always a creation of a minority mathematics, takes a chance on the future of mathematics, just as every new minority science, literature, such as that of Kafka, or philosophy takes a chance on becoming a mathematics or science, art, or philosophy of the future. "A philosophy of the future" is Friedrich Nietzsche's phrase describing his own philosophy, manifestly a minority philosophy, and all true philosophy in his subtitle to *Beyond good and evil: A prelude to a philosophy of the future* (Nietzsche 1966). To become a philosophy of the future, a philosophy, Nietzsche in effect argues, must start as a minority philosophy, which is quite true about that of most major figures in the history of philosophy – Plato, Aristotle, Descartes, Leibniz, Kant, and Hegel. One can take the same view of creative mathematics, such as that of Abel, Galois, Noether, and Grothendieck. Robert Langlands (of the Langlands program fame) compared Grothendieck to "Nietzsche's *Philosoph der Zukunft*" (Langlands and Shelstad 2007, p. 486). This is no less true about Abel, Galois, or Noether, and other key figures mentioned here, or Langlands himself, as the Langlands program has proven.

[8] The concept of a grand narrative is borrowed by Manin from Jean-François Lyotard, who saw it as challenged by the present-day, "postmodern," world, in part in view of twentieth-century mathematics and science, which has shaped this world (Lyotard 1984).

2 Abel and Galois: Minority Mathematics and the Rise of Modern Algebra

Over half a century ago, Jules Vuillemin offered an influential analysis of Abel and Galois, and of the rise of (modern) algebra in *La philosophie de l'algèbre* (Vuillemin 1962), on which, along with other sources, such as Charles Lautman, Deleuze built his commentary on Abel and Galois in his 1968 *Difference and repetition* (Deleuze 1995). Vuillemin's approach had a strong structuralist orientation shaped by the Bourbaki program (the book is dedicated to, among others, Pierre Samuel, a member of Bourbaki), an orientation different from the one of this chapter, on four counts. First, a minority mathematics was never considered, even by implication, by Vuillemin, while it is, as I argue, crucial for understanding both Abel's and Galois' roles in algebra and modern mathematics in general. Deleuze does not consider a minority mathematics in this earlier book either. The concept of minor literature was developed two decades later in the book on Kafka, cowritten with Guattari, building on the ideas of their earlier joint works. Second, this chapter adopts a conceptual approach versus a structuralist one. Third, Vuillemin's book and the corresponding part of Deleuze's book (a broader philosophical project overall) aim to transpose the methods of modern algebra, in particular those of Abel and Galois, into philosophy, which is not my aim here. Fourth, "ideas," in *Difference and repetitions* and then concepts in Deleuze and Guattari's *What is Philosophy?* (Deleuze and Guattari 1996), are defined strictly as philosophical ideas and concepts, even when they are operative in mathematics, specifically as problems that persist rather than disappear in "solutions" to them. By contrast, as explained above, mathematics is, for Deleuze and Guattari, always about solutions of mathematical problems (Deleuze 1995, pp. 163–164, 179–182). One might readily agree that mathematics is commonly in pursuit of solutions to its problems and that there may be a philosophical dimension to a new problem-posing field defined by a new mathematical concept-form, such as that of a group by Galois. In the present view, however, a concept-form is a *mathematical* concept rather than a *philosophical* concept. Concept-forms still enable one to solve, or to advance the possibility of solving, concrete problems, such as, in Galois' case, the problem of finding the algebraic solution to a polynomial equation, which gave rise to the concept of group. This is made possible by embedding this original problem in a new mathematical concept-form, which defines a new problem-posing mathematical field, or even a new field of mathematics, such as Galois theory. An exact definition possible in mathematics is difficult to achieve in a philosophical concept, the rigor of which needs to be, accordingly, defined otherwise, which is a separate issue that will be put aside here.

These differences notwithstanding, it may be helpful to summarize Vuillemin and Deleuze's arguments concerning Abel and Galois' work. According to Deleuze:

> Abel elaborated a whole method according to which solvability must follow from the form of the problem. Instead of seeking to find out by trial and error whether a given equation is solvable in general, we must determine the conditions of the problem which progressively specify the fields of solvability in such a way that 'the statement contains the seeds of the

> solution'. This is a radical reversal in the problem-solution relation, a more considerable revolution than the Copernican. It has been said [by Vuillemin] that Abel thereby inaugurated a new Critique of Pure Reason, in particular going beyond Kantian 'extrinsicism'. This same judgement is confirmed in relation to the work of Galois: starting from a basic 'field' (R), successive adjunctions to this field (R′, R″, R‴ . . .) allow a progressively more precise distinction of the roots of an equation, by the progressive limitation of possible substitutions. There is thus a succession of 'partial resolvents' or an embedding of 'groups' which make the solution follow from the very conditions of the problem: the fact that an equation cannot be solved algebraically, for example, is no longer discovered as a result of empirical research or by trial and error, but as a result of the characteristics of the groups and partial resolvents which constitute the synthesis of the problem and its conditions (an equation is solvable only by algebraic means—in other words, by radicals, when the partial resolvents are binomial equations and the indices of the groups are prime numbers). The theory of problems is completely transformed and at last grounded, since we are no longer in the classic master-pupil situation where the pupil understands and follows a problem only to the extent that the master already knows the solution and provides the necessary adjunctions. For, as Georges Verriest remarks, the group of an equation does not characterize at a given moment what we know about its roots, but the objectivity of what we do not know about them. Conversely, this non-knowledge is no longer a negative or an insufficiency but a rule or something to be learnt which corresponds to a fundamental dimension of the object. The whole pedagogical relation is transformed—a new *Meno* [Plato's dialogue dealing with teaching mathematics]—but many other things along with it, including knowledge and sufficient reason. Galois's progressive discernibility unites in the same continuous movement the processes of reciprocal determination and complete determination (pairs of roots and the distinction between roots within a pair). It constitutes the total figure of sufficient reason. (Deleuze 1995, pp. 179–180)

Manifestly the product of a minority mathematics, this is a radical transformation of mathematical, and, on this pattern, for Deleuze, of philosophical practice, including as the pedagogy of ideas or, in his later works, concepts. This view also implies that the pedagogy of mathematics should be transformed, certainly as it functions in mathematical practice (which, just as that of philosophy, always involves a teaching of concepts) and possibly in the actual teaching of mathematics. The latter, primarily defined by teaching even more a majority mathematics than a major mathematics, would benefit by giving more attention to minority thinking in mathematics. In the absence of a contemporaneous alternative education (possibly informal), such a teaching is not likely to lead to the emergence of mathematical thought such as that of Abel, Galois, and Noether. When B. L. van der Waerden's *Modern Algebra* (van der Waerden 1930) was published in 1930, it was also an introduction to a new way of thinking in algebra, developed by Noether and Emil Artin, and at the time (and for a while) it helped new thinking in algebra and beyond, including as pursued by Bourbaki. But subsequent textbooks on algebra rarely perform this function, and *Modern Algebra* no longer in general does so either. I shall return to this subject below.

Galois' thinking had an even more revolutionary significance for both Vuillemin and Deleuze, given the role of the concept of group, which was (in present terms) a new concept-form and, as such, an even more consequential invention. All concept-forms require a minority practice to emerge, but Galois' concept of group, or his thinking in general, more dramatically exhibited a minority mathematics. As noted

from the outset, the concept of group has radically deterritorialized and reterritorialized mathematics, well beyond algebra. This deterritorialization is, again, not addressed by Deleuze in *Difference and repetition* but is suggested by his later appeal to Galois' "abstract machine," alongside Riemann's "abstract machine," the term designating a vehicle (also in its literal sense of enabling a movement) of deterritorialization (Deleuze and Guattari 1987, p. 142). The term also designates a nomadic, and hence, minority, versus state or royal (major and often majority), practice of mathematics.

I shall consider first Abel's work, arguably the first manifested case of a minority mathematics in modern mathematics, prompting me to designate all minority mathematics as Abelian mathematics. According to Vuillemin, Abel transforms algebra by the invention of "a general method":

> In the first place, one analyzes, in its most general form, a mathematical relation or a defined set of such relations, which make it possible to determine a property, of which we do not yet know whether or not we can attribute it to a class of beings: by example the character of being algebraically solvable, of being convergent, of being expressible by a defined number of functions of a certain class. In the second place, one considers the class of beings to which it is a question of attributing this property . . .; we analyze these beings from a general point of view, we define the relationships to which their nature allows them to be subjected. Finally, this double examination reveals the cases of incompatibility (demonstrations of impossibility) and, possibly, indicates the way to find the new required relationships in cases of possibility. (Vuillemin 1962, p. 214; translation mine)

Thus, rather than looking for the solution to equations of the fifth degree, one asks whether such a solution is possible, in the first place, for any polynomial equation. This shift is the key (minority) move by Abel. Abel's new "idea of a general method consists in giving a problem a form such that it is always possible to solve it" (Vuillemin 1962, p. 209; translation mine). Abel, thus, reversed the method of his predecessors and his contemporary major mathematicians, who would proceed from the particular to the general to proceeding from the general to the particular. As a result, Abel becomes one of the creators of the modern algebraic method. Vuillemin sees this method as, in effect, structuralist in Bourbaki's sense. Against Kant, who limited his construction of the proof of impossibility by positing the possibility of an experience as an exclusive criterion of knowledge, "general demonstrations, in the sense of Abel, change the modality of the proof. Particular demonstrations are actual [*réelles*]: they assume as their grounding principle the possibility of the experience given in the affect of sensation. The general proofs deal with the possible and start from the concept alone, disregarding the restrictive conditions of sensitivity" (Vuillemin 1962, p. 216; translation mine). This initiating concept is, again, defined not by a generalization from particulars, but as a new structured entity, in accord with the present definition of concepts. In this way, Abel introduced a new *critique* of pure reason (in Kant's sense of a critique a rigorous examination of the legitimacy and limits of philosophical claims, such as those concerning causality, and hence concepts), at least in mathematics, but, as Vuillemin and Deleuze argue, extendable beyond mathematics. Mathematics needed Galois in algebra (a group) and then

Riemann in geometry (a manifold) to be expressly rethought in this way, or perhaps *more* expressly. For, one might see Abel's thinking as reaching further in this direction and in general as a more radically transformative than Vuillemin and Deleuze suggest. His minority mathematics was even more momentous in its transformative and, hence, deterritorializing potential. Mikhail Gromov considers Abel to be "a major figure, if not the major figure, in changing the course of mathematics from what could be visualized and immediately experienced to the next level, a level of deeper and more fundamental structure" and hence toward modern mathematics (Raussen and Skau 2010, p. 401).[9] Abel's thinking also becomes even closer to that of Galois in general, beyond the problem of solving polynomial equations. Gromov continues:

> [Abel] changed the perspective on how we ask questions. I do not know enough about the history of mathematics but it is obvious that the work of Abel and his way of thinking about spaces and functions has changed mathematics. I do not know enough history to say exactly when this happened, but the concept of underlying symmetries of structures comes very much from his work. We still follow that development. It is not exhausted yet. This continued with Galois theory and in the development of Lie group theory, due to Lie, and, in modern times, it was done at a higher level, in particular by Grothendieck. This will continue, and we have to go through all that to see where it brings us before we go on to the next stage. It is the basis of all we do now in mathematics. (Raussen and Skau 2010, p. 401)

As such, Abel's minority mathematics becomes a crucial case of a deterritorialization of modern mathematics. Gromov's statement is a reflection on this aspect of Abel's work as well, even if without considering Abel's works strictly from this perspective. My designation of all minority mathematics as Abelian mathematics fits well with Gromov's assessment and with his comments, on the same occasion, on mathematical education. In responding to the question concerning mathematical education or education in general now, Gromov gives a somewhat unexpected answer, by using Abel as an example:

> ***Raussen and Skau****: Education is apparently a key factor. You have earlier expressed your distress about realizing that the minds of gifted youths are not developed effectively enough. Any ideas about how education should change to get better adapted to very different minds?*
>
> **Gromov**: Again I think you have to study it. There are no absolutes. Look at the number of people like Abel who were born two hundred years ago. Now there are no more Abels. On the other hand, the number of educated people has grown tremendously. It means that they have not been educated properly because where are those people like Abel? It means that they have been destroyed. The education destroys these potential geniuses – we do not have them! This means that education does not serve this particular function. The crucial point is that you have to treat everybody in a different way. That is not happening today. We don't have more great people now than we had one hundred, two hundred, or five hundred years ago, starting from the Renaissance, in spite of a much larger population. This is probably due to education. ...

[9] This assessment was given in the wake of Gromov's reception of the Abel prize, which might have inflected Gromov's remarks, without, in my view, undermining Gromov's essentially correct assessment itself.

> ***Raussen and Skau****: You point out that we don't have anybody of Abel's stature today, or at least very few of them. Is that because we, in our educational system, are not clever enough to take care of those who are exceptionally gifted because they may have strange ideas, remote from mainstream?*
>
> **Gromov**: The question of education is not obvious. There are some experiments on animals that indicate that the way you teach an animal is not the way you think it happens. The learning mechanism of the brain is very different from how we think it works: like in physics, there are hidden mechanisms. We superimpose our view from everyday experience, which may be completely distorted. Because of that, we can distort the potentially exceptional abilities of some children. There are two opposite goals education is supposed to achieve: firstly, to teach people to conform to the society they live in; on the other hand, to give them freedom to develop in the best possible way. These are opposite purposes, and they are always in collision with each other. This creates the result that some people get suppressed in the process of adapting them to society. You cannot avoid this kind of collision of goals, but we have to find a balance between the two, and that is not easy, on all levels of education. (Raussen and Skau, p. 402)

Gromov is right to qualify the question if education is not obvious and to note this conflict at the core of the Enlightenment ideal of education. In effect (whether or not Gromov had in mind or even was aware of this connection to the Enlightenment), Gromov describes this ideal by referring to giving people "freedom to [individually] develop in the best possible way." (Conforming to the society one lives in is common to most conceptions of education.) This concept and, with it, the conflict in question emerge with the Enlightenment, especially following Kant, who introduced the term "Enlightenment [*Aufklärung*]," in part by grounding this ideal in, to use the title of his second critique, a "*critique of practical reason*" (Kant 2015). Two influential examples may be noted here. The first, before (and influencing) Kant, Jean-Jacques Rousseau's *Émile*, *ou de l'éducation* [1762] emphasized the importance of this freedom for an individual to develop in the best possible way and the difficulty of achieving the aim of doing so in a society (Rousseau 1997). (Because of one section of the book, it was banned in Paris and Geneva, and publicly burned when published in 1762.) The second, following (and yet displacing) Kant, Friedrich Schiller's *Über die ästhetische Erziehung des Menschen in einer Reihe von Briefen* [Letters on the Aesthetic Education of Man] (1795) (Schiller 2004), aimed at reconciling both aims within a framework, which, however, poses major questions of its own.[10]

The question of education is indeed far from obvious. Abel and others to whom Gromov is referring under an apt collective name "Abels," certainly Galois, or any number of Renaissance figures who could be mentioned, such as Galileo, were not uneducated, quite the contrary. Nor were Abel and Galois merely self-educated in mathematics either, even if to some degree they, especially Galois, were more so than others. But if one considers the likes of Gauss and Riemann, one encounters a reasonably conventional mathematical, as well as broader, education. (Kafka was remarkably educated and not only when it comes to knowledge of literature, and

[10] For a critique of Schiller's "aesthetic ideology," including his misreading of Kant, see (De Man 1996) and for the connections between the general problematic of "aesthetic ideology" and the idea of algebra, in connection with Paul de Man's analysis (Plotnitsky 2001).

Gromov, perhaps not coincidentally, brings up Russian literature in his interview, and some of its greatest figures, comparable to Kafka, including as, in some cases, representing a minority literature.) Gromov must have been aware of these qualifications. His point was, I would surmise, different, and it may be expressed in terms of a minority thinking in mathematics or elsewhere. As indicated above, even more than individuality, our education resists and discourages orientations toward a *minority* thinking, not the least because while transforming major thinking it challenges even more majority thinking. As I argue, however, without a minority thinking in mathematics and a chance, and a freedom, to put it into practice the likes of Abel and Galois are not possible or in any event not likely to emerge. The problem is equally acute elsewhere, including in literature and art, which has managed to still produce their "Abels," such as Kafka, throughout much of the twentieth century, although there are now no more Kafkas or Joyces around either. Still, minority literature or art *might* have a greater chance, a chance diminished by the contemporary nature of education in mathematics and science, although there are (hence, I qualify by "might") societal and specifically educational forces operative against pursuing minority ways in literature and art.[11] Mathematics or other fields could also be transformed *more* within major practices – more, but never entirely so. Instead, such cases show (and hide) more incremental multistep punctuated processes, with a lesser impact of minority thinking entering from a manifested exterior, such as that exhibited in Abel and Galois' thinking.

Galois is an equally exemplary case in both his uniqueness as a minority mathematician and in the role of "the concept of underlying symmetries of structures" in mathematics invoked by Gromov, who mentions Galois theory as an example following Abel's "revolution." It would, however, be difficult to argue that Galois theory merely follows Abel in this regard, and Gromov would probably admit its greater overall significance. It was the first expressly formulated actual theory of the type Gromov invokes. For one thing, it is as a product of a group theory,

[11] More generally, as I argue here, if there is no opening toward minority thinking, there is no creative thinking in any domain, but only a proliferation of opinion and forms of programing according to preestablished rules, which are essentially equivalent to or are generative of opinions. Although I mean the term "programming" in a broader sense here, I do imply that the recent development of and claims for the so-called artificial *intelligence* (a misleading term), such as, now ubiquitous, ChatGPT and its avatars, have nothing to do with thought, but are merely forms of programing. In this respect, the term artificial intelligence (AI) is misleading, although it is difficult to replace it at this point, for example, by a much more accurate "digital robotics." As such, such programs merely propagate knowledge defined by or defining opinions, with no space for a minority thinking and hence creativity. Even if such programs use things derived from minority thinking gathered from Internet archives, they will convert them to preestablished information or rigid articulations of ideas. While recognizing many extraordinary accomplishments of digital technology, one should not confuse a clever programing with thinking. A remarkable and in many respects distressing aspect of ChatGPT and related software is that they do what they do *without* thinking. Their use in mathematics, much discussed recently as well, is a separate issue, which I put aside. I merely note that, in my view, it does not seriously challenge my main point concerning the difference between programing and creative thinking, which is always a minority thinking. ChatGPT can only help to propagate opinions.

which, as I have stressed throughout, enacts a broad deterritorialization of modern mathematics, as well as physics and other sciences, natural and social. It is hard to think of a broader one. Some elements of group-theoretical thinking are found in Abel, or Legendre, earlier, and Abel's thinking in general has deeper affinities with Galois in rethinking the fundamentals of mathematics as such. But the concept of group carries Galois' signature. It was also accompanied by another important concept, that of an action of a group on another structured entity, such as an algebraic field or vector space. Besides, Galois theory is much more than only part of group theory.

For Vuillemin, deeply steeped in Bourbaki's ideology, the emphasis is on the idea of structure, and he sees the concept of group as the first formal algebraic structure in the history of mathematics. Galois' thinking, then, is both akin to that of Abel as concerns Abel's philosophy of solving problems and reaches beyond Abel, even if it is, as Gromov argues, not as far beyond as is sometimes claimed. It does so, again, by bringing in the role of a structure and the concept of group as an entity (we would now say a set) with a structure, a relationally organized multiplicity. Galois, for Vuillemin, becomes the first *modern* algebraist, who associates with solving a problem the analysis of the structure from which this problem arises and which makes it possible or not to solve it, such as the problem of finding algebraic solutions by radicals of polynomial equations. Vuillemin's structuralist perspective is not out of place. One cannot avoid structures or merely dismiss structuralism, an important movement, conceptually and historically (Corry 2006). For one thing, concepts are also structures. On the other hand, one might, as I do, see structures as emerging from and as concepts, which thus precede structures in creative thinking in mathematics.

Indeed, as in the case of Abel's thinking, one of Vuillemin's main points in considering Galois is more about concepts than structures, keeping in mind that a concept is a structure, too, and conversely any given structure is a concept. Sometimes, the structure of a mathematical concept, such as that of a group, may coincide with the mathematical structure defined by this concept. Still, a structure qua structure must be defined and thus comes from a concept, possibly a concept-form. Vuillemin distinguishes two types of abstraction: The first is conventional, defined by an increasing generalization from the particular to the general, and the second, found in group theory, is conceptual in the present sense. It defines the differences between specific individual cases because it constructs these cases from the initial concept. Vuillemin sees the second abstraction, which he terms "formalization," as a double abstraction: The first is that of the formal presentation of the group, as a concept, by algebraic symbols and their relations; the second is that defined by providing a method that makes it possible "to construct individuals, no longer in intuition according to imperfect [arbitrary] schemes, but [determinately] in the concepts themselves" (Vuillemin 1962, pp. 288–289; translation mine).

Thus, one deals with an algebraically formalized conceptual practice and redefines algebra accordingly, as a deterritorialization of algebra by means of a minority algebra. In Galois' case and, more extensively, in Abel's case, one also deals with a parallel shift to the conceptual algebraization of analysis, as well as geometry, where

this shift was initiated with the analytic geometry of Fermat and Descartes. In noting that, in the wake of Galois, "modern mathematics is therefore regarded as based upon the theory of groups or set theory rather than upon differential calculus," Deleuze adds: "Nevertheless, it is no accident that Abel's method consisted in giving a problem a form such that it is always possible to solve it, concerned above all the integration of differential formulae" (Deleuze 1995, pp. 180–181).

Galois' concept of group as a multiplicity with a structure was an entirely new type of concept, created by a minority mathematics from within and transforming, reconstructing, the major mathematics of his time and of the future. As a concept-form, it defined a new problem-posing field through the new mathematical formulations of existing problems (such as that of the solution of polynomial equations by radicals) and posing new problems, and the simultaneous establishing of their conditions of solubility. This new thinking changes the future of mathematics as a field of solving problems, because these problems themselves and the conditions of their solubility change, by asking under what conditions a given problem can be solved. While Abel and already Ruffini did something similar, there was no specific concept of the type a group is in its power and generality. Galois, again, also creates the concept of an action of a group on another structural entity, such as a field in algebra or a manifold in geometry.

One has now a new abstract concept, an invention of thought, that of a group. This new concept governs a previously established object, an equation, or eventually governs a field (another new concept-form), or a class of such objects, *similarly* to the way a Platonic form precomprehends a given concrete reality. As indicated earlier, however, there are also major differences (hence my emphasis) between these two conceptions. The objects considered, such as equations or fields, are not "shadows" of a group as this new abstract form, which does not preexist them, as Plato's form or idea would. Each such object or instantiation of a concept, such as an equation or a field, has its own definition. Just as that of a group, a more general concept of an equation (which has a long and complex history) or a field, like algebra, only preceded a particular equation, or area of algebra, locally, and not as a Platonic form, preexisting them in some "eternal" domain. (Where, one wonders, would a mathematical Platonist place such a domain?) In the present view, any new concept is a local invention of human thought and, to one degree or another, is always a product of a minority thinking. As such, it relates and handles the reality already in place and the problem this reality posed and, by doing so also, establishes a new problematic field, such as Galois theory in the case of a group. In fact, in the process it creates a new mathematical reality (Plotnitsky 2022, pp. 83–95). It always does so, however, locally and contingently, in the interaction between a minority and a major mathematics, rather being governed by one or another preexisting Platonist reality or a single transforming Ur-reality governing all possible local transformations. Such Ur-reality would imply a possibility, at least in principle, of a single major mathematics to which a minority mathematics could contribute but that it could not change by an independent act of creation. A minority mathematics could, in this case, only participate in transformations of a single major mathematics, Ur-mathematics, defined by this Ur-reality. In the present view, the possibility of

either this type of Ur-reality or this type of Ur-mathematics is precluded in principle. So is, it follows, a grand narrative of mathematics, replaced by multiple narratives of its continuous and discontinuous developments, with multiple mathematical practices (minority, major, and majority ones, among them) in multiple interactions.

3 The Three Mathematics of Emmy Noether

Emmy Noether, a *major* figure in twentieth-century mathematics, is also an important case of a minority mathematics. Her case has additional complexities, first, because the relationships between a major and a minority mathematics in her work in different areas of mathematics were different, and second, because of the "geography" of mathematics at the time, with Göttingen, where she worked, as one of its centers or even the center of major mathematics in most key areas of modern mathematics then. Although her achievements and the importance of her work have always been acknowledged by mathematicians and historians of mathematics, her role as a shaping figure in twentieth-century mathematics has remained an underappreciated subject for a long time, although the situation has changed in recent years. Described by some of the greatest twentieth-century mathematicians and physicists, Hilbert, Einstein, and Weyl, among them, as the most important woman mathematician in the history of mathematics, she was once referred to, in *The New York Times*, as "the most significant mathematician you've never heard of" (Angier 2012). A decade old now and no longer as applicable, this assessment still reflects both the status of mathematics in our culture and the status of women in mathematics. While the second subject has been extensively considered in literature, including in connection with Noether's work, the first has not received much attention, although it has been given more attention in recent years as well. This chapter does not intend to offer an analysis of either subject as such. It might, however, suggest a new perspective on both by considering Noether's work as a minority mathematics.

In geometry, the primary field of her earlier work, she followed the tradition, defined by the role of symmetry and group theory, established by Riemann, Felix Klein, Sophus Lie, and others, and by that time also shaping physics, specifically general relativity, in which Noether worked as well. In algebra, the primary field in her later work, she followed the tradition initiated by Galois and developed especially by Dedekind. She also made important and, in some respects, revolutionary contributions, to algebraic topology. All three fields were by then parts of major mathematics, even though continuous innovations within each involved (in the present view, unavoidably) minority mathematical thinking and practices. Noether's thinking and practice were minority ones both in their purely mathematical aspects and given her social and specifically institutional situation, because she was a female mathematician in a (vastly) male dominated field, as mathematics was then, including in all areas of her work. Here, I shall be primarily concerned with her mathematics, without offering an analysis of the second aspect of her minority practice, addressed in several recent studies, including her biographies. I shall argue that,

while all three facets of her work still represented, in view of their innovative nature, minority mathematics, each case was different. Her work on her celebrated theorems was more firmly within what was major mathematics in geometry at the time, her work in algebra had much more significant minority dimensions, and her contribution to algebraic topology was the most pronounced manifestation of her minority thinking in mathematics. All three of *Noether's* mathematics, however, also confirm that a minority mathematics depends on and is not possible without working with a major mathematics. One might read in this way Noether's refrain "*Es steht alles schon bei Dedekind* [this is all already in Dedekind]," even if she herself meant it more directly, a claim that is difficult literally to apply to Noether's ideas in algebra, many of which were too original to be thus attributed to Dedekind (McLarty 2006, p. 212). Instead, these connections to Dedekind, whose work was by then a well-established part of major algebra, reflect the dependence of Noether's minority mathematics on its interaction with her contemporary major mathematics in making possible her contributions, profoundly innovative as they were. This, I argue here, is always the case. In sum, this section presents a new angle, that of a minority or Abelian mathematics, on Noether's work.

During the last half a century or so, Noether, has become especially known, including in her recent public recognition, for her theorems, published in 1918. (Most of the studies devoted to her work focus on these theorems.) By contrast, she has always been world-famous for her contributions to modern algebra and (to a somewhat less degree) algebraic topology among mathematicians and historians of mathematics. The significance of her contribution in topology was due to Noether's realization that algebraic operations, related to homotopies and homologies, in topology should be considered in terms of abstract algebraic concepts, such as groups. This view, quickly adopted by her contemporary topologists and, at least in the case of homotopies, by earlier figures, such as Henri Poincaré, had proven exceptionally fruitful for the development of algebraic topology and has come to define both cohomology and homotopy theories there. (Both, especially cohomology theory, were also developed in algebra and algebraic geometry.) As discussed below, however, Noether's thinking in this field and in algebra itself was more innovative and more radical, giving her use of what Wolfgang Krull, a major algebraist in his own right, referred to as "Noether's principle" (Krull 1935, p. 5; McLarty 2006, p. 218). The principle is grounded in the view that abstract mathematical concepts, such as groups, rings, or modules, should be primarily defined, in terms of their structure, a view that came to define modern algebra and much of modern mathematics, in part following Bourbaki's structuralism. This understanding as such was not especially new, although Noether was a key figure in establishing it. Noether's principle, however, was new. It says that the study of these objects should focus on the relationships, *morphisms*, between algebraically structured objects (sets), such as groups, rings, or modules, rather than merely on these objects themselves.

Innovative as it was in algebra, Noether's work was even more so in topology at the time, although it has become routine since, including as translated into categorical terms. Noether's principle and, in the first place, Noether's ideas concerning the

role of groups in considering homotopies and homologies of topological spaces were developed in algebraic topology by her disciples and followers, such as Heinz Hopf and Pavel S. Alexandrov, as well as independently by others, such as Leopold Vietoris. Noether's principle is a *precursor* of later categorial and functorial principles, as considered earlier in this study, especially in Grothendieck's work. It would, in my view, be difficult to claim that Noether herself did go that far. There is, in her work, no suggestion of the relations, functors, between categories or protocategories that she considered. In retrospect, algebraic topology is inherently categorical. What made it an exact mathematical discipline was the fact that one can associate algebraic structures (initially numbers and algebraic operations, eventually groups and other algebraic structures) to the architecture of spatial objects that are invariant under continuous transformations, independently of their geometrical properties, associated with measurements. It thus relates, functorially, objects of topological and algebraic categories. This nature of algebraic topology had, however, *to be made* categorical in its rigorous sense, which took a while and happened about a decade after Noether's death (in 1935). Her thinking in algebraic topology was, nevertheless, a contribution to this history. Alexandrov, one the topologists influenced by Noether, commented on this new, *minority*, thinking (addressing a Russian audience), in commemorating Noether, first by comparing her work on algebra and differential geometry with that of Sophia Kovalevskaya:

> It is often forgotten that in this period Emmy Noether obtained excellent results concerning the concrete algebraic problems of Hilbert. These results and her work on differential invariants would have been enough by themselves to earn her the reputation of a first-class mathematician and are hardly less of a contribution to mathematics than the famous research of S. V. Kovalevskaya. (Alexandrov 1936, cited in Dick 1981, p. 156)

He added, giving Noether a greater credit for her contribution to algebra and then algebraic topology:

> But when we think of Emmy Noether as a mathematician, we have in mind not these early works, important though they were in their concrete results, but rather the main period of her research, beginning in about 1920, when she became the creator of a new direction in algebra and then leading, the most consistent and prominent representative of a certain general mathematical doctrine–all that which is characterized by the words 'begriffliche *Mathematik*' [abstract mathematics]. (Alexandrov 1936, cited in Dick 1981, p. 186)

It is worth noting that "*begriffliche*" means conceptual, which does not exclude abstract, but is not quite the same (regardless of what Alexandrov thought).

I shall, however, consider first Noether's celebrated theorems by way of contrast as an example of a primarily major mathematics, while, again, keeping in mind that, as any innovation, they contained ingredients of a minor mathematics, even in purely mathematical terms, aside from the gender aspects of Noether's minor mathematics, which would require a separate analysis. Noether's theorems, especially Noether's first theorem, were mathematical generalizations of previously known mathematical expressions of physical conservation laws (those of momentum, energy, and angular

momentum) in classical mechanics and relativity. General relativity introduced mathematical complexities into the formulation of the energy-conservation law, which complexities were handled by Noether in her article introducing her theorems. Her theorems were, however, formulated abstractly (a minority move), and they can be considered apart from any reference to physics, in the style of symplectic geometry. (The latter originates in the Hamiltonian formulation of classical mechanics where the phase spaces of certain systems assumed the structure of a symplectic manifold, defined by a closed, nondegenerate 2-form.) When applied in physics, Noether's theorems state that every differentiable symmetry of the action of a physical system has a corresponding conservation law. The action of a physical system is an integral over time of a Lagrangian, which allows one to determine the system behavior by using the principle of least action (the quantity defined as the integral of the momentum over a given distance traveled by a body). The theorems are an application of the principle, arguably, stated first by Pierre Louis Maupertuis in 1774 and mathematically developed by Leonhard Euler around the same time, and then by Joseph Louis Lagrange and Sir William Rowan Hamilton. Leibniz had related ideas earlier. Philosophically, the idea that nature follows the most efficient path possible can be traced to much earlier, even to ancient Greek thinking. According to Yvette Kosmann-Schwarzbach's account, closely following Noether's article:

> Noether's first theorem, a generalization of several conservation theorems that were already known in mechanics ... She considers a multiple integral,
>
> $$I = \int \dots \int f\left(x, u, \frac{\partial y}{\partial x}, \frac{\partial^2 y}{\partial x^2}, \dots\right) dx,$$
>
> of a higher-order Lagrangian f that is a function of n independent variables, $x_1, \dots, x_\lambda, \dots, x_n$, and of μ dependent variables, $u_1, \dots, u_i, \dots, u_\mu$, as well as of their derivatives up to a fixed but arbitrary order, κ. She then considers a variation of u, $\delta u = (\delta u_i)$, and derives identity (3),
>
> $$\sum_{i=1}^{\mu} \psi_i \delta u_i = \delta f + \mathrm{Div}\, A,$$
>
> where the ψ_i are the Lagrangian expressions, which is to say the components of the variational derivative (Euler–Lagrange derivative) of f, and where the components A_λ of A are linear in the variation δu and in its derivatives. The opposite of the quantity A is now called the Legendre transform of the Lagrangian f. Here Div is the ordinary divergence, $Div\, A = \sum_{\lambda=1}^{n} \frac{\partial A_\lambda}{\partial x_\lambda}$, of $A = (A_1, \dots, A_n)$ considered as a vector in n-dimensional space, and δf is the variation of f corresponding to the variation δu of u, while the variation of x is assumed to vanish. Identity (3) is obtained by an integration by parts. In the case where $n = 1$, the case of a simple integral, Noether gives an expression for A for an arbitrary μ, first for $\kappa = 1$, which yields what she calls Heun's "central Lagrangian equation," then for an arbitrary κ, and then she states her theorem:

I. *If the integral I is invariant under a [group] $\mathfrak{G}_\rho$, then there are ρ linearly independent combinations among the Lagrangian expressions which become divergences—and conversely, this implies the invariance of I under a [group] $\mathfrak{G}_\rho$. The theorem remains valid in the limiting case of an infinite number of parameters.*

Noether explains that "in the one-dimensional case," that is, when $n = 1$, one obtains first integrals, while, "in higher dimensions," i.e., when $n > 1$, "one obtains the divergence equations which, recently, have often been referred to as conservation laws." By the "limiting case" included in the statement of Theorem I is meant the case in which the elements of the group depend on an infinite but denumerable set of parameters, as opposed to the case dealt with in her Theorem II (Kosmann-Schwarzbach 2011, p. 57).

Noether's second theorem, in which this limitation no longer applies, is:

II. *If the integral I is invariant under a [group] $\mathfrak{G}_{\infty\rho}$ depending upon arbitrary functions and their derivatives up to order σ, then there are ρ identities among the Lagrangian expressions and their derivatives up to order σ. Here as well the converse is valid.* (Kosmann-Schwarzbach 2011, p. 4)

The physical meaning of the theorems easily follows given that the mathematics used (ideally) *represents* the key physical features of the systems considered, in an essentially geometrical way, notwithstanding the algebra of the theorems, that of symmetry groups. For systems with suitable Lagrangians (which allow for this representation), as most classical and relativistic systems are, symmetry under continuous translations in time implies the conservation of energy, symmetry under continuous translations in space implies the conservation of linear momentum, and symmetry under continuous rotations implies the conservation of angular momentum. These formulations apply straightforwardly in classical physics, with the mathematics of the proof automatic by Noether's first theorem. As noted, general relativity involves certain mathematical complexities, in part leading Noether to her second theorem. Noether did important work on general relativity earlier, and her work on her theorems was in part prompted by Hilbert's questions concerning energy conservation there, on which he consulted Noether and that Noether resolved by a subtle argument in her article (Noether 1918; Kosmann-Schwarzbach 2011, pp. 63–64). Noether closes her article, by citing Klein's famous pronouncement that relativity is an invariance under group transformation, a view that of course applies in mathematics itself (Noether 1918; Kosmann-Schwarzbach 2011, p. 22, note 27, pp. 63–64). These complexities do not affect the geometrically representational (realist) character of her theorems. Just as is classical physics, relativity, special and general, remains a realist theory, which means that Noether's theorems or symmetry principles apply in essentially the same way as in classical physics. In principle, her theorems are, again, independent of physics, with which, however, they have been primarily associated, including by Noether herself. The situation becomes different when Noether's theorems appear in quantum mechanics or quantum field theory, where one can still use them. More accurately one can use certain *versions* of these theorems, because they have to be reformulated even for the same dynamical variables – momentum, angular momentum, and energy – as those used in classical

physics in view of the nature of the formalism of quantum theory versus that of classical physics or relativity. In quantum theory, these variables are no longer functions of real quantities but are operators in Hilbert spaces over $\mathbb{C}$, in the case of these variables, infinite-dimensional Hilbert spaces. The theorems can also be generalized to variables, especially discrete variables, such as spin, and symmetries that are strictly quantum and have no classical counterparts. The subject will be put aside, because these versions of Noether's theorems have only remote connections to Noether's work; they are no longer *Noether's* Noether's theorems. I have considered this subject in detail in (Plotnitsky 2022, pp. 205–210). My point here is that her theorems as such, *Noether's* Noether's theorems, were by and large the products of what was then a major mathematics, important and innovative as these theorems were and, as such, unavoidably dependent on a minority mathematical thinking in their discovery. Thus, as noted, formulating them *abstractly* apart from any reference to physics was a minority move, characteristically Noetherian in nature, arguably, a link to her work in abstract algebra and then algebraic topology, where, however, the minority nature of her thinking becomes much more pronounced.

Noether's work in abstract algebra is one of the greatest representations of the idea, and the ideal, of modern algebra as abstract algebra. Algebra was part of and shaped modern mathematics in the present definition, as abstract mathematics in general (vs. representing natural objects, specifically in physics), from around 1800 on. On the other hand, the term "modern algebra" has immediate connections to and even originates in Noether's work, because it appears to have been used for the first time in the famous book, under this title, "Modern Algebra [*Moderne Algebra*]," by her close associate and collaborator, van der Waerden (1930). The book was based on lectures given by Noether and Emil Artin. It was one of the first books to use an abstract (axiomatic) approach to algebraic structures, such as groups, rings, and fields, and as such became, transitioning from a minority to a major approach, one of the most influential texts on algebra in the twentieth century. It reflected Noether's mathematical practice, again, initially as a minority practice, quickly transformed by Noether and her followers, into a major practice, with Galois and especially Dedekind as the main precursors.

The grounding principle of modern algebra is what Vuillemin, as discussed above, defined, in considering Galois' concept of group (but clearly following post-Noetherian algebra, as shaped by Bourbaki structuralism), as a double abstraction, or "formalization." The first abstraction is that of the formal presentation of the group, as a concept, in terms of algebraic symbols and their relations; the second is that defined by a method that makes it possible "to construct individuals, no longer in intuition according to imperfect [more arbitrary] schemes, but [determinately] in the concepts themselves" (Vuillemin 1962, pp. 288–289; translation mine). In other words, this is an abstraction as a creation of new general (abstract), but in their construction concrete, *intrinsically* concrete, mathematical concepts. Such concepts can also borrow elements from elsewhere and mathematize them, thus abstracting them from their source areas. Symmetry is an example of such a concept: It was borrowed from general phenomenal spatial considerations, but made into invariance under transformations, which may form a group, an algebraic concept that can be

used, as it was by Galois, outside geometrical considerations, and, as a mathematical concept, defined by that of invariance, it came to geometry from algebra.

In Noether's work, then, and, in part under the influence of her work, in general, modern algebra is practiced as abstract algebra – algebra defined by means of its abstract concepts and structures. Commonly, as in van der Waerden's book, and in most commentaries on Noether, the emphasis is on structures and axioms. I would argue, however, that concepts are equally important to Noether, thus making Noether an heir of Riemann as well as Dedekind, who was of course himself an heir of Riemann. For one thing, as noted, a structure is a concept or a set of concepts first, even though concepts are in turn defined by their structure as an organization, *composition*, of their elements. As such a concept and a structure often coincide in the case of purely mathematical concepts, but the concept of concept and the concept of structure are still different. According to van der Waerden's (reported) recollection: "The maxim by which Emmy Noether was guided throughout her work might be formulated as follows: 'Any relationships between numbers, functions, and operations become transparent, generally applicable, and fully productive only after they have been isolated [abstracted] from their particular objects and been formulated as universally valid concepts'" (Dick 1981, p. 101). Structures are, however, essential for defining morphisms between (in present-day terms) categorical entities, and morphisms are central for Noether's work in algebra and algebraic topology.

Thus, integers (which do not form a field) become studied as a commutative ring – a concept with a formally defined abstract structure. One of the outcomes of this approach is Noether's proof of the unique factorization theorem, the Lasker-Noether theorem. The theorem extends the fundamental theorem of arithmetic, which states that every positive integer can be factored uniquely into primes, which is not so for the ideals of commutative rings in general, but is true for Noetherian rings, a very beautiful mathematical discovery. A Noetherian ring satisfies the ascending chain condition on left and right ideals. The ring is left Noetherian or right-Noetherian if the chain condition is satisfied only for the left or the right ideals, which means that every increasing sequence $I_1 \subseteq I_2 \subseteq I_3 \subseteq \cdots$ of left or right ideals has the largest elements, that is, there exists n such that $I_n = I_{n+1} = \ldots$. Equivalently, a ring is left or right Noetherian if every left ideal (or right ideal) is finitely generated, or Noetherian if both conditions are satisfied. The Lasker-Noether theorem states that every Noetherian ring is a Lasker ring, a ring in which every ideal can be decomposed as an intersection, called primary decompositions, of a finite number of primary ideals (which are not the same as prime ideals, which share many key properties of prime numbers).[12] The theorem was proven by Emanuel Lasker (famous as a world chess champion) in 1905 for polynomial rings and convergent power series rings, and in full generality by

[12] An ideal Q of a commutative ring A is primary if whenever xy is an element of Q then x or y^n is also an element of Q, for some $n > 0$. In the ring of the integers $\mathbb{Z}$, (p^n) is a primary ideal if p is a prime number. An ideal P of a commutative ring R is prime if: (a) If a and b are two elements of R such that their product ab is an element of P, then a is in P or b is in P; and (b) P is not the whole ring R.

Noether in 1921. Lasker's proof, fully in accord with an established major algebra then, was no small achievement, but it was technical (calculational) and cumbersome, and of course limited. Noether's proof is conceptual and elegant. It was also an example of how conceptual abstraction worked in commutative algebra as, at the time, a minority mathematics.

Noether's later remarkable and highly influential article *Abstrakter Aufbau der Idealtheorie in algebraischen Zahl- und Funktionenkörpern* [*Abstract Structure of the Theory of Ideals in Algebraic Number and Function Fields*] (Noether 1927) characterized the rings in which the ideals have unique factorization into prime ideals as the Dedekind domains: integral domains that are Noetherian, 0- or 1-dimensional, and integrally closed in their quotient fields. This article also contained what is now known as the isomorphism theorems, which concern certain fundamental natural isomorphisms, and other key results on Noetherian and Artinian modules. Noether was "the first to develop a general representation theory of groups and algebras, valid for arbitrary ground fields," presented in the important article "*Hyperkomplexe Grössen und Darstellungstheorie*" (Noether 1929). According to van der Waerden:

> [The article] has had a profound influence on the development of modern algebra. . . . In the introduction Emmy Noether states that in recent publications the structure theory of algebras and the representation theory of finite groups have been separated completely. She, on the other hand, aims at a purely arithmetical foundation, in which the structure theory and the representation theory of groups and algebras appear as a unified whole, namely as a theory of modules and ideals in rings satisfying finiteness conditions. (Van der Waerden 1985, p. 244)

In her later work, Noether also made important contributions to the study of noncommutative algebras, including division algebras.

The discussion just offered only considered a very limited set of examples of Noether's work in abstract algebra, sufficient to argue that the high degree of abstraction in her approach could be seen as, at the time, a minority mathematics. I should add, however, that even these examples show (while the methods of modern algebra sometimes hide) the history that shaped these concepts, as a historical part of their intrinsic mathematical concreteness, and as such, also the history of the interaction between established major and minority mathematical practices. Only a few prominent names were mentioned here as part of this history, such as Galois, Dedekind, Hilbert, and Artin. Dozens of other figures, however, even if one thinks only of major ones, are part of this history, even if some of them, such as Kronecker, fought against abstractness, in part, I would argue, by failing to appreciate the intrinsic concreteness of this abstractness. I now move to Noether's use of the *concepts* of abstract algebra, especially that of a group, in algebraic topology, a more dramatically minority intervention, if localized to the relationships between a "minor" role of abstract algebra and the major mathematics in topology.

The history of Noether's engagement with topology is well known, although there is more to Noether's thinking than most accounts convey, and none of them considered this engagement from the viewpoint of a minority mathematics. The situation is complicated by the fact that Noether did not publish on the subject. She

only mentioned it in passing, as "an application of a group theory," in a single article, devoted to another subject: "*in den Anwendungen des Gruppensatzes – z.B. Bettische und Torsionszahlen in der Topologie* [in an application of a group theory—for example, Betti and torsion numbers in topology]" (Noether 1925). This mention is, however, revealing in conveying her contribution, that of bringing group theory into topology and thus helping to make it more fundamentally algebraic, although others, such as Vietoris, did this independently around the same time. Yet again, however, Noether's contribution was more innovative and far-reaching than only that of rethinking homology theory by means of group theory. Equally significant was the way in which she did so, nearly, even if not quite, functorially. Her ideas had a great immediate influence, quickly reshaping the major practice of topology, through the work of such figures as Alexandrov and Hopf. According to a widely circulated statement by Alexandrov:

> When [Noether] first became acquainted with a systematic construction of combinatorial topology, she immediately observed that it would be worthwhile to study directly the groups of algebraic complexes and cycles of a given polyhedron and the subgroup of the cycle group consisting of cycles homologous to zero; instead of the usual definition of Betti numbers, she suggested immediately defining the Betti *group* as the complementary (quotient) groups of the group of all cycles by the subgroup of cycles homologous to zero. This observation now seems self-evident. But in those years (1925–1928) this was a completely new point of view. (Alexandrov 1936, cited in Dick 1981, p. 174)

It was also a minority *algebraic* thinking in topology, or rather a new minority algebraic thinking, because there is no algebraic topology without algebra. How can topology be algebraic otherwise? On the other hand, what algebra brings into topology may be and in this case was a matter of a minority thinking, and the very emergence of algebraic topology was of course a minority thinking. Noether reportedly also noted that the idea of a Betti group makes the Euler-Poincaré formula easier to understand (Dick 1981, pp. 174–175). There is a clear consensus, which included Alexandrov and Hopf themselves, that their work greatly benefited from Noether's insights, unpublished but extensively discussed in her circle at Göttingen at the time. On the other hand, there is less consensus and some debate concerning whether homology groups were used before, specifically by Poincaré, who clearly used homotopies as groups and spoke of them as such. A helpful historical and conceptual discussion and references are found in several articles by Colin McLarty (2006, 2011, 2017). In assessing Noether's contribution, McLarty goes beyond previous arguments concerning Noether's work. He credits Noether with a more radical and significant innovation than only using groups. He sees her main achievement by connecting this work to Noether's developing of, in her words, "set-theoretical foundations of algebra" (McLarty 2006, p. 212).

This would, in present terms, be seen as a more radical example of a minority mathematics by virtue of introducing homomorphisms (rather than merely groups) to bear on topological maps. The "set-theoretical topology" of his title "Emmy Noether's set-theoretical topology" of (McLarty 2006) is a pun: Part of his argument concerns how *algebraic* topology (rather than set-theoretical topology, also known

as general topology) was affected by Noether's concept of set. Luitzen E. J. Brouwer, who worked on these topological maps, becomes part of this history.

McLarty's opening is of some interest in the present context. He uses, as an epigraph, a famous statement by Weyl: "In these days the angel of topology and the devil of abstract algebra fight for the soul of each individual mathematical domain" (Weyl 1939, p. 500). The devil, as a fallen angel in the first place, is a quintessentially minority figure. McLarty then comments as follows:

> If Hermann Weyl ever put faces on these spirits they were his good friends, the angel Luitzen Brouwer, and the devil Emmy Noether. Weyl well describes the scope of their ambition. But topology and algebra were not fighting each other. They would come to share the soul of most of mathematics. And the angel and devil had worked together. In 1926 and 1927 Emmy Noether induced young topologists gathered around Brouwer to use her algebra to organize the kind of work on topological maps that Brouwer taught. This created the still current basis for 'algebraic topology.' It was a huge advance for the structuralist conception of mathematics. And it turned Noether from a great algebraist to a decisive figure for twentieth-century mathematics. (McLarty 2006, p. 211)

This history is an example of the interplay of geometrical and algebraic thinking (in the broad sense, so as to include topology), which sometimes haunted and sometimes inspired mathematics from the Pythagoreans on, as discussed in detail in Plotnitsky (2022). It is true that the angel (of topology) and the devil (of algebra) sometimes worked together. But they also fought against each other, and changed their role, with algebra becoming a major (but not necessarily majority) angel and topology a minority (but not necessarily minor) devil, keeping here the asymmetry of terms that is part of my argument.[13]

Formally, my emphasis is on concepts and the *conceptual* conception of mathematics, rather than on structures and the structuralist conception of mathematics (à la

[13] This suspicion concerning algebra is often found in geometrically oriented mathematicians, such as Michael Atiyah, who goes as far as stating, quite beyond Weyl's more genial ironic assessment, that "algebra is the offer made by the devil to mathematicians," which even makes one "stop thinking" (Atiyah 2002, p. 7). This is not something that Grothendieck, let alone Noether (even at her early geometrical phase), would have been likely to agree with. It is not easy to so unconditionally distinguish algebra and geometry either, as the present chapter shows and as Atiyah indeed acknowledged, still, however, holding on to his negative sentiment toward algebra. It may well be, however, that, even for Atiyah and certainly for Weyl, the devil of algebra was only the devil of algebra as the "machine" (Atiyah's word) of calculation, algebra deprived of geometry, or topology. In the present view, algebra may also embrace and create geometry and topology, just as geometry and topology embrace and sometimes create algebra. It would in fact be difficult to find greater manifestations of this interplay than Weyl or Atiyah's own work, including that in Atiyah's case on the mathematics of the Yang-Mills theory, which grounds the standard model. The Yang-Mills theory then played a key role in the topology of four-dimensional manifolds, courtesy of the work of Atiyah's student Simon Donaldson, on which Atiyah reflects at some length in his article (Atiyah 2002, pp. 12–13) and which was considered in this context by this author in (Plotnitsky 2022, pp. 275–278). See also Athanase Papadopoulos' article on René Thom, who was equally suspicious about algebra (Papadopoulos 2022, p. 15). Papadopoulos also commented on Atiyah's view under discussion (Papadopoulos 2022, p. 15).

Bourbaki), which governs McLarty's analysis, in part via (Corry 2006), referred to throughout his article. As noted above, the present emphasis does not invalidate this perspective on "modern algebra," for which Noether was one of the founding figures, or the role of structures elsewhere. They are important. Morphisms, central to Noether's (re)algebraization of modern algebra, require structures, as do functors, which are maps between categories as (higher-level) structures. Nevertheless, the present view shifts a perspective, including in Noether's case. Morphisms and functors are concepts first. The same considerations would apply to Grothendieck, who appears to be seen by McLarty along structuralist lines in this article and on several other occasions (McLarty 2006, p. 218, n. 14; 2018). McLarty's analysis of Noether could be easily accommodated by the present view. He summarized his argument as follows:

> The time is important because Noether was just then developing what she called her set-theoretic foundations for algebra. This was not what we now call set theory. It was not the idea of using sets in basic definitions and reasoning. She took that more or less for granted, as did other Göttingers by the 1920s. Rather, her project was to get abstract algebra away from thinking about operations on elements, such as addition or multiplication of elements in groups or rings. Her algebra would describe structures in terms of selected subsets (such as normal subgroups of groups) and homomorphisms. Alexandro[v] applied her tools to Brouwer's use of continuous maps—though Vietoris was the first to make it work.
>
> Noether brought something much deeper and more comprehensive to topology than just the use of homology groups. The next section (and a more technical appendix) will show that groups were familiar in homology before her. She brought an entire programme of looking at groups, and other structures in algebra, and other structures outside of algebra like topological spaces, in terms of the homomorphisms between them. She called this 'set-theoretic foundations.' (McLarty 2006, p. 212)

Noether's "chief tools for making this work," McLarty adds, are "her homomorphism and isomorphism theorems" (McLarty 2006, p. 212). In other words, abstract algebra is now the algebra of morphisms, which is "Noether's principle," as Krull called it. As McLarty says, citing Krull:

> Noether used the homomorphism theorems to prove isomorphism theorems, which show that certain relations among subsets imply that certain morphisms are isomorphisms. These and other ideas served Noether's well-known goal, in Krull's terms:
>
> > Noether's principle: base all of algebra so far as possible on consideration of isomorphisms. (Krull 1935, p. 4)
>
> Van der Waerden captured the method exactly: To understand ring ideals is to understand their analogy with normal subgroups, for which 'we proceed from the concept of homomorphism!' (van der Waerden 1930, p. 55). (McLarty 2006, p. 218)

It is worth noting that van der Waerden, who, as noted, invoked concepts in reflecting on Noether's work, speaks here of the *concept* of a homomorphism, which, or that of a morphism, is a concept-form in the present definition, and is seen as such by Noether, or along with the concept-form of a functor, functorially by

Grothendieck. This point does not affect McLarty's argument as such, because Noether's use of homomorphism implied that abstract algebraic concepts such as a group, field, ring, or module, in fact, function as concepts-forms, without, in the present view, implying the Platonist view of these concepts (even if Noether had such a view, which is unclear). McLarty concludes:

> Noether emphasized homomorphisms, and her influence on homology forced topologists and algebraists to bring their methods together. So algebra shifted to an ever-greater focus on homomorphisms. All this algebra looked too abstract to a tough-minded geometer like Solomon Lefschetz. In the 1920s, he made tremendous but obscure progress applying homology in algebraic geometry. It was a major source of his reputation for never stating a false theorem or giving a correct proof. Realizing that his arguments needed serious improvement, he went to work on the homology of topological spaces. His first book on it says:
>
> > The connection with the theory of abstract groups is clear. . .. Indeed everything that follows in this section can be, and frequently is, translated in terms of the theory of groups. It is of course a mere question of a different terminology. (Lefschetz 1930, p. 29)
>
> But Poincaré had said, in promoting analysis situs, that we must not "fail to recognize the importance of well-constructed language" (Poincaré 1908, p. 180). Whether or not Lefschetz noticed this passage, he shared the thought.
>
> Soon his topology was heavily algebraic (Lefschetz 1942). He kicked off the spate of articles on what became category theory when he asked for an appendix by Eilenberg and Mac Lane (1942). This became the standard foundation for algebraic topology and for the huge proliferation of cohomology theories in the 1950s and since. The unprecedentedly vast machinery gave unprecedented power in solving concrete problems from topology to abstract algebra to number theory. Lefschetz wrote:
>
> > As first pointed out by Emmy Noether, the proper and only adequate formulation of the relation between chains, cycles, . . . requires group theory. (Lefschetz 1949, p. 11, Lefschetz's ellipsis)
>
> In fact, it required Noether's formulation of group theory [in terms of morphisms], and that soon required functors. (McLarty 2006, p. 230).

It is difficult to say how close Noether came to functoriality, and McLarty does not appear to claim that she ever reached this concept. The concept, concept-form, of a functor is the next step, which is, however, far from obvious and was only, and could have only been, created as part of category theory. It then became one of Grothendieck's key concepts, which, while not invented by him, was made by him his own, as I shall discuss in the next section. One might say that in Noether's remarkable approach to algebra, or algebraic topology, there may already have been, if implicitly, categories, those of groups, rings, or modules, even if there were no functors between categories. In Grothendieck, by contrast, functoriality becomes dominant, as one of the most important concept-forms of his mathematics, as both (initially) a minority mathematics and (eventually) a major mathematics, a mathematics that became central to the advancement of mathematical thought in algebraic geometry and beyond.

4 Topos Theory and Grothendieck's Parliamentary Mathematical Ontology

Grothendieck's work on algebraic varieties over a finite field, ultimately allowing one to study them by the tools of algebraic topology, is among the greatest achievements of the twentieth-century *major mathematics* and a remarkable case of a *minority mathematics*, thus also a manifested example of the essential connections between major and minority mathematics, emphasized throughout this chapter. The project of extending these tools to finite fields was initiated by André Weil, a key figure in bringing together algebraic geometry and number theory, in which he was an heir of Fermat (and probably saw himself as one), as well as of Kronecker (in this case, Weil did see himself as one). Arguably, Weil was less of a practitioner of a minority mathematics, except to the degree the latter is always involved in a creation of new mathematics, and Weil has created plenty of it. The project has a complex history, including the development, beyond algebraic geometry itself, of algebraic and differential topology, group theory, elliptic functions, and other fields, in which Weil did important work, eventually leading him to his work on algebraic geometry, culminating in his 1946 *Foundations of Algebraic Geometry*, with the second edition published in 1962 (Weil 1962). The book is distinguished by many important technical contributions, which would be difficult and, for the present purposes, not necessary to discuss here. Eventually (in 1949), Weil suggested that a cohomology theory for algebraic varieties over finite fields, now known as Weil cohomologies, could be developed by analogy with the corresponding theories for complex algebraic varieties or topological manifolds (considered in algebraic topology) in general. Weil's motivation was a set of conjectures (going back to Gauss, they were stated for algebraic curves by Emil Artin in 1924, and hence are part of the history of the major mathematics in this field), known since as the Weil conjectures. They concern the so-called local ζ-functions, which are the generating functions derived from counting numbers of points on algebraic varieties over finite fields. These conjectures, Weil thought, could be attacked by means of a proper cohomology theory, although he did not propose such a theory itself. The idea, stated somewhat vaguely in the first place, was initially met with much skepticism. Obstacles were formidable, and the way of overcoming them advanced by Grothendieck was remarkable, almost miraculous. This way is, however, less of a miracle if viewed from within Grothendieck's mathematical thinking and practice, as minority ones, in several respects unique to him. In this regard, his thinking was similar to that of Abel and Galois, both among earlier predecessors of Grothendieck's work.

As far as Weil's work is concerned, my focus, defined by the differences between Weil and Grothendieck's philosophy of algebraic geometry, is Weil's concept of a "universal domain," assumed by him to be necessary, versus Grothendieck's multiple ontologies of topos theory. As against previous approaches to algebraic geometry, that of Weil required, in addition to the base field of definition of the objects (algebraic varieties) considered, an assumption of an (algebraically closed) "universal domain" encompassing all fields that may appear in any constructions made over the base field. The Platonist implications of this claim are tempered by his view that

such a domain need not be unique. Weil argued that the theorems of algebraic geometry will remain the same regardless of the choice of this domain if it has an infinite transcendence degree and is closed. Grothendieck abolished the idea of a universal domain on his way to solving a problem of Weil's cohomologies posed by Weil, by creating a remarkable array of concept-forms, eventually leading to several concept-forms, such as a topos, that allow one to define Weil's cohomologies. These concept-forms gave Grothendieck's work a unique place in algebraic geometry and beyond. Grothendieck's definition of "Weil's cohomologies," or more accurately Grothendieck's cohomologies that accomplished the task in question, was a result of his, in its key aspects, minority mathematical practice, even when adopting major concepts of major mathematics of his time. This practice and the ways of thinking grounding it were initiated in his earlier work in functional analysis, his original field of research, although developed, as more directly connected to algebraic geometry, in his work on cohomological algebra and Teichmüller theory.[14]

A remarkable manifestation of this thinking in algebraic geometry was his invention of the concept of scheme, a radically innovative concept, a concept-form, even though it was *almost* a natural extension of by then the standard view of algebraic varieties. Nobody, however, thought about it at the time, which fact made it a minority concept. This type of event (which is not uncommon in creative mathematics and science) also requires a rethinking of the idea of "natural," the naturalness of the natural. Grothendieck's key idea was replacing maximal ideals with prime ideals of a ring, a *natural*, Noetherian, move in commutative algebra, by then an established major field. It is, however, a different matter, when one connects it to algebraic varieties, replacing the latter by schemes, thus introducing a new form of multiplicity insofar as the same algebraic variety can arise from different schemes. It also allows one, which may be seen as another post-Noetherian move, to define algebraic varieties over any commutative rings, such as integers. In its ultimate formality (favored by Grothendieck), a scheme is a topological space with commutative rings associated to all of its open sets, by gluing together spectra (defined as spaces of prime ideals) of commutative rings along their open subsets. Thus, a scheme is locally a spectrum of a commutative ring. This also leads to a relational view, according to which algebraic geometry should be developed for a morphism $X \to Y$ of schemes (designated as a scheme *X over Y*), rather than for an individual scheme. In some cases, the family of all varieties of a given type can itself be viewed as a variety or scheme, a moduli space. The approach led to an enormous amount of new mathematics, much of which quickly became major mathematics, although not majority mathematics. As is, again, always the case, these concepts, even apart from their interconnections, have their history (as do some of these interconnections, while others are new), for example, in Noether's work or in more immediately

[14] The genealogy of his work on Teichmüller space originates in Riemann's moduli problem, recast by Grothendieck in his framework. The theory provided an important example of Grothendieck's use of functoriality, a major concept by then, but given a new life by his minority use of it. For the discussion of this work, see A'Campo et al. (2016).

preceding works in algebraic geometry by Jean-Pierre Serre. A subtler earlier link is the Stone representation theorem, which states that every Boolean algebra is isomorphic to a certain field of sets. The theorem emerged from the *spectral* theory of operators in a Hilbert space, a subject close to Grothendieck's early work in functional analysis.

The concept of topos was introduced nearly simultaneously with that of scheme, by relating the history of algebraic geometry just sketched to the history of algebraic topology and adopting the method of the latter in algebraic geometry over the finite field. This (unlike their automatic application to algebraic manifolds over $\mathbb{C}$) proved to be impossible to do merely by shifting from varieties to schemes. To be able to do so, one needed a proper topology, which was nontrivial because the objects in question are topologically discrete. A "native" topology that could be defined by them, known as Zariski's topology, did not work, because it had too few open sets, even if one uses schemes instead of varieties. The decisive insights came from Grothendieck, helped by sheaf-cohomology theory and category theory, "cohomological algebra," by then the standard tool of algebraic topology, and as such part of major mathematics, already transformed by Grothendieck previously, on which I shall comment below. Using these tools, a hallmark of Grothendieck's thinking throughout his career, and his previous concepts, such as that of "scheme," led him to topos theory and étale cohomology as a viable candidate for Weil's cohomology, which it had quickly proven to be. As Grothendieck said: "The two crucial driving ideas [*idées forces*] in launching and developing the new geometry were that of scheme, and that of topos. Appearing almost at the same time and in close symbiosis with each other, they were as if a single sinew in the spectacular flight of the new geometry, and this from the very year they appeared" (Grothendieck 2022, p. 50, cited in McLarty 2018, p. 109; McLarty's translation). Soon thereafter, he introduced a more general concept of motivic cohomology, a kind of ultimate cohomological concept-form. By using étale cohomology, Grothendieck (with Michael Artin and Jean-Louis Verdier) and Pierre Deligne (Grothendieck's student) were able to prove Weil's conjectures, a bit later generalized by Deligne.

Grothendieck's key insight was to generalize, in terms of category theory, the concept of "open set," beyond a subset of an algebraic variety. This was possible because the concept of sheaf and of cohomology of sheaves could be defined for any category, rather than only that of open sets of a given space. Étale cohomology is this type of replacement, specifically by using the category of étale mappings of an algebraic variety or a scheme, which become "open subsets" of the finite unbranched covering spaces of the variety, a vast generalization of Riemann's concept of a covering space. Grothendieck was in part building on ideas of Serre. The origin of this generalization was in the fact that the fundamental group of a topological space, for example, and (in the present context) in particular, a Riemann surface, could be defined in two ways. First, it can be defined, more geometrically but still by means of algebra, as a group of equivalence classes of sets of loops at a given point, with the equivalence relation given by homotopy. Alternatively, a fundamental group can be defined even more algebraically, as a group of transformations of covering spaces over the topological space considered. In this second definition, it is analogous to the

Galois group of the algebraic closure of a field, as Serre was first to consider for finite fields, which prepared grounds for Grothendieck's work on étale cohomology. The idea has, thus, both Galois' and Riemann's concepts as important parts of its genealogy. The connection had been established in the case of Riemann surfaces long before Serre's work, and found, for example, in Weyl's 1913 book on a Riemann surface, undoubtedly known to Serre:

> The group of cover transformations, regarded as an abstract group, expresses purely and completely everything in the relation between the normal covering surface $\overline{\mathcal{F}}$ and the base surface $\mathcal{F}$ which has the character of analysis situs [topology]. This group is also called the *Galois group* of $\overline{\mathcal{F}}$. It is in fact the analog of the Galois group of a normal algebraic field (of finite degree) over a base field. (Weyl 2013, p. 58)

Étale mappings give a sufficient number of open sets to define adequate cohomolgy groups for some coefficients for algebraic varieties over finite fields. In the case of complex varieties, one recovers the standard cohomology groups with coefficients in any constructible sheaf. The category of étale mappings is a topos, a concept that is, for now, the most abstract algebraic form of spatiality in mathematics. It was seen as such by Grothendieck himself, who compared his contribution to the idea of space in mathematics to that of Einstein in general relativity in physics and that of Erwin Schrödinger in quantum mechanics (Grothendieck 2022, p. 68).[15] Étale cohomologies could be defined for most practical uses in simpler settings, without using the concept of topos. The concept of topos has, however, never lost its importance. It also came to play a major role in mathematical logic. The subject cannot be addressed here, apart from noting that mathematical logic is the culminating development of the trajectory, initiated by Georg Cantor's work, with radical epistemological implications, concerning the nature of mathematical reality, to which the concept of topos, as a *logical* concept, may be connected (e.g., Plotnitsky 2022, pp. 82–95). By contrast, Grothendieck's use of his topoi in algebraic geometry is

[15] A reference to quantum mechanics may appear strange, but it is astute. In quantum mechanics, one deals with Hilbert spaces over $\mathbb{C}$, in the case considered by Schrödinger in his discovery of the theory, infinite-dimensional ones, using which enables one to predict the probabilities of quantum events. (Adding the so-called Born's rule, which is, essentially, a form of complex conjugation, to this formalism over $\mathbb{C}$ allows one to move to probabilities, which are real numbers.) The astuteness of Grothendieck's reference comes from the fact that quantum mechanics establishes an entirely new relationship between a purely mathematical space, here Hilbert spaces over $\mathbb{C}$, and the actual (three-dimensional) physical space, mathematically represented as a real manifold, as considered in detail in (Plotnitsky 2021). Technically, it was Werner Heisenberg (not mentioned by Grothendieck) who defined this situation as such in his discovery of quantum mechanics a few months before Schrödinger (who discovered it independently in a different but mathematically equivalent form). Ironically, Schrödinger became discontented with and repudiated quantum mechanics on the account of its epistemological features defined by the situation just described, in particular the role of complex numbers and the probabilistic nature of the theory. He came to see quantum mechanics, as did Einstein, as merely a convenient method of calculations rather than as a proper fundamental theory of the ultimate constitution of nature (Plotnitsky 2021, pp. 145–166). I am not sure whether Grothendieck was aware of this attitude on the part of Schrödinger and Einstein.

essentially ontological rather than logical. His overall position concerning the nature of mathematical reality remains somewhat unclear, for example, as concerns whether it conforms or not to mathematical Platonism. On the other hand, as discussed below, the mathematical architecture of Grothendieck's algebraic geometry, as different from that of Weil's algebraic geometry, as defined by a universal domain, may, even if against Grothendieck's own grain, lead to questioning all known forms of Platonism.

To better see why this is the case, I shall offer brief informal remarks on category and topos theory, in connection (direct in the case of topos theory) with Grothendieck's thinking. First, consider the following way of endowing a space with a structure, generalizing the definition of topological space in terms of open subsets. One begins with an arbitrarily chosen space, X, which may initially be left unspecified in terms of its properties and structure. What would be specified instead are the relationships between spaces, which are applicable to X, such as mapping or covering one or a portion of one by another. This structure is the arrow structure $Y \rightarrow X$ of category theory, where X is the space under consideration and the arrow designates the relationship(s) in question. One can also generalize the notion of neighborhood or of an open subspace of (the topology of) a topological space in this way, by defining it as a relation between a given point and space (a generalized neighborhood or open subspace) associated with it. This enables one to specify a given space not in terms of its intrinsic structure (e.g., a set of points with relations among them) but "sociologically," throughout its relationships with other spaces of the same category, say, that of algebraic varieties or schemes over a finite field of characteristic *p* (Manin 2002, p. 7). Some among such spaces may play a special role in defining the initial space, X, and algebraic structures, such as homotopy and cohomology, as Riemann realized in the case of covering spaces over Riemann surfaces. (Proper homotopy and cohomology theories were developed later.) Riemann's idea of a covering space was, as noted, one of the inspirations for Grothendieck's concept of étale topos.

To make this description more grounded, I shall briefly, and again, informally, sketch the key ideas of category theory. It was introduced as part of cohomology theory in algebraic topology in 1940 and extensively used by Grothendieck in his approach to cohomological algebra and algebraic geometry. Category theory considers multiplicities (which need not be sets) of mathematical objects conforming to a given concept, such as the category of differentiable manifolds or that of algebraic varieties, and the arrows or morphisms, the mappings between these objects that preserve this structure. Studying morphisms allows one to learn about the individual objects involved, often to learn more than we would by considering them only or primarily individually. As discussed earlier, a shift toward studying morphisms, even if not categories, was one of the key new features of Noether's work in both algebra and topology. In a certain sense, in his Habilitation lecture (Riemann 1854), Riemann already thinks in terms of morphisms and even categories (although he did not of course have either concept) because he does not start with a Euclidean space. Instead, the latter is just one specifiable object of a large protocategorical

multiplicity, that of differentiable or, more narrowly, Riemannian manifolds, defined by a particularly simple way we can measure the distance between points.

Categories themselves may be viewed as objects defined by the relationships between them, and in this case one speaks of "functors" between categories rather than "morphisms" between objects in a given category. Functoriality is a crucial aspect of category theory and, as emphasized here, of Grothendieck's work. Grothendieck did not invent the concept of functor, but he made it his own and used it with great effectiveness in his work, including in his invention of new concepts, often, as in the case of his cohomological and homotopical concepts, defined by functoriality, as are, however, cohomology theories in general. Topology relates topological or geometrical objects, such as manifolds, to algebraic ones, such as homotopy and cohomology groups. Thus, in contrast to geometry (which relates its spaces to algebraic aspects of measurement), topology, by its very nature, in effect deals with functors between categories of topological objects, such as manifolds, and categories of algebraic objects, such as groups, rather than only with morphisms, which of course remain essential. There are no functors without morphisms, while morphisms do not require functors. Functors, however, give morphisms their categorical meaning and, as a result, a deeper and more fundamental mathematical meaning and significance.

With Grothendieck, mathematical practice becomes that of functoriality: It no longer primarily deals with objects but categories of objects. Although, arguably, less of a minority thinking insofar as it had a tradition by then, it was still highly transformative vis-à-vis previous uses of functoriality, and much of it was new and hence a minority mathematics. Grothendieck's use of it, as a concept-form, led him to numerous conceptual innovations, beginning with those in *Sur quelques points d'algèbre homologique*, a long article, now known as the "Tohôku paper" (Grothendieck 1957). The article, as part of its minority and, thus, Abelian mathematics, also introduced abelian categories, an important new concept, and used this concept to show that sheaf cohomology can be defined as certain derivative functors in this setting. The name "abelian category" merits a brief comment in the context of this chapter. The concept was independently introduced earlier (in 1955), by David Buchsbaum, under the name of "exact categories." Grothendieck's well-known penchant for selecting his mathematical names with both flair and precision (schemes, étale mapping, and motives, among them) also served him here, even apart from the present context, in which the name carries additional resonances linked to the idea of a minority mathematics. It is unlikely, although not inconceivable, that Grothendieck also had in mind Abel's thinking in defining modern mathematics, as an example of Abelian mathematics in the present sense of a minority mathematics. The origin of the name had most likely to do with the fact that a prototypical example was the category of abelian (commutative) groups. Grothendieck gave an axiomatic definition, which is secondary for the moment. An abelian category is a category in which objects and morphisms can be added and in which kernels and cokernels exist (and possess certain useful properties). Their significance in Grothendieck's works and elsewhere in algebraic geometry, cohomology theories, or category theory, as such, has to do with their strong stability

aspects, such as the fact that the category of chain complexes or the category of functors from a (small) category to an abelian category are abelian. Among the examples of abelian categories is that of finitely generated left modules over a left-noetherian ring, which implies that the category of finitely generated modules over a noetherian commutative ring is abelian. This is one of several junctures in which Noether's work in commutative algebra enters the history leading to Grothendieck's work, as part of the sequence considered here from Abel to Galois to Noether to Grothendieck. There are, again, many other proper names in between and beyond (or before) this history, some of which, but only a small sample, were mentioned here in this chapter. As already in his earlier work in functional analysis (where he introduced several new concepts, such as topological vector spaces), but more significantly in the present context, *Sur quelques points* confirmed the essential role of inventing new concepts, in particular new concept-forms, in creative mathematics. So did Grothendieck's subsequent work, defined by a massive proliferation of new concepts and concept-forms. Even those (a large number as well) of such concepts and concept-forms that are contained in thousands of pages of his unpublished works, kind of reinstating his work as minor mathematics, had major impacts during the last half of a century and continue to do so. Those of scheme and topos, however, remain arguably the greatest examples, again, seen as such by Grothendieck himself.

A topos in Grothendieck's sense is a category of spaces and arrows over a given space, used for the purpose of allowing one to define richer algebraic structures associated with this space, as explained above. There are additional conditions such categories must satisfy, but this is not essential at the moment. As a simple example, for any topological space S, the category of sheaves on S is a topos. The concept of topos extends far beyond spatial mathematical objects (thus, the category of finite sets is a topos); it replaces the latter with a more algebraic structure of categorical and topos-theoretical relationships between objects. On the other hand, it derives from the properties of and (arrow-like) categorical relationships between properly topological objects. The conditions, just mentioned, that categories forming topoi must satisfy have to do with these connections.

One might think of this ontology as an assembly, a "parliament," of ontologies (Grothendieck's concept of topos is, again, ontological, rather than logical, as is the concept of topos in mathematical logic), in the absence of any ultimate ontology, or even, as against physics, any ultimate mathematical or otherwise mental reality, as explained in Plotnitsky (2022, pp. 82–95). As against Weil's universal domain of algebraic geometry, topos theory enables a new mathematical ontology by allowing for different (mathematical) universes associated with a given space, possibly a single-point one. Grothendieck's topoi are possible worlds, or compossible worlds in Leibniz's sense, without assuming, as Leibniz did (in dealing with the actual world), the existence of only one of them, the best possible one. Hence, I refer to this ontology as a parliamentary assembly of possible ontologies, in the absence of any encompassing ontology, implied by the idea of a universal domain, assumed in Weil's "imperial" vision of algebraic geometry. According to David Reed's summary:

> Grothendieck's constructions [beginning with schemes replacing the varieties of Weil] are far from the 'palaces' which Weil suggests belong to algebraic geometers by birthright. Rather than refurbishing and renewing the old constructions he has instead created an entirely new type of architecture and in the process is forced to make extensive use of the 'makeshift algebraic constructions' Weil carefully thought to avoid placing reliance upon. Both Weil and Grothendieck seek generality in order to be able to analyze rigorously geometric situations to which the older algebraic geometers paid little attention. This generality permits consideration of 'degenerate' cases, objects with singularities, 'non-reduced' objects and the like. Whereas Weil sought this generality through a large 'domain' in which the result of his constructions could be contained, Grothendieck seeks generality by expanding the category of objects under considerations until a certain 'self-sufficiency' is acquired, i.e. until a natural reflexivity can be found so that the objects in the category can be related to each other and operations on them can be undertaken without going outside the original category. Furthermore, the objects do not require a predetermined 'fixed point' outside of the category for their specification. ... This relativity also extends to the set theoretical foundations of the theory. Grothendieck introduces a set theoretic 'universe' which provides the sets used in his constructions and then studies those properties which remain invariant under a change of universe! (Reed 1995, pp. 131, 177n.36)

In question, then, are two very different (mathematical) ontological philosophies – that of unification or encompassment and that of multiplicity, which is *relational* but has no single encompassing domain. In other words, this multiplicity is a multiplicity without unity, "the multiple without One," as Alain Badiou would have it (Badiou 2006). This multiplicity was made possible in part by functoriality as a key part of Grothendieck's mathematical practice, initially a minority mathematical practice. It is true that Grothendieck often speaks of "unity" (also associated with "simplicity") as more profound than "generality" (e.g., Grothendieck 2022, p. 47; McLarty 2018, p. 124).[16] This unity, however, appears to me more as a unity of his vision, although I cannot exclude that Grothendieck might have envisioned an ontology (different from that of Weil) unifying his multiple universes. I am, however, more concerned here with a philosophical view that Grothendieck's mathematics may support, even if against his own grain.

From this perspective, Grothendieck's generality or, better (Reed is right to switch to this term), *relativity* of construction, a crucial aspect of his functorial thinking, is a mathematical instantiation or model of the capacity of mathematics as a human endeavor. This model is that of the creation of mathematical realities (as mental ontologies, of which Grothendieck's topoi are examples), on the basis of, while creatively transforming, previously established realities, in the absence of an ultimate underlying or encompassing Platonist reality. It is a creation of mathematical worlds (plural!) from the materials of human thought, by endowing them with logically rigorous conceptual structures, the novelty of which is especially striking and prolific in Grothendieck.

[16] McLarty's article as well as his (McLarty 2016) offers an informative account of these concepts in Grothendieck, although neither article addresses the question of the multiple, or the implications of Grothendieck's conceptions of mathematical multiplicities for the question of reality and realism in mathematics, considered, also in connection with Grothendieck's thinking, in Plotnitsky (2022).

Topoi are conceptual multiplicities by virtue of bringing together the concept of algebraic geometry and algebraic topology, a strategy that, while already in place in general, was, ironically, motivated by Weil's cohomological ideas in the case of étale cohomology. One needed to get rid of the concept of a universal domain, but one also needed, in order to do so in the first place but also to be able to work in multiple domains, new concept-forms. The creation of such concept-forms was, again, prolific in Grothendieck's mathematical practice, the grounding principle of which was functoriality, just as the grounding principle of Noether's mathematical practice, Noether's principle, was defined by the mathematics of morphisms between sets with structures (rather than only the structures of sets). It might be added that functoriality was not found in Weil either. *Foundations of algebraic geometry* (still following Noether's approach focusing on morphism vs. functors) mentions categories and functors once, somewhat condescendingly and that in 1962 (obviously aware of Grothendieck's breakthroughs by using categories and functors): "Any reader interested in expressing these facts [concerning morphisms of algebraic varieties over topological fields] in the language of categories and functors will presumably be able to do so" (Weil 1962, p. 358). There is, however, no Weil cohomologies without functoriality, implicit in any cohomology theory, as Weil must have been aware. As noted, Weil cohomologies can be defined in simpler settings. However, they were *invented* through functoriality, a key tool of Grothendieck's mathematical practice helping many of his conceptual inventions. The concept of functor itself was not one of them, but, as I said, Grothendieck made it his own by his innovative use of it throughout his work.

Grothendieck's philosophy of *mathematical practice*, and perhaps his *philosophy* of mathematics, especially as manifested in the relativity of topos theory, may be seen as mirroring the ultimate task of mathematics, that of creating new mathematical worlds. The multiple ontologies of Grothendieck's topos theory may be seen as all having their possible voices in the parliament of topos theory, and a similar view can be taken concerning mathematics in general, making it a parliament of various mathematics. These voices, again, can only be given to them by us, by our mathematical thought, individual or collective (Plotnitsky 2022, pp. 82–95).[17]

[17] As I argue on the same occasion, an analogous multiplicity is also a consequence of Gödel's undecidability, as exemplified by Cantor's continuum hypothesis. This hypothesis was crucial not only for the question of continuity but also for the question of Cantor's hierarchical order of infinities (the infinity of which was one of his discoveries, in, it might be added, his own minority mathematics at the time) and thus for the whole edifice of Cantor's set theory. The hypothesis was proven undecidable by Cohen in 1961, with Gödel contributing a crucial part earlier. It follows, however, that one can extend classical arithmetic in two ways by considering Cantor's hypothesis as either true or false, that is, by assuming either that there is no such intermediate infinity or that there is. This allows one, by decisions of thought, to extend arithmetic into mutually incompatible systems, ultimately infinitely many such systems, because each of them will contain at least one undecidable proposition. Gödel's incompleteness theorems may not be a necessary condition of the multiplicity of possible mathematics, as Grothendieck's ontological relativity suggests. The existence of Cantorian and non-Cantorian set theories, or the existence of Euclidean and the various

Grothendieck's relativistic ontological architecture "formally" captures or provides a model for the architecture of the mathematical practice as allowing the space for alternatives to a dominant major mathematics. It is not only a *metaphorical* model because this type of mathematical practice can be enacted within an architecture of the type defined by Grothendieck. In this chapter, this practice is expressly considered not merely as some alternative mathematics but as a minority mathematics defined as operative inside and transforming what is the established major mathematics at the time. I further argue that a major mathematics cannot be transformed otherwise, however hidden or implicit a minority practice may be in these transformations. This transformational dynamic is not contained by a model strictly based on Grothendieck's relativistic architecture but instead underlies this architecture as a more general conception. His own mathematics, including that defining the ontological multiplicity in question, was a minority mathematics aimed to affect and transform an important and very rich part of the major mathematics of his time. As he realized, he was not always successful in this aim at the time when some of his new concepts were introduced (especially after he left *Institut des Haute Études Scientifiques*, where his role was akin to that of Hilbert in Göttingen in the early twentieth century) although some of his, initially marginal, ideas became more widespread subsequently. The view of a minority mathematics as something inside a major mathematics, rather than outside it, also helps to explain why Grothendieck continued to reflect on the nature of the major mathematics of his time, especially in the fields related to his work but, at least by implication, in general. Our major mathematics, he thought, did not pay enough attention to foundational issues, did not ask the right foundational questions, as Abel would have it.[18]

non-Euclidean geometries established earlier, does not depend on these theorems. Gödel's theorems, however, imply the inevitability of such a multiplicity in principle, on mathematical grounds, whether one pursues such alternatives or not, in the way say mathematics has pursued both Euclidean and non-Euclidean geometry. In this case, however, one could still unify them with the same broader framework, say, as defined, following Riemann, by the concept of manifold. In the case of undecidable propositions, the only thing that these alternative forms of mathematics share is the fact they are forms of mathematics, which are, however, incompatible with each other. The role of a decision of thought, in general important for my argument here, especially in the case of Gödel's theorems, is a key aspect of this situation. Allowing one, by such a decision and a freedom, even if relative, of making it, to extend arithmetic or any system containing it into two mutually incompatible systems, and (by iteration) to infinitely many such systems, has been seen as a troubling and even intolerable situation for some. One might, however, also find an appeal in it, as the present author or Badiou does (Badiou 2006, p. 99).

[18] His long later manuscripts, such as, famously, *Pursuing Stacks,* a long letter to Daniel Quillen (Grothendieck 1983) may be seen along these lines. (Quillen's work, inspired by that of Grothendieck, is another example of a creation of new category- and functoriality-based concept-forms). On the other hand, Grothendieck's return to Montpellier university, his alma matter, after he left Paris, might be seen as (or at least conjectured to be) aimed to reinstate his position as a minority mathematician and to affirm a minority mathematics, as a revolutionary condition of all creative mathematics and hence mathematics itself, as I argue here. An enormous amount of new mathematics, including new concept-forms, was created by him in his post-Paris years.

5 Conclusion

"Mathematics is *a thought*," Badiou says (Badiou 2006, p. 43). I give this statement a meaning beyond Badiou's own, correctly juxtaposing mathematics to merely a rigorous and refined form of logic, which is necessary but not sufficient for mathematics. While I fully agree with this view, I use this statement more in accord with Deleuze and Guattari's view of *thought* in *What is Philosophy?* as creative thinking (rather than merely referring to our mental states), specifically in art, philosophy, and mathematics and science (Deleuze and Guattari 1996, pp. 202–281). As I argue here, however, in accord with their view of creative thought as a minority thought, as exemplified by Kafka's literary thought, all creative thought depends on the possibility, and freedom, of pursuing a minority thinking, sometimes against odds. It was not easy for Kafka or Abel and Galois to have this freedom, but they had the capacity and boldness to be free and create new literature and new mathematics. Any instance of creative thinking is, in the present view, an instance of a minority thinking, and only a minority thinking is creative. If there is no minority thinking (however relative in its scope), there is no creative thought and, hence, no creative literature or mathematics, which still needs to be created, *made* by us.

I have argued here that the creative, or *poetical*, essence of creative thought and hence a minority thought in mathematics is composition, in the sense of the ancient Greek *poeien* as making, just as it is for poetry or all creative endeavors, respecting their specificity as such; I have also argued here that the *political* essence of creative or minority thought in mathematics or elsewhere is freedom. In this sense, a minority mathematics and hence all mathematics are political: It requires the politics of freedom, manifested in the possibility of a minority mathematics. Hence, the essence of mathematics is ultimately the power of compositions, conceptual or other and the freedom to create them, not rules, logical or other, necessary as such rules are for mathematics as a human endeavor and a disciplinary field. In spite, however, and sometimes because of its logical and other constraints, mathematics gives human thought an extraordinary freedom. Mathematics is a combination of an extraordinary precision or exactitude and an extraordinary freedom. I would be tempted to say the ultimate precision or exactitude, if not the ultimate freedom, except that as creative thinking, science, philosophy, and literature and art have their own ways of precision and exactitude, and all creative thought is a manifestation of freedom, again, always the freedom of minority thought.

This freedom is, as I argued, not merely a free choice in our decision in pursuing our projects, including as a minority mathematics, because, as in all human decisions, such decisions may involve factors that shape and complicate our choices, including as concerns their freedom. A choice, at least a free choice, is difficult, if ever entirely possible as free, even in a democracy, mathematical or other. This fact, as I explained, makes decision a better category. As I also argued, however, this does not mean there is no freedom in our decisions. At stake, politically, is creating the *possibility* for freedom in our endeavors, for pursuing a minority thinking, the necessary condition of creative thinking. No creative thought or justice anywhere is possible otherwise. It is this *possibility* of freedom that is the political essence of a

minority mathematics and hence of mathematics itself, which cannot advance by creating new mathematics and thus remain alive without a minority thinking and a freedom to pursue it.

Abstract

This is an overview of the life and works of Pavel Florensky, an important and singular figure of the period rightly described as the *Silver Age of Russian mathematics*, with a substantial overlap with the *Silver Age of Russian literature, poetry and philosophy*. Florensky is certainly among the great philosophers-theologians of the twentieth century, with a very atypical trajectory of life. His

work in philosophy is imbued with mathematical ideas. Talking about his life and works is also an opportunity to reflect upon the Russian mathematical school of the first third of the twentieth century, its philosophical foundations, and the conflicts it underwent. It is also an occasion for discussing poetry, literature, and art during the Russian Silver Age.

1 Introduction

Pavel Aleksandrovich Florensky (1882–1937) is a complex and singular figure in the landscape of twentieth century culture. His complete works contain more than 1000 items (see Florensky 2012, Note p. 7). In the last three decades, his books and manuscripts have been continuously edited and published in several languages and the literature on him has been growing at an exponential rate. Symposia on his case are regularly organized in Europe and elsewhere in the world, and a number of doctoral dissertations on his work have been written. Biographers and people who knew him dubbed him the Russian Leonardo,[1] and others called him the Russian Pascal,[2] sometimes the Gulag Pascal. Cédric Villani, in the preface to his book (Florensky 2016), describes him as "one of the most original thinkers of his times." Florensky is invariably presented as a mathematician, physicist, chemist, botanist, theologian, engineer, philosopher, art historian, specialist in electrodynamics, marine botany, linguistics, languages, symbol, esoterism, gnoseology, logic, esthetics, semiotics, and other fields of knowledge. Strictly speaking, I am not sure he may be called a mathematician, since I do not know of any mathematical discovery he made, and I cannot really judge about most of the other fields I mentioned. But without any doubt, his writings and thought encompass all these fields, and mathematics is always present there as a background. His highly unusual versatility led Nikolai

[1] In (Lossky 1952, p. 178), the philosopher Nikolai Onufriyevich Lossky (1870–1965) quotes an article by B. Filistinsky titled *A Russian Leonardo da Vinci in a concentration camp*, in which the latter says about Florensky: "A new Leonardo da Vinci was standing before us and we all were conscious of it."

[2] See Vassili Rozanov (Rozanov 1984, p. 413).

Lossky to describe him as possessing "inhuman erudition" (Lossky 1926). Perhaps this is where his strength and originality lie. When I started writing this chapter, my intention was to concentrate on Florensky's mathematical inclination, since the chapter is addressed primarily to mathematicians. But I soon realized that it is impossible to isolate the mathematical dimension of his thought from the rest of his works and vision of life. Florensky certainly had a mathematician's liking in his view of the world; it is this view, and some reflections that go with it, that I would like to outline.

Speaking of Florensky, I cannot avoid to begin by saying a few words about his life, and that is what I shall do in the next section.

2 Vita

Pavel Aleksandrovich Florensky was born on January 22 (Old Style: January 9), 1882, deep in the steppe, near the town of Yevlakh, today in Azerbaijan, to an Armenian mother, Salomé Saparian, from an aristocratic family, and a Russian father, Aleksander Ivanovich Florensky, who was working as an engineer in the construction of the Caucasus railroads. Azerbaijan was part of the Russian Empire, and Aleksander Florensky was in charge of the railway section that passed through Yevlakh. Pavel was born before the city's railroad station was built, and the family lived in freight cars "dressed in oriental carpets," he recalls.[3] Thus, it is possible that it is in a train carriage that Pavel was born. His childhood was spent in Tbilissi, then in Batumi,[4] another Georgian town, under the guidance of a father who had a "distaste for convention." Family life, Pavel says, "was like being on an island cut off from the world, that is, a desert island, because we didn't particularly like people and we always tried to keep ourselves out of the way. People would have taken hold of the purity, the unchanging calm and the rigorism of this insular paradise, which is why they were barely tolerated, and only occasionally." During these childhood years, Pavel was fascinated by the abundant nature of the Caucasus, of which he would later speak on several occasions. Especially, he recalled this landscape with particular emotion many years later, while he was a deportee in the Solovki Archipelago of the White Sea, the Gulag where he spent the last 4 years of his earthly existence. It is conceivable that it was because of the powerful influence of nature, especially that of the Caucasus, which fascinated him as a child, that Florensky remained deeply attracted, throughout his life, by the study of natural sciences and all the phenomena of the living.

[3] In this section, unless otherwise specified, the sentences in quotation marks are taken from Florensky's autobiographical notes addressed to his children, which he wrote between 1916 and 1926 (Florensky 2007). Here and elsewhere, I have translated from the French (I cannot do it from the Russian).

[4] Batumi, situated on the Black Sea, experienced its expansion with the construction of the Batumi-Tiflis-Baku Transcaucasus Railway, completed soon after Pavel Florensky's birth. Incidentally, Batumi is a town where Joseph Stalin lived, organizing strikes since 1901.

At school, Florensky was a gifted pupil, interested in all subjects, even if attending school every day bored him. Those who knew him at that age described him later on as a solitary child, extremely shy and very much an insomniac. In his recollections, we read: "I would fight long and hard not to go to bed, and once in bed, I would go on for hours without falling asleep, turning from side to side and studying the pattern of the wallpaper and blanket for a million times. These were hours of almost torture, when I was in bed unable to sleep." Pavel reads a lot, sets up a chemistry laboratory in his room, and works alone at night. He is interested in ancient languages. Later, he was able to speak most European languages, besides being proficient in Latin and ancient Greek, of course, but also in Hebrew and Syriac, which he learned at the Theological School. Several years later, from his exile in the Gulag, he wrote to his 15-year-old son Mikhal (Florensky 2021, Letter no. 77, p. 497, dated 23.X.1936):

> I wish I could have been with you to teach you how to work properly and accumulate knowledge. [. . .] When I was your age, every minute lost seemed to me like a misfortune or a crime, and I tried to fill my time as much as possible. I had diaries where I tried to record the essentials of my reading and reactions to books, notebooks of interesting quotations, albums of sketches from nature, copybooks where I methodically recorded the results of experiments, and others for onsite observations. Every evening, I would write myself a (motivated) note for the day's work. In this way, I acquired a wealth of knowledge, practical skills and, above all, the ability of making my own judgements based on what I had observed. I tried to compare and synthesize the data I collected in the form of tables, diagrams and curves, as this condensed aspect made them easier to understand; they become alive and acquire meaning. Immediately and automatically, you get an 'empirical generalization.'

In 1899, Florensky, who was 17, arrived to Moscow, where he was to enter university. At his arrival, he underwent a profound existential crisis. Having been brought up away from religion, in a positivist climate and an atmosphere of secular humanism, he realized the limitation of the natural sciences and became interested in social, religious, and moral issues, in the life of the ordinary and poor people, and in the human soul, striving for a meaning to life. The crisis is recounted in the last part, titled *Avalanche*, of the autobiographical text (Florensky 2007). We read there: "On top of my own magical idealistic understanding of the world, a film had formed that prevented me from breathing freely; the idea of continuity, fundamentally excluding the miraculous, was trying to take possession of my intelligence." He was already seeing the world with the eye of a mature mathematician. The ideas of continuity and discontinuity, which for him had become philosophical concepts, were to follow him for the rest of his life. Florensky's existential and religious crisis was often compared to that of Pascal, who, at age 29, experienced a similar experience which led him to a life centered on philosophical and theological reflection, without leaving science. Pascal had, like Florensky, a strange personality. T. S. Eliot described him as "a man of the world among ascetics, and an ascetic among men of the world" (Eliot 1951, p. 411).

Under pressure from his parents, Florensky enrolled as a mathematics student at the Faculty of Physics and Mathematics of the Imperial University of Moscow. His

mentor there was Nikolai Vasilievich Bugaev (1837–1903), a well-known mathematician who was the president of the Moscow Mathematical Society, of which he had been a cofounder. Bugaev was engaged in the philosophy of mathematics and its repercussions in the social, historical, and religious spheres. For him, questions like continuity, discontinuity, the finite, and the infinite were intimately linked to philosophical issues such as free will, scientific and social revolutions, evolution in history, etc. I shall talk later in this chapter about Bugaev, whose ideas were to have a definite influence on Florensky. The other teachers of Florensky included Boleslav Kornelievich Mlodzievsky (1858–1923), a representative of the Moscow school of metric geometry who, like Bugaev and several other Russian mathematicians of that period, spent some time in Western Europe on several occasions, in cities like Göttingen, Paris, and Zürich, where he came into direct contact with Western mathematicians and philosophers. According to I. H. Anellis in (Anellis 1994), Mlodzievsky gave the first course on set theory and the theory of functions at Moscow University, two topics which became important parts of Florensky's background. Anellis adds that it was Mlodzievsky who established the Russian terminology in these subjects. According to Demidov (Demidov 2014), Mlodzievsky's synopsis of his lectures was preserved thanks to notes compiled by Florensky (Medvedev 1986).

Florensky's teachers also included Leonid Kuz'mich Lakhtin (1863–1927), a student of Bugaev, who studied nonorientable surfaces, in particular the question of representing them by explicit equations, see (Lakhtin 1904). We shall see below how nonorientable surfaces became part of Florensky's later interests, mathematically and symbolically. A nonorientable surface represents the fusion of two contraries. In a note in his booklet titled *The imaginaries in Geometry*, which we mentioned in the introduction, which we shall discuss at length below and in which the notion of nonorientability plays a key role, Florensky says that he wrote that booklet during the month of August 1902 while he was a student, and that he showed it to Lakhtin (see Florensky 2016, p. 79). Among the Russian mathematicians of the same epoch who studied nonorientable surfaces, one should mention Nikolai Borisovich Delaunay (1856–1931) who addressed the problem of finding a locally Euclidean parametrization of the Möbius band, in his memoir (Delaunay 1898) published in 1898 in the Bulletin of the French Mathematical Society, and which Florensky also mentions in a note to his work *Imaginaries in geometry* (see Florensky 2016, p. 82). In the same note, Florensky declares that in the *Encyclopedia of mathematics* of which he was in charge, he wrote an article on the division of surfaces in orientable and nonorientable.

Below, I shall discuss the booklet *Imaginaries in Geometry*, which was essentially written in 1902, at the time Florensky was a mathematics student.

The young Florensky became quickly interested in formal logic. Questions of contradiction, antinomy, and the nature of the relationship between mathematics and the physical world found an echo in him, both philosophically and theologically. He writes (Florensky 2007, p. 42):

> In mathematics, Fourier series and other topics which represent any complex rhythm as an infinite set of simple objects resonate with me, speak to me, correspond to my innermost

> feelings. Continuous functions without derivatives and discontinuous functions where everything unravels, where all elements are *standing*, hold a dear language for me. If I listen to the depths of my being, I discover in the rhythm of my inner life, in the sounds that fill my consciousness, the rhythm of the waves that have been retained forever, inscribed in my memory for all time, and I know that they seek their conscious expression in me through the schema of these mathematical concepts.

Leonid Sabaneeff,[5] who knew Florensky since they were both mathematics undergraduates at the same university, writes in a set of recollections (Sabaneeff 1961) that Florensky rarely attended lectures, preferring to read books at home. He also recalls that Florensky seemed oddly old for his age, to the point that one of their fellow students said about him: "he looks as if he had already lived a thousand lives." Sabaneeff continues: "One had an impression of genius, of unusual depth and power of thought, and at the same time there was something of black magic, dark, devoid of divine grace." He had the feeling that Florensky possessed an immense spiritual experience and was endowed with hypnotic power. He recalls Florensky speaking of "many facets of any true thought and of the compatibility of contradictions at the deepest levels," asserting that "every perceived law generates its own negation" and that "logic is valid for the earthly life, for the lower levels; but the true world is one where contradictions are compatible—a realm of antinomies." Sabaneeff adds that Florensky "obviously regarded antinomy as the basic law of the universe, encompassing all others." In Florensky's mind, the notions of contradiction and antinomy have no negative connotation. Contradiction, nonprovability, and paradoxes in set theory fascinated him, and he often referred to them in his mathematical and nonmathematical writings.

At university, Florensky, besides studying mathematics, attended lectures at the philosophy department, by Lev Mikhailovich Lopatin (1855–1920), a psychologist and philosopher inspired by Leibniz' monadology, and by Sergei Nikolaevich Trubetskoy (1862–1905), who belonged to the Russian tradition of universal theism, trying to unite Christianity with Platonism. Both philosophers were imbued with spiritual ideas, in search of universal wisdom,[6] and their ideas had a definite impact on Florensky.

Bugaev died in 1903. Dmitri Fedorovich Egorov (1869–1931), who had been a student of Bugaev, took over the direction of the mathematical school founded by his

[5] Leonid Sabaneeff (1881–1968) graduated in mathematics from the Imperial University of Moscow and studied music under Rimsky-Korsakov and Taneyev. He became a composer and musicologist. He wrote an authoritative and influential book on Skriabin. He taught at the State University of Moscow and he founded the Moscow Institute of Musicology. He remained close to Florensky and to Nikolai Nikolaevich Luzin (1883–1950), whom I discuss in the sequel, until the year 1926, when he left the Soviet Union. He lived in Paris, London, the United States and Nice, where he is buried.

[6] Florensky, in the notes of his major theological work, *The pillar and ground of the truth (*Florensky 1975*)*, quotes several works by Lopatin, among which are *The positive tasks of philosophy*, *The philosophical worldview of N. V. Bugaev*, and *The present and future of philosophy*. He also quotes books by Trubetskoy, among which are *The metaphysics of ancient Greece*, *Foundations of idealism,* and *The doctrine of Logos*.

mentor. At that time, Florensky had already become friends with Bugaev's son, Boris Nikolaevich Bugaev (1880–1934), 2 years his senior, poet and writer, known by the pseudonym Andrei Belyi, who was a leader and theorist of the Russian Symbolist movement. Belyi's novel *Petersburg* (first edition completed in 1913) made him later one of the greatest writers of the twentieth century. Like Florensky, Belyi was interested in the impact of mathematics in life sciences and philosophy.

During his study years at the Mathematics and Physics Department of the University of Moscow, Florensky initiated a "Circle of mathematics students" within the Russian Mathematical Society, with the collaboration of his friend and fellow student Nikolai Luzin, who was to become later one of the best-known Russian mathematicians of his generation, respected in Russia and France. On this occasion, he wrote a *Sketch for a discourse for the inauguration of the Circle of mathematics students of the Moscow Mathematical Society* which was published in 1990 (Florensky 1989), discussing there, among other topics, Cantor's set theory and Bugeav's arithmology (the theory of discontinuous functions). At about the same time, Florensky founded a "Religious-Philosophical Society of Writers and Symbolists" and a "Union of Christian Struggle," a movement dedicated to social Christianity, opposing the then current subjugation of the Church to the State, which had started under Peter the Great.

I will say more about Luzin in Sect. 7.

In 1904, Florensky completed his mathematics studies with a dissertation titled *On singularities of plane curves as loci violating their continuity.* Part of this dissertation is published in (Demidov and Parshin 1986). According to Oppo (Oppo 2022, p. 72), this dissertation was part of a wider doctoral project titled *The Idea of discontinuity as part of a postulated worldview.* Florensky wrote an introduction to this work and published it under the title *On a certain premise of a worldview* (Florensky 1904b) in the symbolic journal *Vesy.* Oppo gives further details on this publication in a note (Oppo 2022, p. 87).

Florensky's dissertation was well received by his teachers. Egorov considered him as one of the most brilliant and original mathematics students. One of Florensky's teachers, Nikolai Yegorovich Zhukovsky,[7] offered him the possibility of pursuing a specialization curriculum which would lead him to a doctorate. But to the surprise of his teachers, Florensky turned down this opportunity and enrolled as a student at the Moscow Theological Academy. He delegated the function of secretary of the Students' Mathematical Circle to Luzin (Demidov 2014). The Theological

[7] Nikolai Yegorovich Zhukovsky (1847–1921) was a mathematician, physicist, and engineer. He is considered to be the founder of the Russian schools of hydromechanics and aeromechanics. In 1904, he established, near Moscow, the first aerodynamical research institute in Europe. He is often called the "father of Russian aviation"; see (Grigorian 1970). In the theory of conformal mappings, the transformation $z \to \frac{1}{z}$ is called the *Zhukovsky transformation.* Zhukovsky's work had a definite impact on Mikhail Alekseyevich Lavrentieff (1900–1980), the Russian founder of the theory of quasiconformal mappings whom we shall mention later in this chapter. Lavrentieff was a specialist of partial differential equations and hydrodynamics and the founder of the Institute of Hydrodynamics of the Siberian Division of the Russian Academy of Sciences.

Academy is situated in Sergiyev Posad, a city about 70 km northeast of Moscow which also hosts the Trinity-Saint Sergius Lavra.

Even though Florensky distanced himself from the profession of mathematician, mathematics remained for him, for the rest of his life, a way of thinking and a basis for his philosophical and religious work.

Florensky's strained relations with the state police started in 1906. That year, he was sentenced to 3 months' jail for having called for the abolition of the death penalty[8] and for having protested, along with some fellow students, against the execution of Lieutenant Piotr Petrovich Schmidt, a naval officer who had been one of the leaders of the Black Sea Fleet revolt in Sebastopol during the 1905 revolution.[9] Florensky spent a week in the Tagansky prison in Moscow (March 23–30, 1906), before being released after the intercession of several people, including the rector of the Theological Academy. During the week he spent in prison, he wrote a paper titled *On the elements of the α number system* (see Demidov and Ford 2005, p. 601).

A few words on the 1905 social movements are in order, because these movements had a definite impact on several of the figures we will be talking about.

The origin of the 1905 social movements goes back several years. In 1881, the year before Pavel Florensky was born, Tsar Aleksander II, who was ready to give his country a constitution, was assassinated by members of the *Narodnaya Volya* ("People's Will"), a late nineteenth-century revolutionary socialist political organization. With this assassination, Russia started being in the grip of a political effervescence and a state of siege that culminated in the bloody events of 1905 that left their mark on Florensky, as they did on a large number of Russians. The 1905 revolt started with a peaceful demonstration by workers who had a request for the Tsar, and it ended in a terrible shoot-out. What happened during these events was later called the First Russian Revolution and was regarded as the beginning of Imperial Russia's agony.

In a sense, the 1905 revolution was a culmination of the idealistic traditions of the Russian intelligentsia. Chapter 2 of Pasternak's *Doctor Zhivago*, titled *A Girl from a Different World*, starts with the words "The war with Japan was not yet over when it was unexpectedly overshadowed by other events. Waves of revolution swept across Russia, each greater and more extraordinary than the previous."[10] In relation with the events we are recalling, it is also interesting to know that, in 1925–1927, Pasternak wrote two long poems dedicated to the 1905 revolution, one of them titled *Lieutenant Schmidt*.

[8] Florensky made his statements against the death penalty in a homily, first delivered at the Lavra and then published clandestinely. Demidov and Ford note in (Demidov and Ford 2005) that "the Moscow Theological Academy had the practice of allowing seminarians to preach in the Cathedral."

[9] Lieutenant Piotr Petrovich Schmidt, an idealist sympathizer of the 1905 revolution, was a typical representative of the Russian intellectuals during this episode. He founded a *Union of People's Friends Officers* and addressed several revolutionary meetings that culminated in a general insurrection of the Black Sea fleet crews on November 11, 1905.

[10] Modified English translation from (Pasternak 1958).

Florensky obtained his theology diploma in the spring of 1908, with a dissertation titled *On spiritual truth*, a work that was expanded later to a treatise titled *The pillar and ground of the truth: An essay in orthodox theodicy in twelve letters* (Florensky 1975), which became his first doctoral dissertation, defended in 1914. This work had a definite impact on the Russian theological circles.

Upon his graduation in 1908, Florensky was entrusted with the teaching of history of philosophy at the Moscow Theological Academy, a position he held until the Academy's closure in September 1918. Figure 1 is extracted from the album of illustrations of his course on the history of classical Greek philosophy.

Florensky was ordained priest in 1911, after his marriage. Just as philosophy accompanied him during his mathematical studies, mathematics constituted an important element of his background during his theological studies. The discussions around the mathematical notion of discontinuity that were taking place at that time, the recent developments of set theory, the language of mathematical logic, and other mathematical subjects were at the basis of his treatise *The pillar and ground of the truth*. Since the book was addressed to theologians rather than mathematicians, Florensky included there several sections containing technical mathematical explanations. For instance, Section XV is titled *Certain concepts from the theory of infinite*, Section XVII is titled *Irrationalities in mathematics and in dogma*, Section XIX is titled *The concept of identity in mathematical logic*, Section XXX is titled *The basic symbols and elementary formulas of symbolic logic*, etc. I shall say more about this work below.

In 1917, the teaching of theology in Russia entered a period of upheaval as a result of the October revolution, and the Academy closed for good in September 1918.[11] Florensky could no longer teach philosophy there. He became a teacher of history of Byzantine art at the MIKhIM.[12] In October 1919, he was appointed scientific secretary of the committee for the Preservation of Art Monuments and Antiquities of the Sergiyev Posad Lavra, which belonged then to the Commissariat of People Instruction. He prepared a treatise on religious art, titled the *Reverse perspective* (Florensky 1992), which was the occasion for him to expand his ideas on space in drawing and painting. I will say more about this work in Sect. 3 below. This was also the epoch where Florensky became close to the writer Vassili Rozanov. The latter wrote about Florensky in a letter to the art critic Mikhail Spasovsky,

[11] The Moscow Theological Academy reopened in 1944. In 1930, the name of Sergiyev Posad, in reference to Saint Sergius of Radonezh, considered as the heart of Russia – it was from there that Russian culture expanded – was changed to Zagorsk, named after Vladimir Mikhailovich Zagorsky, a revolutionary who had been assassinated and whose real name was Wolf Mikhelevich Lubotsky. Zagorsky was a party activist who had taken part in the 1905 revolution. He was Secretary of the Moscow Committee of the Russian Communist Party (Bolsheviks) when he was killed, on September 25, 1919, by a bomb thrown by an anarchist. It was only in 1991 that the town of Zagorsk recovered its original name of Sergiyev Posad.

[12] This is the acronym of Moskovskii Institut Istoriko-Khudozhestvennykh Izyskanii i Muzeevedeniia, that is, the Moscow Institute of Historical and Artistic Research and Museum Studies.

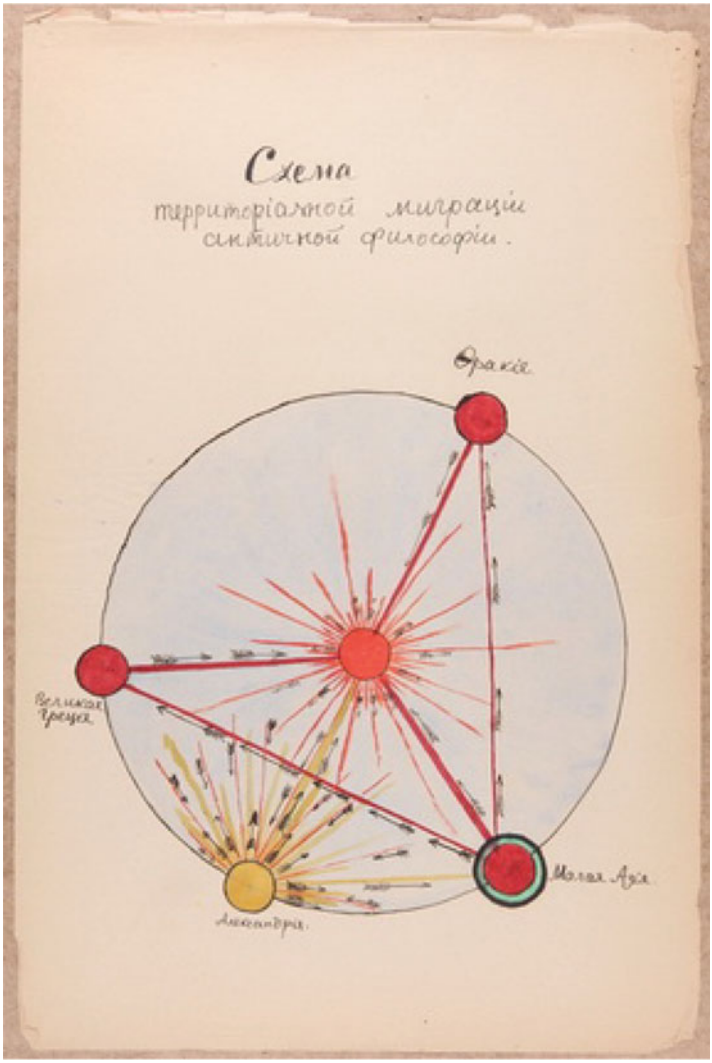

Fig. 1 From the album of illustrations of P.A. Florensky's course on history of classical Greek philosophy 1908–1909. The translation of the page title is "The scheme of territorial migration of ancient philosophy." Around the circle, starting from the top, clockwise, one reads: Thrace, Asia Minor, Alexandria, and Great Greece. Paper, watercolor, pencil, and ink. Multimedia Art Museum, Moscow

quoted in part in (Rozanov 1984, p. 413) and in the introduction of the French version of the *Imaginaries* (Florensky 1992, p. 15):

> He is the Pascal of our time, the Pascal of our Russia. You know, sometimes I even get the impression that he is a *saint*, so exceptional is his mind, so out of the ordinary. . . . I think and I am firmly convinced that he is even infinitely greater than Pascal, both in his essence—on

> the level of a Plato with all that is so *exceptional* about him—and in his intellectual discoveries, intellectual visions.

By that time, Florensky had already produced a large amount of writings. He signed a contract with the Pomor'ye publishing house to have his works appear in 19 volumes. Eventually, only his book *Imaginaries in geometry* (Florensky 2016), which I shall review in Sects. 3 and 4 below, was published by Pomor'ye before its closing.

Pavel Florensky, with his family, lived in a small wooden house near the Sergiyev Posad monastery. For the rest of his life, including the years he spent in prison or in a Gulag, he used his scientific skills to work as a specialized technician in a plastics factory, as a teacher and encyclopedia editor, and as an engineer in several research institutes. He also taught mathematics and physics at the Zagorsk Pedagogical Institute. With all the troubles he had to deal with, work was what allowed him to survive psychologically, besides supporting his family. At some point, he was called as an engineer on an important project to electrify Russia, which was known under the name GOELRO.[13] There, he had the occasion to meet Stalin, who considered him, like many intellectuals and clerics, an enemy of the people, but who tolerated him because the state needed his skills. Trotsky, at some point, took an interest in Florensky and to some degree protected him, before he was driven out himself. The following episode is reported in the book by V. Chentalinsky who collected KGB documents concerning literary figures when the KGB archives were made available, in the 1990s (Chentalinsky 1993, p. 174):

> One day, long before his disgrace, Leon Trotsky[14] was astonished to see Florensky's white cassock.
>
> "Who's that?" he asked.
>
> The leader of the world revolution, who thought he was as wise as King Solomon, held a multitude of positions. He was also head of the *Glavelectro*,[15] and as such visited the institute where the priest worked.
>
> "This is Professor Florensky", came the reply.
>
> – "Ah yes, I know..." Trotsky approached him and invited him to an engineering conference.
>
> "Naturally, he said, you wouldn't come dressed like that...
>
> – I haven't renounced my vows and can't wear any other clothes," Florensky replied.
>
> "– Oh, you can't, . . . so come in this outfit"
>
> When Florensky stepped up to the podium to address the conference, a murmur of astonishment ran through the hall: a priest at the pulpit! And, more than by his brilliant communication, the audience was struck by the enigma he represented: a cleric, and therefore an obscurantist, who possessed such knowledge of the exact sciences!

[13] GOELRO is the transliteration of the Russian abbreviation for "State Commission for the Electrification of Russia."

[14] Trotsky was banished in 1929.

[15] This is the Central Directorate of Electricity.

Trotsky's indulgence for Florensky would later prove fatal, as we shall recall below.

Florensky, besides carrying out several assignments for the state, was teaching drawing and history of art, and most of all, he was writing and writing. At some point, he was offered to leave the country on one of the "philosophers' boats"[16] that had already taken a large part of the Russian Intelligentsia.[17] He refused, declaring that he wanted to stay in his country. Of this refusal, Sergei Bulgakov, who was his disciple and friend and who had been expelled, in 1922, said in an address he gave in Paris in 1943, when the news of Florensky's death reached him (Bulgakov 1989): "He had not the shadow of naivety and idyllic primitiveness, [. . .] but he loved this native land, like the Mother of all men, the Demeter of the Ancients." In staying in his country, Florensky knew what he was expecting. He was not put straight into prison, and he was always given new tasks, even when he was in the Gulag.

At dawn on May 21, 1928, Florensky was arrested and taken to the Lubyanka.[18] The episode is recounted in the book (Chentalinsky 1993). He was required there to fill in a questionnaire. To the question of whether he had ever been prosecuted, he replied: "Yes, in 1906, for a sermon against Lieutenant Schmidt's death sentence." This could have played in his favor, but at the same time he added: "I have practically nothing to say on political questions. Because of my character, my occupations and my conviction, based on the lessons of history, that events still develop according to as yet unclarified laws of social dynamics and not according to the will of the participants, I have always avoided the political struggle." In those times, it was dangerous to declare oneself politically neutral. Thus, Florensky was arrested along with 79 other people, accused of a plot in connection with the shooting of a revolutionary. The minutes of his arrest at that date and of later arrests are published in the book (Chentalinsky 1993).

Florensky was placed under house arrest in Nizhny Novgorod. The photo reproduced in Fig. 2 was taken there. A few months later, he was granted early

[16] The "philosophers' boats" is the name that was given to the steamships that transported intellectuals expelled by the Soviet government in 1922, soon before the creation of the Union of Soviet Socialist Republics. Leon Trotsky had decided that "there was no pretext for shooting these people, but it was no longer possible to tolerate them," cf. (Nikolski 2012).

[17] Among those who were expelled and with whom Florensky was closely associated, we mention the symbolist poet Vyacheslav Ivanov (1866–1949), the religious philosopher Nikolai Berdyaev (1874–1948), and Sergei Bulgakov (1871–1944), who was a theologian, philosopher, and economist. We also mention the philosopher Simon Frank (1877–1950), the theologian Vladimir Nikolaievich Lossky (1903–1958), the writer and journalist Mikhail Andreyevich Osorgin (1878–1942), the sociologist Pitirim Alexandrovich Sorokin (1889–1968), and Valentin Fyodorovich Bulgakov (1886–1966), a Christian anarchist and antimilitarist who had been the last secretary and biographer of Leo Tolstoy. A large number of the persons expelled participated in the 1905 revolution and belonged to the Socialist Revolutionary Party.

[18] This is the building in Moscow that hosts the headquarters of the Political Police, called State Political Directorate (known by the acronym GPU), with its affiliated prison.

Fig. 2 Pavel Florensky in exile in Nizhny Novgorod, 1928

release, after the intervention of influential people, among them Ekaterina Peshkova, Maxim Gorky's ex-wife. Peshkova was at that time director of the political Red Cross and was on good terms with Stalin. Florensky returned to Moscow and resumed his work for the state. In 1930, he was made deputy director of the Electrical Engineering Institute K. A. Krug in Moscow and in 1931 member of the central directorate for the study of electro-insulating material. Meanwhile, he continued to teach philosophy clandestinely at the Danilovski and Petrovski monasteries, where the Theological Academy continued to exist informally, after it was officially closed in 1918. Florensky continued to publish in scientific journals until his deportation. In 1932, he published several articles in the journal *Socialist Reconstruction and Science*, among them an article in which he describes an analogical calculator for finding approximate solutions of algebraic equations of high degree [see (Demidov and Ford 2005), p. 608 and the reference there].

Between 1927 and 1933 (the year of his deportation), Florensky filed almost 50 patent applications, but most of them were rejected because he was a priest, automatically accused of obscurantism.

The existence of a cleric, always dressed in cassock, who was a scientist and useful to the nation, became more and more unbearable for the Soviet authorities, and at some point they ran out of patience. At dawn on February 26, 1933, Florensky was arrested at his home and beaten up at the Lubyanka, again accused of plotting and antirevolutionary propaganda. V. Chentalinsky, based on the KGB documents, writes about his arrest (Chentalinsky 1993, p. 164): "Today we can see Florensky's true face, but his case file presents him as a dangerous criminal for society, as an obscurantist placed under permanent and strict surveillance until his death."

This time, Florensky spent 6 months at the Lubyanka. During his captivity, he worked around the clock. On July 26 of the same year, after a sham trial based on false accusations, he was sentenced to 10 years in the Gulag, with the obligation to continue his scientific work.[19] He was again offered the possibility to leave Russia. In fact, Tom Masaryk, the president of the Czechoslovak Republic, offered to take him in, so that he could continue his scientific work there. But once again, Florensky refused to leave his country. In August of the same year, he was transported to Eastern Siberia on a train full of common criminals. He arrived at his destination, a camp whose name translates as "free," exhausted, starving, and penniless: Everything he possessed was stolen during the journey. In February 1934, that is, a few months after his arrival to the camp, he learned from a courier that his library had been confiscated during a search at his family home in Zagorsk. Shocked, he wrote to the OGPU:[20]

> My whole life has been devoted to science and philosophy, and I have never known rest, leisure or pleasure. Not only did I devote all my time and energy to the service of humanity, but I also spent a large part of my modest salary on buying books, etc. My library was not simply a collection of books, but selections for specific, established subjects. One might say that many of the works I intended to write were already half-finished in the form of notes in books whose arrangement on the shelves, the intellectual key, was known to me alone [. . .] My whole life's work is now destroyed [. . .] This is for me far worse than physical death. (Misler 2006)

In November 1934, after seeing for the last time his family who was visiting him, Florensky was forbidden visitation rights and sent to the Solovki Islands, an austere place in the White Sea, 160 km from the Arctic Circle. There lies an ancient monastery, known under the name *Solovetsky*, surrounded by an enclosure of walls and towers and encircled by immense frozen expanses. In the days of the Tsars, it was the place where recalcitrant monks were sent. In 1920, the monastery was transformed into a Gulag, and it remained so until 1937, the year Florensky was shot. Prisoners there were crammed into the former monks' cells, several to a cell. Later, the monastery came to be regarded as the most terrible of the Soviet camps,

[19] It is probably time to recall that the word Gulag is an acronym for "Glavnoye Upravleniye Lagerey," which means Main Administration of Camps. In theory, the Gulags were "camps for re-education through work."

[20] The OGPU is an acronym for "Joint State Political Directorate," which was the Soviet Union's state police.

where half a million people perished. Aleksandr Solzhenitsyn called this place "the mother of Gulags."

About Florensky, Solzhenitsyn wrote that he was "perhaps the most remarkable person devoured by the Gulag." Chapter 2 of the second volume of his *Gulag Archipelago* opens with a historical account of the Solovki Islands, where the story of the Gulag starts (Solzhenitsyn 1975):

> On the White Sea, where the nights are white for half a year at a time, Bolshoi Solovetsky Island lifts its white churches from the water within the ring of its bouldered kremlin walls,[21] rusty-red from the lichens which have struck root there—and the grayish-white Solovetsky seagulls hover continually over the kremlin and screech.

On October 10, 1934, Florensky sent his first letter to his family from his new exile. He was still in Kem, 200 km as the crow flies from the Solovki Islands. He wrote (Florensky 2021, Letter No. 1, p. 13):

> On arrival at the camp, I was robbed by an armed attack and threatened with three axes, but as you can see, I am safe and sound, albeit without luggage or money; some of my belongings have been found. All this time I have been cold and hungry. It was much harder than I had imagined when I left the Skovorodino train station.[22] I was supposed to go to Solovki, which in itself would not be so bad, but I am held up in Kem where I am busy making and filling out control forms.

In the Gulag of the Solovki Islands, a new life for Florensky started, although he spent his time on exactly the same activity as before: working. I have reproduced here a recent photograph of the Solovetsky monastery; see Fig. 3.

In a letter dated 8–9.VII.1936, addressed to his wife (Florensky 2021, Letter No. 67, p. 435), he writes: "I never see the sun or nature, even through the window: I am constantly busy. All my time is spent developing and deepening technological processes, equipping the algae workshop as much as possible, given the increasing demands for quality and quantity." Besides, Florensky also set up a theater for the detainee and taught classes there, keen to passing on his knowledge to the other prisoners. His work force sustained and guided him through all his hardship, as the enormous correspondence with his family shows. The prison authorities, aware of Florensky's talents and keen to exploit them to the full, arranged workshops for him and let him organize his courses and lectures. In a letter addressed to his son Vassili, dated 27–28.IV.1935, he writes (Florensky 2021, Letter no. 17, p. 111): "I just gave a talk on Maxwell's theory and related questions. I got home at 11:30 p.m. and it was perfectly clear outside. [. . .] The light here is transparent: everything seems to be seen in a dream, and in fact non-existent. This is particularly true at night, but also during the day, when the sun is shining." He would have liked to do mathematics, but

[21] The Russian word "kreml" (kremlin) refers to a fortified complex or citadel, and not just the one in Moscow.

[22] Skovorodino is a city situated on the Trans-Siberian Railway, 7306 kilometers from Moscow.

Fig. 3 The Solovetsky Monastery, where the prisoners were crammed together. This recent and romantic photograph does not give any idea of the atmosphere in the monastery during the time it was used as a Gulag, between 1926 and 1939, but the sky above it and the sea surrounding it have not changed. (Photo: Cultural heritage object in Russia, No. 2910179018, GitaOggg)

this was not easy. In a letter to his mother, dated 24.VI.1936, Florensky writes (Florensky 2021, Letter no. 65, p. 422):

> I deal a bit with mathematical questions; for more serious work in this field, I have neither time, nor the necessary books, and finding everything in one's head is too unproductive a task. With the most advanced workers at Idoprom, where I work, i.e., with those who have completed eight years of school or technical institute, or a few years of higher education, I have organized a physics circle with the aim of learning how to reactivate one's knowledge of physics, mathematics and a little chemistry, really assimilate them, deepen them and complete them. So, the sum of the various tasks and activities occupies all the time, not only during the day, but also most of the night. I try, after dinner, from 7–7.30, to get about two hours of sleep, so that I can work with a fresh mind at night.

He accepted his new situation philosophically. Perhaps with a touch of humor, but also with great sadness, he wrote to his wife on 7.XI.1934 (Florensky 2021, p. 17):

> I have long since come to the conclusion that desires in our lives are realized, but with great delay, in a caricatured way that makes them unrecognizable. In recent years, I wanted to live in the immediate vicinity of a laboratory, and that came true; in Skovorodino. I wanted to take care of the soil, and that came true here too. Before that, I wanted to live in a monastery,

> and that came true, but in Solovki. As a child, I used to fantasize about living on an island, seeing the tides, handling seaweed, and now here I am on an island, there are tides and I may soon be handling seaweed. But the realization of desires is such that one no longer recognizes them, and it happens when the desire has already passed. I send you a big kiss, my dear Annoulia, don't lose courage.

In fact, early in 1920, he had written in his autobiography about this call of the sea (Florensky 2007, p. 41):

> The call of the sea, the fractional sound of the surf, the infinite, glittering surface in which I could distinguish ever-smaller flakes, down to the tiniest particles, but which never merged, all this resonated endlessly in my soul. My body was craving the saltiness of the sea, the salty, iodine-soaked air, but also the fractionated air carrying the tiniest crystals: sometimes it feels good to hold at least one vial of tincture of iodine close to you. I crave the taste of the sea. . . It seems to me that if I could find a pile of seaweed, I would devour them all.

Florensky set up a laboratory to process seaweed and extract iodine and agar-agar, a substance used as a glue, and also in cooking. He conducted research in biology and organic chemistry. During his stay in Solovetsky, he registered seven patents. Among the prisoners were engineers, scientists, and academics, educated people as well as workers; he gave courses to all of them, working at an inhuman pace. Since he worked more than double the required time, he was allowed to send three letters a month to his family. He sent long letters, sometimes a dozen of pages long, to his wife, mother and, children, and also, from time to time, to friends such as the pianist Maria Yudina, who was Stalin's favorite pianist and who had become Florensky's spiritual daughter. He also corresponded with Vladimir Ivanovich Vernadsky, a member of the Russian and Soviet Academies of Sciences.[23] In his letters to his family, he used to describe his everyday life in the Gulag, giving advice to each family member.

In some of his letters, Florensky gave mathematics and physics lessons to his children. For instance, in the letter dated 5.XII.1935, to his son Vassili (Florensky 2021, Letter no. 40, p. 245), he formulated a problem in mathematical physics and he developed its solution. In the letter dated 24.III.1936 (Florensky 2021, Letter no. 54, p. 341), he explained a mathematical problem to his daughter Olga. Several times, in his letters, he wanted to know about his confiscated books. On September 16, 1935, he wrote to his wife: "On occasion, enquire about the fate of my work on permagel and my mathematical articles, and in particular the articles on four-color maps." The works were never found. On February 25, 1936, he wrote, again to his wife (Florensky 2021, Letter No. 50, p. 311):

[23] Vladimir Ivanovich Vernadsky (1863–1945) was a famous mineralogist and geochemist. He is the author of a book titled *The Biosphere*, published in 1936, in which he defends the ideas that life and human cognition are the forces that are at the origin of the Earth's development and the transformation of the biosphere. Vernadsky was one of the fathers of the Soviet atomic bomb. He never sought to hide his friendship and respect for Pavel Florensky.

> Now that I live in the laboratory, I can also work at night, especially as the work is done 24 hours a day and needs to be supervised all the time. At the moment, it is already nearly 3 o'clock. Next to me, a worker is cutting the agar into pieces for freezing, and on the other side, pumped water is gurgling in a large tub. [. . .] Try not to get bored and to find interest in work in addition to that which is immediately essential. Life must be embellished.

He tried to keep abreast of developments in all the sciences, and every small information he could get was important for him. In the same letter, he wrote:

> In the Pravda of February 9, 1936, No. 39 (6645) p. 5, I came across the composition of a liquid for toothache, that of Professor Hartman, an American from Columbia University. As this liquid is very easy to obtain and, according to the newspapers, gives 80% positive results, you need to have some on hand. Here is the formula: one part etyl alcohol, 2 parts ether, 1.25 parts timol.

He is worried again about his books: "Have you received my books and materials from P. N.? Ask him to send them to you, because I have spent a whole year putting them together, and I want the boys to use them: I am already giving them nothing, so do not neglect the little they can get." He is thinking not only about his past, but also about the past of the universe. In one of his last letters, dated 20.22.1937, (Florensky 2021, letter No. 71, p. 455), Florensky writes, to his son Kyrill: "A distant past absorbs my thoughts: the formation of the island's rocks some two billion years ago, the history of the formation of the Earth's crust in these very special places, the appearance of new rocks based on electronic waste, the movements of the glacier, its advance and retreat." With his meager salary, he is also sustaining his family. In the same letter, he writes to his son: "Did you receive the small sum I sent you?"

V. Chentalinsky describes the last days of Father Florensky. We are in June or July 1937. The camp had been recently reorganized under a new management which had recently arrived. The iodine production plant, where Florensky was the leading scientist, was closed. The detention conditions were tightened. Prisoners were herded off to an unknown destination. Florensky was arrested after a report, made by an informer. Chentalinsky records this denunciation in the following terms (Chentalinsky 1993, p. 191):

> Florensky and another inmate walked to the library, talking loudly and gesturing forcefully. The informer "Comrade" follows them closely and listens attentively. They are talking about the upcoming war:
>
> "The predictions of Trotsky, the eminent Party strategist and ideologist, according to which war will soon break out seem justified to me, says Florensky. That is the rule: war breaks out periodically every fifteen or twenty years . . . "
>
> This short, seemingly innocent report had unfortunate consequences. It was used to draw up a special attestation on Florensky's conduct:
>
> "Engaged in counter-revolutionary propaganda in the camp, praising the enemy of the people Trotsky." [. . .]

Very soon after this, Florensky witnessed the destruction of his research facilities and learned that his discoveries on algae (in Solovki) and permagel (in Siberia) have been attributed to others. References to him in the *Technical Encyclopedia* of which he was an editor were canceled in the second edition [see (Demidov and Ford 2005), p. 608]. Florensky was again sentenced, this time to death, by a three-judge emergency court. He was immediately transferred to the mainland, in the Leningrad region, with a large group of prisoners from Solovki. The execution act was signed, and on December 8 of that year, he died riddled with bullets, along with 508 other people, on the outskirts of Leningrad. The execution act is reproduced in Chentalinsky's book (Chentalinsky 1993, p. 194): "The ruling of the troika of the Leningrad region NKVD leadership concerning the death row inmate, Pavel Aleksandrovich Florensky was executed on December 8, 1937, as attested by the present deed."

Florensky's body, along with those of the other shot, was dumped in a mass grave, which has since become a place of memorial. We were in the middle of the period known as the "Great Stalin Terror" (1937–1938), during which 750,000 people were executed in the USSR.

Meanwhile, life went on at the mathematics departments of Leningrad university, a few kilometers from that place. At the beginning of his historical review (Zalgaller 2012), V. A. Zalgaller writes:

> In 1937, enrolment in the Mathematics and Mechanics Faculty of Leningrad University (MatMekh) was unusually high: 210 students. The "big Chemistry lecture hall" in the main building on the Neva embankment hardly contained us. At the beginning, analytic geometry was taught by Professor A. R. Kulisher (1878–1937). But in September, he was already arrested and replaced by a 25 year old Professor Aleksandr Danilovich Aleksandrov. [. . .]

On May 5, 1958, the Moscow City Court overturned Florensky's conviction of July 16, 1933.

The rehabilitation court order reads: (Chentalinsky 1993, p. 184):

> Florensky's arrest (like that of the others judged for the same case) is not based on any document in the case file. Witnesses were not questioned, and those who took part in the investigation of the case were subsequently convicted of forgery. Florensky (and the others) were unjustly convicted, in the absence of proof of their guilt.

On March 5, 1959, the Arkhangelsk Oblast Court overturned his conviction of Nov. 15, 1937. It was only in 1989 that Florensky's family and descendants learned, through a letter from the KGB, of the date and place of his execution.

In this section, I tried to draw, with words, some features of Florensky's face. For an extended biography, the reader can refer to (Pyman 2010). A complete biography should take several volumes and is still to be written. There are a number of portraits of him. I have reproduced three of them here, in Figs. 2 and 4.

Fig. 4 Pavel Florensky, shortly after his arrest in 1933

3 Imaginaries

The book, for which I shall refer to the French version (Florensky 2016), is titled *Imaginaries in geometry*, with two subtitles: *Extension of the domain of geometric images to two dimensions* and *An essay of a new materialization of the imaginaries*. The work is complex, as are all of Florensky's writings, because of the continuous intermingling of philosophy, science, and symbolism. In the following pages, I shall extract a few ideas from this book, which deserves a very thorough analysis that would go beyond the scope of the present chapter. Villani, who wrote the preface to the French edition, declares there: "We find the exposition of a brilliant dreamy dissertation on the notion of duality, illustrated with advanced mathematical concepts, all designed to lead the reader's mind to the point where it can absorb a daring metaphysical thesis evoking a duality between matter and ideas." The physicist Pierre Vanhove, in the introduction to the same edition, writes: "This singular book should not be read as a work of mathematics or physics, but rather as an attempt to use the geometry of the imaginary to analyse the fundamental notion of duality between the real and spiritual worlds." At the same time, the *Imaginaries* is an illustration of the fact that Florensky's mathematical works do not consist of theorems and proofs, as one would usually expect from a mathematician; the mathematics that it is about is nonmainstream, close to art and to symbolism; and it is the language of a new imaginary world. To mention the opinion of a contemporary to Pavel Florensky, let me quote a fragment from a letter that Luzin wrote to

his wife about Florensky, after a visit he made to him in 1908; the fragment is reproduced in an article by C.E. Ford in (Ford 1998): "[. . .] But as soon as he showed me his works in mathematics, my old opinion came back to me: that all his works are of no value in the area of mathematics. Suggestive hints, beautiful analogies—very attractive and promising, provocative, beckoning, but without any results." On the connection between Luzin and Florensky, see the article (Demidov et al. 1989) by Demidov, Parshin, Polovinkin, and Florensky Jr., the discussion in (Sinkevich 2019) by Galina Sinkevich, and Sect. 7 below. Establishing a relation, which, in Florensky's *Imaginaries*, takes the form of a mathematical duality, between matter and ideas, between the rational and spiritual worlds, etc., are objectives that Florensky sought to achieve throughout his life.

Let me start with a clarification concerning the word "Imaginaries" in the title of the work. This word, in the first few pages of the book, has the meaning that mathematicians give it, when they talk about an "imaginary number," that is, the "imaginary" refers to one of the two coordinates of a complex number. Later in the book, this word designates the world of Platonic ideas, which Florensky considers as living in a space which is "inverted" with respect to our own. The fact that a complex number is the sum of a real and an imaginary number becomes a symbol of the fact that the world consists of a combination of concrete and abstract elements.[24]

In the same way as Florensky declares that the real and imaginary numbers constitute the two sides of the same surface, he sees the two worlds, the physical and the spiritual, as the two sides of the same reality. Gradually, in the book, the word "imaginary" takes on a literal meaning, as something that does not exist in reality, but rather as a tale that belongs to the realm of our imagination. As a result, the discussion quickly turns philosophical and symbolic, and the book becomes a poetic, historical, and cosmic metaphor on space and time, and on man and mankind. The book culminates in a fabulous reference to Dante's *Divine Comedy*, discussing the Florentine poet's geometrical vision. Talking about geometry in Dante's work has caused considerable ink flow in recent years, by authors who have taken up Dante's allegory, without any reference to Florensky and missing an essential point of what he actually discovered; I will discuss this in Sect. 4.

The *Imaginaries* has also a cosmological side, and it may come as a surprise to the reader that Florensky, in the last section of the work, invoking Einstein's theory of relativity, defends Ptolemy's geocentric system against that of Copernicus.[25] This section of the book, which is its culmination, should be taken (as several parts of the work) as a metaphor, continuing there the exposition of Dante's poetic and spiritual worldview. In his commentary, Vanhove, restoring Florensky's considerations in

[24] Let me add here the following remark made to me by Stelios Negrepontis: "The sensible entities according to Plato are the imperfect approximations of the true Being to which they participate. The eventual construction of an intelligible true being employs a quadratic conjugation between binomial and apotome lines, according to Theaetetus' Book X of Euclid's *Elements*, a conjugation that inspired Rafael Bombelli around 1558 in his discovery of complex numbers, which Bombelli called 'binomio', exactly because of this similarity."

[25] Florensky had to explain and defend himself before the state authorities on this issue; see Footnote 36.

context, writes that "far from having misunderstood the relativity revolution, Florensky wants to make Einstein's formalism compatible with his spiritual vision of the world."

Let me review the book in some more detail.

I start with the part that concerns complex numbers.

In this part, Florensky, showing his great erudition, refers to a host of mathematicians who worked on the foundations of the theory of complex numbers and their various uses. He mentions, in Sect. 1 and especially in the first and second notes, works of Gregory, Marie, Truel, Gauss, Argand, Kühn, Wessel, l'Abbé Buée, Français, Warren, Lambert, Mourey, Bellavitis, Cauchy, Matzka, Scheffler, Möbius, Riecke, Hoüel, and Gomes Teixeira. I know of no other work on this topic that contains such a large number of references.[26] "The various *interpretations* of the complex variable are," he says, "interpretations through which this variable manifests itself symbolically." This leads him to a literary and poetic digression (Florensky 2016, p. 36):

> We know that several translations of the same poetic work in one or more languages, far from hindering each other, actually complement each other, although none of them can totally replace the original. Scientific representations of the same reality can and should also be increased without detracting from the truth. Knowing this, we have learned not to blame this or that interpretation for what it does not give, but to be grateful to it whenever we have the opportunity to use it.
>
> Yet we are forced to point out the limitations of an interpretation as soon as we notice the hypertrophy of this or that translation which attempts to identify itself with the original and substitute itself for it, i.e., which monopolizes a certain entity jealously cutting off all other interpretations.

I will address later in this chapter the question of interpreting poetry. The problem of the "limitations of an interpretation" will also appear in the discussion on theology.

Talking about functions of a complex variable, Florensky discusses the works of Lejeune Dirichlet, Riemann, Weiertrass, and others. He notes in passing that the notion of function as a "correspondence" is "insufficient, for if we take into consideration only the **content** (the 'material cause') of the function, we miss the essential point, the function itself as a whole, as a **form** linking this content into a whole (the 'formal cause')"[27] (Florensky 2016, pp. 36–37).

Then comes a part on projective geometry, a geometry dear to the Renaissance mathematicians and artists,[28] and it is not surprising that it fascinated Florensky, especially later on; he taught perspective drawing, and he wrote articles and a book on this topic. The importance of projective geometry for the rest of this work will

[26] Rafael Bombelli, whom we mentioned in Footnote 24 before, is however missing in this list.

[27] The bold face and the quotation marks, here and in other quotes, are Florensky's.

[28] Leonardo da Vinci and Albrecht Dürer come to mind first, but there are many others, and I would like to mention just a few of those discussed by Florensky in his important book on religious art, *The Reverse Perspective* (Florensky 1992): Leon Battista Alberti, Filippo Brunelleschi, Paolo Uccello, Piero della Francesca, Donatello, Masaccio, Fillippo Lippi, Raphael (Raffaello Sanzio), Michelangelo Buonarotti, and there are others. The history of perspective is developed by Florensky in this book and in other articles referred to there.

also become clearer when Florensky will explain, in the last section of the *Imaginaries*, with Dante's poem in the background, that the projective plane is an important part of our physical universe. I will comment on this below. Florensky proposes to develop analysis (in the mathematical sense of the term) on two sides of the same surface, to which he refers as a real side and an imaginary side. He attempts to extend the duality of projective geometry to a philosophical context. Villani, in his Preface to the book, insists on the fact that Florensky's interest lies not only in the mathematical side of things: "We must seek the reason for this duality in something else, something deeper." Florensky expounds a metaphor concerning the real world and the imaginary one, and the visible world and the spiritual one, which finds its apogee in the evocation of the *Divine Comedy* that I shall review below.

In a relatively long section of the book, titled *Explanation of the cover*, Florensky comments on the book cover,[29] the work of the artist Vladimir Favorsky, a well-known graphist, woodcut illustrator, and painter who was his friend and colleague at the VKhUTEMAS.[30] In this section, Florensky, reviewing the phenomena of perception and the psychology of vision, talks about a duality in concrete visual perception which is an expression of the dualistic nature of the geometric plane, where the visual images correspond to the real side of this plane, and the abstractly visual images to its imaginary side.

Since we are talking here of projective geometry, let me also note that Florensky's *Reverse Perspective* (Florensky 1992) contains several mathematical and historical notes on this topic and its complex and long development, with mention of works of Ptolemy who, in his *Geography*, described the stereographic projection from the sphere onto the plane, together with other projections that were used in the art of drawing geographical maps, as well as works of Lambert, Loria, Aschieri, Enriques, Chasles, Poncelet, von Staudt, Fiedler, Wiener, Kupfer, Burmeister, Wilson, and the writings of the historian of mathematics Moritz Cantor on this subject.

Florensky completed his book in July 1922. At that time, he was teaching at VKhUTEMAS. It was the occasion for him to explain his ideas on space and time in art. Vassily Kandinsky was teaching at the same institute. The scientist and the artist, who were both art theorists as well, were friends. Kandinsky was influenced by Florensky; there are several articles on this topic (see Taroutina 2016; Sokolova 2015). The book (Misler 2006) contains a collection of writings of Florensky on art.

4 Dante

Section 9 of the *Imaginaries*, which is the last section of the booklet, is dedicated to the 600th anniversary of the death of the founder of Italian poetry. This event was celebrated in Russia on September 14, 1921. I will comment now on this section of Florensky's work.

[29] This cover won a Silver Medal at the 1925 *Exposition des Arts Décoratifs* held in Paris.

[30] VKhUTEMAS is an abbreviation for the Russian expression "Higher Art and Technical Studios." This is the state art and technical school where Florensky lectured from 1921 to 1924.

A certain number of modern mathematicians and other authors have quoted passages from the *Divine Comedy*, in order to point out a mathematical idea that they consider Dante expressed there, though in a hidden way, namely, that the universe is a three-dimensional sphere. Let me mention some of these authors, approximately in a chronological order: The physicists I. Ozsvàth, and E. Schücking, in the article *An anti-Mach metric*, published in the book *Recent Developments in General Relativity* (Ozsvàth and Schücking 1962), and the same authors 34 years later, in the article *The world viewed from outside* (Ozsvàth and Schücking 1998); M. Peterson, in his paper *Dante and the 3-sphere* (Peterson 1979), and the same author some 30 years later, in his paper *The geometry of paradise* (Peterson 2008) published in the Mathematical Intelligencer; R. Osserman, in his book *Poetry of the Universe: A Mathematical Exploration of the Cosmos* (Osserman 1995); W. Egginton, in his paper *On Dante, Hyperspheres, and the Curvature of the Medieval Cosmos* (Egginton 1999); M. Wertheim, in her book *The pearly gates of cyberspace: A history of space from Dante to the internet* (Wertheim 1999); G. Mazzotta, in his article *Cosmology and the Kiss of Creation (Paradiso 27–29)* (Mazzotta 2005); S. L. Lipscomb in his book *Art Meets Mathematics in the Fourth Dimension* (Lipscomb 2011); Curt McMullen in his survey, *The evolution of geometric structures on 3-manifolds* (McMullen 2010), published in the Bulletin of the American Mathematical Society;[31] M. Bersanelli, in his article *From Dante's universe to contemporary cosmology* (Bersanelli 2016); C. Rovelli, in his article *Michelangelo's stone: an argument against Platonism in mathematics*, published in a philosophical journal (Rovelli 2017); E. Ghys, in his book *A singular mathematical promenade* (Ghys 2017); and K. Sunada, in the article *From Euclid to Riemann and beyond: how to describe the shape of the universe*, published in a book I edited (Sunada 2019).

Let me also mention the interesting and beautifully illustrated article (Dreyer 1921) by J. L. E. Dreyer, *The cosmology of Dante*, in *Nature*, in which the author surveys Dante's cosmological ideas expressed in his poem (with no mention of the topology of the space described there). The article ends with the words: "To the student of the history of science it is a never-failing source of pleasure to find medieval cosmology so beautifully illuminated in the writings of the great Florentine poet" (Dreyer 1921).

I think that all these authors failed in two ways: First of all, none of them refers to the work of Florensky which was written between 40 years and almost a century earlier, although for several among them, this is understandable because Florensky's booklet, until its first translation in French in 2016, existed only in Russian.[32] Let me

[31] McMullen's survey starts with the sentence: "In 1300, Dante described a universe in which the concentric terraces of hell—nesting down to the center of the Earth—are mirrored by concentric celestial spheres, rising and converging to a single luminous point. Topologically, this finite yet unbounded space would today be described as a three-dimensional sphere."

[32] First edition, Moscow, Pomor'ye 1922 (1000 printed copies), new edition, Moscow, Lazur, 1991.

mention incidentally that one rarely finds authors on this list who quote others on the same list who made equivalent statements. Among the few authors who cited others are Rovelli, Sunada, and Ghys, who quote Peterson.

The second way I think these authors failed is that all of them declared, omitting an important part of Dante's poem which was highlighted by Florensky, that the space which is described by the Florentine poet is the three-dimensional sphere. In fact, they missed the part on the nonorientability and projectivity. The only paper I am aware of where the authors mention nonorientability is a commentary on Florensky's *imaginaries* by Bayuk and Ford (2003), in which the mathematical phrasing is very shaky but where the authors reach the conclusion that "[. . .] All these considerations brought Florensky to the conclusion that the geometry of Dante's cosmos is very similar to that of the single-sided elliptical surface described by Riemann and Klein."

Before developing this, I would like to point out that Florensky, with his acute intellectual honesty, noted that three authors before him had observed that the geometry of the *Divine Comedy* is non-Euclidean, namely, the American mathematician George Bruce Halstead (1853–1922), the German mathematician Heinrich Martin Weber (1842–1913), and the German historian of mathematics Maximilian Simon (1844–1918).[33] For the fact that Dante's world is non-Euclidean (which presumably means, in this setting, that it carries a geometry of positive curvature), Florensky refers to a passage in the *Divine Comedy* where the author speaks of "triangles whose angle sum is not equal to two right angles." Indeed, at some point of the exposition, Dante quotes King Solomon who asks the Lord whether there exists a triangle inscribed in a semicircle, with one side being the diameter, and no right angle (*Paradiso*, Canto XIII, v. 101–102):[34]

non *si est dare primum motum esse*,	nor *si est dare primum motum esse*,[35]
o se del mezzo cerchio far si puote	nor if in a semicircle a triangle can be formed
triangol s'ı ch'un retto non avesse.	without its having one right angle.

The question of nonorientability needs a longer quote and is based on Florensky's analysis, which I will review now.

Florensky starts by recalling Dante's description of the Ptolemaic model of the universe, composed of spheres: the Earth, the celestial bodies and the spheres on which they stay, together with the Empyrean stratum, surrounding the whole universe and occupied by the element of fire. Dante recounts a long imaginary journey he makes on his way to visit God, who dwells in the last circle after the Empyrean. The path he takes leads successively through Hell, Purgatory, and Heaven. In this journey, Dante is accompanied by Virgil, the Roman poet from the first century BC, author of the *Aeneid*, who guides him through Hell and most of the Purgatory. On

[33] Personally, I looked for written texts where these authors made such a statement, but I could not find any.

[34] Transl. Henry Wadsworth Longfellow (1807–1882).

[35] "nor if we have to admit a prime motion" (Dante wrote this line in Latin).

their way, the two poets start by going downward, traversing one after the other the spirals of Hell. It is important to note that during this descent, they always maintain a standing position, their heads pointing toward the point from which they started, that is, the city of Florence, and their feet directed toward the center of the Earth. When the two poets find themselves at the bottom of Hell, they see Lucifer with legs up and head down. It is conceivable (and mathematically equivalent) that at this point they are themselves turned upside down, with their feet directed toward the surface of the Earth and their heads on the opposite side (see Fig. 5). Here is the passage of the *Divine Comedy* quoted by Florensky (*Inferno*, Canto XXXIV, v. 76–96):

Quando noi fummo l dove la coscia	When we were come to where the thigh revolves
si volge, a punto in sul grosso de l'anche,	Exactly on the thickness of the haunch,
lo duca, con fatica e con angoscia,	The Guide, with labour and with hard-drawn breath,
volse la testa ov'elli avea le zanche,	Turned round his head where he had had his legs,
e aggrappossi al pel com'om che sale,	And grappled to the hair, as one who mounts,
sì che 'n inferno i' credea tornar anche.	So that to Hell I thought we were returning.
"Attienti ben, ch per cotali scale",	"Keep fast thy hold, for by such stairs as these,"
disse 'l maestro, ansando com'uom lasso,	The Master said, panting as one fatigued,
"conviensi dipartir da tanto male"	"Must we perforce depart from so much evil."
Poi uscì fuor per lo fóro d'un sasso,	Then through the opening of a rock he issued,
e puose me in su l'orlo a sedere;	And down upon the margin seated me;
appresso porse a me l'accorto passo.	Then tow'rds me he outstretched his wary step.
Io levai li occhi e credetti vedere	I lifted up mine eyes and thought to see
Lucifero com'io l'avea lasciato,	Lucifer in the same way I had left him;
e vidili le gambe in s tenere;	And I beheld him upward hold his legs.
e s'io divenni allora travagliato,	And if I then became disquieted,
la gente grossa il pensi, che non vede	Let stolid people think who do not see
qual quel punto ch'io avea passato.	What the point is beyond which I had passed.
"Lvati s", disse 'l maestro, "in piede:	"Rise up," the Master said, "upon thy feet;
la via lunga e 'l cammino malvagio,	The way is long, and difficult the road,
e gi il sole a mezza terza riede".	And now the sun to middle-tierce returns."

The two poets, after having avoided the center of the world, continue, following the same way, but now they find themselves moving upward, until they traverse a crater track, to find themselves in the clear world. This is illustrated here in Fig. 5, from a manuscript in the Vatican Library (Inferno, Canto XXXIV, v. 130–139):

Lo duca e io per quel cammino ascoso	The Guide and I into that hidden road
intrammo a ritornar nel chiaro mondo;	Now entered, to return to the bright world;
e sanza cura aver d'alcun riposo,	And without care of having any rest
salimmo s, el primo e io secondo,	We mounted up, he first and I the second,
tanto ch'i' vidi de le cose belle	Till I beheld through a round aperture
che porta 'l ciel, per un pertugio tondo.	Some of the beauteous things that Heaven doth bear;
E quindi uscimmo a riveder le stelle.	Thence we came forth to rebehold the stars.

Fig. 5 Illustration of canto XXXIV of Dante's *Inferno*, with Lucifer upside down, from a manuscript in Rome, Vatican Library, Ms. Urb. Lat. 365, fol. 95v. Ferrara, 1474–1482

Beyond this limit, Dante begins the ascent toward the celestial spheres, always following the same line, passing through the Empyrean where he is able to contemplate the Glory of God, and eventually ending up again in Florence, where he began his journey. In other words, the poet, having traveled along a (non-Euclidean) straight line in the three-dimensional world, finds himself at the same place and in the same position, but after having undergone a complete reversal. The surface on which he has traveled is nonorientable. Obviously, Dante did not have the technical means to express this fact in the way a mathematician would today and, likewise, he did not have the technical means to say that the universe is a three-dimensional sphere. Florensky commented on Dante in his own way, using the tools he had, and letting his imagination do the rest.

Florensky calls Dante "the greatest master of world design" (Florensky 2016, p. 70), and the last sentence of the *Imaginaries* reads: "Thus, beyond time, the *Divine Comedy* is not behind, but in front of contemporary science" (Florensky 2016, p. 78).

I said earlier that all the modern authors I mentioned failed to understand Dante's cosmology, and I explained why. In fact, Florensky himself considered that his

predecessors failed to understand Dante's cosmology, for another reason. Let me quote him on this. Before he gives his own description to which I have just referred, he writes, on p. 71 of (Florensky 2016):

> The following image is usually given in commentaries on the *Divine Comedy*. The terrestrial sphere is surrounded by the sphere of celestial bodies, by the sky of unchanging, immovable stars, by the crystal sky and finally by the Empyrean, and Dante's path from the bosom of the Earth follows a broken line spiraling through the concentric spheres and curving 180° towards the zenith of Sion. But this drawing corresponds neither to Dante's narrative, nor to the foundations of cosmology.

I noticed long ago that Dante occupies a special place in Russian culture. Talking with some Russian colleagues and friends, I realized that some of them can recite passages of the *Divine Comedy*; they learned it at school. I cannot resist mentioning the first three lines of this poem, which my Russian colleague, Mitia Millionschikov, to whom I recently told about the article I was writing, spontaneously recited:

Nel mezzo del cammin di nostra vita,	Midway upon the journey of our life,
mi ritrovai per una selva oscura	I found myself within a forest dark,
ch la diritta via era smarrita.	For the straightforward pathway had been lost.

I will mention Andredi Tarkovsky later in this chapter. The opening of the *Divine comedy* is recited (twice) in his film *The mirror*.

Let me end this section by mentioning that in his major theological work, *The pillar and ground of the truth*, which I will quote several times, Florensky refers to another grand epic poem in which a long journey is recounted, the *Odyssey*.

5 Time, Relativity, and Literature

In the *Imaginaries* (Florensky 2016), after the passage on Dante, comes a discussion of Einstein's theories of special and general relativity, an important component of the book. Florensky's goal is to show that, in the same way as "space must be represented as an elliptic space and recognized as limited, time is limited and is closed in on itself." (Florensky 2016, p. 73].

Sabaneeff, who kept notes of his conversations with Florensky, recalls that the latter had the following thoughts (Sabaneeff 1961, p. 322–323):

> Time, like space, can be not only straight but also curved (Einstein's time is curved). It can be infinite, but it can also be closed (analogous to a closed line). The concept of a single future is nothing but a theory of predestination. Furthermore, at every moment, the future divides itself into a multitude (infinity) of actual new futures. The "closed" time, after having run its cycle, "returns" and is inevitably drawn into the "sphere of eternal repetition," into a vicious circle, which he was inclined to identify with the idea of "hell" in religion.

I think that every sentence in this quotation could be analyzed in the context of scientific and philosophical culture of those times, and of today. In fact, one could

make relations with the idea of eternal return which is associated with Pythagoreanism, Platonism and Stoicism in Ancient Greece, then Proclus, Maximus the Confessor, and many others. Closer to us, the idea of eternal return was revived by Nietzsche, late in his life, in his search for a way to combat nihilism.

Florensky understood early on that the theory of relativity has changed the worldview of scientists, and that in this context, Copernicus' heliocentric system was no more valid than the geocentric theory of the Ancients. More than that, he maintained the following (Florensky 2016, p. 75):

> It would be a serious error to declare that the two systems, Copernicus' and Ptolemy's, are equally legitimate: they are so only in terms of abstract mechanics, but in terms of all the data, it is the latter that is true and the former that is false. This is a direct confirmation of the great poem, albeit more than six hundred years later.

Florensky is talking here about "data." Ptolemy collected a huge amount of data for the drawing of geographical maps, in his *Almagest*, for celestial maps, and his *Geography*, for terrestrial maps. It is true that Ptolemy's data, and the maps that were drawn using them, are amazingly precise, despite the rudimentary means used for collecting the needed astronomical observations, and despite the fact that the theory is based on a geocentric system. Florensky's defense of Ptolemy's system, a defense which was not being accepted by some of his contemporaries, was the cause of subsequent troubles with the authorities who accused him of obscurantism. These problems are reported and commented on in an interesting addendum to the French edition of the *Imaginaries* (Florensky 2016, p. 95–118).[36] Although at some point Florensky gives a reasonable exposition of some elements of the theory of relativity, he introduces other thoughts that are part of the expression of his atypical view of science, which irritated the authorities, accusing him of antimodernism, and which were termed irrational by readers of that work. At the end of his book, after his excursus on the *Divine Comedy*, Florensky, returning to the *imaginaries*, writes:

> The domain of the imaginary is real, conceivable, and in Dante's language it is called the **Empyrean**.[37] We can represent all of space as **double**, being formed of surfaces with

[36] The Postface to the French edition of the book, written by Pavel Vassilievich Florensky, the author's grandson, contains the translation of a letter sent by Pavel Aleksandrovich Florensky to the *Political Department*, dated September 13, 1922. The letter starts by the words: "This is not to claim everyone's 'right' to print whatever comes to his mind, and while recognizing that, in the name of goals concerning the whole state, the authorities cannot yield to the interests of literature, but I assume that in the case at hand, of my little brochure on *Imaginaries*, there is a *quid pro quo*, which can be explained by the novelty of the object, which is why I will take the liberty of disturbing the censors in order to set out the following considerations. . . ." The passage that was censored is the one about Dante, and Florensky recalls in his petition the context in which he wrote this passage (the 600th anniversary of the death of the Florentine poet) while defending the use in geometry of poetic images as the expression of a certain *psychological factor*. He ends his letter with a reminder of the work he is conscientiously doing to serve the State. His request not to have the book censored was eventually accepted.

[37] The bold face letters are Florensky's.

> Gaussian coordinates, real surfaces and imaginary ones corresponding to them, but the transition from the real to the imaginary surface is only possible through the **fracture** of space and the **turning** of the body inside itself. In the meantime, we only represent this process through the acceleration of motion, perhaps through the motion of certain small parts of the body, beyond the speed limit c, but we have no proof that other means are impossible.

In this passage, the expressions *fracture* and *turning* that Florensky emphasizes refer to the discontinuous operation of orientation-change that occurs after one describes a complete geodesic in the projective plane. In Fig. 6, I have reproduced an illustration of Florensky's *Imaginaries in geometry*, of a man walking in a nonorientable world. As to the mathematical notion of discontinuity, I already mentioned that it was already at the service of the philosophy of Bugaev, Florensky's first mentor who exerted a strong influence on him. I shall elaborate on this in Sect. 6. Let me quote here another passage of the *Imaginaries* in which Florensky talks about discontinuity (Florensky 2016, p. 76):

> What does the speed limit $c = 3 \times 10^{10}$ cm/second actually mean? It does not mean that velocities equal to or greater than c are impossible, but it does mean that with them would appear entirely new conditions of life that we cannot yet visually represent, and, perhaps, forms transcendent to our Kantian terrestrial experience. But this does not at all mean that such conditions are impossible, and perhaps as the realm of experience expands, they will become representable. In other words, the life of a world with velocity equal to c is qualitatively different from that observed with velocities below c, and *the transition between the domains of this qualitative difference can only be thought of as discontinuous*.

In a manuscript on religious art, written in 1922 and published in Russia in 1999 and in French translation a little bit later (see the historical note in Florensky 1992, p. 121), Florensky expresses a similar idea:

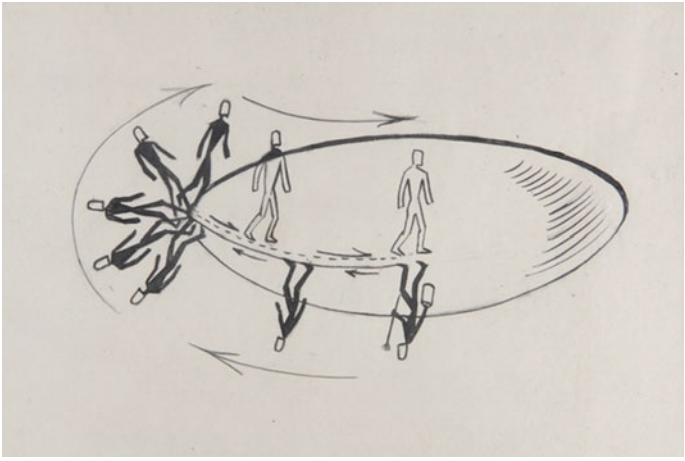

Fig. 6 Illustration from Florensky's *Imaginaries in geometry.* 1922. Paper, ink

> [. . .] While everyone agrees, even without knowing the principle of relativity, that every system (at least in relation with the case under consideration) has its own time, its own rhythm and its own measure, very few people have thought about the possibility of time running at an **infinite** speed, and even turning around completely, once this infinite speed has been exceeded, and **reversing** its course. But time can really be instantaneous, flowing from the future to the past, from consequences to causes, teleologically speaking, and this is what happens when our lives move from the visible to the invisible, from the real to the imaginary.[38]

The last three quotes express similar ideas, in different contexts, poetry, science, and the imaginary. The reversal of time is a counterpart to the idea of reversal of space, expressed in the *Reverse perspective*.[39]

The *Imaginaries* had an impact on the symbolist and Neoplatonic trend in Russian philosophy. In the Postface, written by Florensky's grandson (p. 104–105 of the French edition), there is a passage on the influence of this work on the philosopher Aleksei Fedorovich Losev (1893–1988), who referred to the last section of the *Imaginaries* for the possibility of a motion at a velocity greater than that of light, where "the body collapses into itself; its surface folds up within itself, turning inside out, through itself, and time begins to flow backwards, i.e., the consequence precedes the cause . . . The cause is transformed into a goal, an ideal."

I would like to end this section by a few words on the influence of the *Imaginaries* on literature, and for this I will quote another passage from the Postface of the French edition (Florensky 2016, p. 105–106). It concerns Mikhal Bulgavov, one of the best Russian writers of the twentieth century:[40]

> Mikhal Bulgakov's widow, Elena Sergeyevna Bulgakova, testifies that the writer liked Florensky, and that his library contained a copy of the *Imaginaries*. This book was one of the writer's first purchases in Moscow, and he would hide it from onlookers. One of the most inspired and lyrical passages of the novel *The White Guard*, written in 1923–1924, appears as a paraphrase of the concluding paragraph of *The Imaginaries*. [. . .] While working on his novel *The Master and Margarita*, Bulgakov reread the *Imaginaries* more than once. His copy of the book contains underlined words and exclamation marks in the margins of the pages of paragraph 9. Elena Bulgakova recounts that when the first listeners of *The Master and Margarita* heard, dumbfounded, the novel's finale, Bulgakov pointed out to them the

[38] Here, Florensky refers to the work of Carl Du Prel (1839, 1899), who wrote about instantaneous time (without mentioning inverted time).

[39] It may be useful to recall here that "reverse perspective," or "inverted perspective," is a technique of drawing, used in Byzantine and Russian icon painting, which is in opposition with the rules of perspective that are followed in Western classical art and theoreticized by the Renaissance artists. In reverse perspective, objects depicted that are supposed to be further away from the viewer of the painting are drawn as larger, whereas closer objects are drawn as smaller. In reverse perspective, parallel lines that move away of the viewer of the picture are drawn as diverging instead of converging lines, as they are drawn in the usual linear perspective drawing.

[40] Mikhail Afanasyevich Bulgakov (1891–1940) is best known for his novel *The master and margarita*, one of the important pieces of literature of the twentieth century. It was written under the Stalin regime. Bulgakov was a medical doctor. During his lifetime, the novel belonged to the underground literature in the Soviet Union. It was published posthumously, for the first time as a book, in Paris, in 1967.

> pages of Florensky's book that scientifically confirmed his ideas. In Florensky's mathematical and philosophical interpretation of Dante's journey with Virgil, Bulgakov saw the basis for the final chapters of his novel.

We have been naturally led to literature, and I will say more about this in Sect. 8. I would like to end this section by quoting again Sabaneeff, from his article (Sabaneeff 1961, p. 321), on the mathematical tendency of Florensky:

> [Florensky was] an excellent mathematician who concentrated his attention primarily on the latest trends in mathematics, he expressed time and again the idea that mathematics was broader and more comprehensive than the human mind. Mathematics, according to him, "is more intelligent than the human brain; it leads man farther ahead into regions inaccessible to the brain and not corroborated by sensual images." It was clear to me that mathematics was his guide even in the area of mystic speculations: it helped him not only through the elementary language of numbers (as in the case of many earlier mystics) but by means of the whole panoply of the modern mathematical apparatus: analysis, the theory of sets, and all the latest theories on the boundary between physics and mathematics.

6 Bugaev and Florensky: Mathematics and Philosophy of Discontinuity

If one wishes to mention a single mathematician who exerted a definite influence on Pavel Florensky during the years he was a student at the Imperial University of Moscow, Bugaev's name comes naturally. Nikolai Vasilievich Bugaev taught mathematics at Moscow University from 1867 till his death. Besides being a founder and president of the Moscow Mathematical Society, he was also an active member of the Moscow Psychological Society. He is considered as the main founder of the Moscow school of function theory, about which I will say a few words in Sect. 7. Some of his students became first-order mathematicians; these include Nikolay Yakovlevich Sonin (1849–1915), Konstantin Alekseevich Andreev (1848–1921), and Dmitri Egorov, whom we already mentioned. He also exerted a strong influence on Boleslav Kornelievich Mlodzievsky, who was one of Florensky's teachers and whom we already mentioned as well.

Besides being a mathematician, Bugaev was a philosopher steeped in humanism and Christian philosophy. For him, mathematics was a means of expressing philosophical ideas. Notions like continuity and discontinuity, which formed the basis of the theory of functions that was at the heart of his mathematical investigations, were for him, at the same time, part of the language of metaphysics, used in theories concerning free will, continuity in history, social revolutions, etc. It was through his influence that Florensky made some of these mathematical notions the basis of his philosophical thought. Sabaneef writes about Florensky, in the article we mentioned (Sabaneeff 1961, p. 321): "It seems to me that the dominant motive of his life was the idea of the alliance and fusion of science and revelation, the termination of the antagonism between these two spheres that had developed in the course of the historical process."

To give an idea of Bugaev's world and his influence on Florensky, I will make a short overview of the talk he delivered at the 1897 International Congress of Mathematicians held at Zurich.[41] The talk was naturally in French and is titled *Les mathématiques et la conception du monde au point de vue philosophie scientifique* (Mathematics and the conception of the world from the point of view of scientific philosophy) (Bugaev 1898a). The aim of this talk is to develop the idea that some fundamental principles of mathematics are at the basis of important philosophical conceptions of the world. Thus, the subject of the talk involves science, philosophy, and the description of the world.[42] The mathematical concepts that are referred to are those that accompanied Florensky in his later philosophical writings: discontinuity, contradiction, the infinite, antinomy, etc.

Bugaev declares in his talk:[43]

> It is very important to examine presently the influence of these parts of mathematics on the scientific and philosophical conception of the world. [. . .] At present, this need for number and measurement seems to be the vital issue of the day, not only in science, but also in art and human relations. Finding the measure in the realm of thought, will and feeling is the problem of the contemporary philosopher, politician and artist.

Bugaev, in his speech, wants to show how man, with the help of "number and measure," can get out of the realm of instinct. He considers that what is needed for that purpose is the theory of functions. He makes a distinction between *analysis*, the theory of continuous functions, and *arithmology*, the theory of discontinuous ones.[44] He states that mathematical analysis is distinguished by its generality and universality while arithmology bears the stamp of an original individuality, and is attractive because of its mysterious character and striking beauty. He believes that this explains the fact that some thinkers have linked various questions of mystical philosophy to questions related to the integers. He adds that the elegant truths of arithmology awaken in the scientist a sense of scientific beauty that fully satisfies him. He then talks about the applications of mathematical analysis in philosophy. Continuous functions explain mathematically some natural phenomena. It is interesting that he quotes a poem by the poet Sichler

[41] Initially, the first International Congress of Mathematicians was scheduled for the year 1900, and the Zurich congress of 1897 was planned as a trial congress. But eventually, the latter was so successful that it was considered later as the first ICM.

[42] This kind of philosophical topic, chosen as the subject of a lecture delivered at an ICM, was not exceptional. Poincaré, in his lecture to the same congress, titled *On the relationship between pure analysis and mathematical physics*, (Poincaré 1898) makes a comparison between mathematics cultivated for its own sake and that which has applications and used as a language for physics. He discusses these analogies in mathematics, the reason why mathematics needs other sciences to develop, questions of rigor, and, like Bugaev, issues of continuity and discontinuity.

[43] My translation from the French.

[44] In his article at the same congress, Poincaré also talks about the ideas of continuity and discontinuity. In particular, he says: "The only natural object of mathematical thought is the [natural] number. It was the external world that imposed the continuous on us, which we undoubtedly invented, but which it forced us to invent. Without it, there would be no infinitesimal analysis; all of mathematical science would be reduced to arithmetic or the theory of substitutions."

(translated from the Russian), expressing the analytic conception of the world. Having a closer look at natural phenomena, he concludes that the point of view of discontinuity is necessary, in particular in atomic physics, chemistry, biology, and sociology. "Discontinuity always appears, he says, where independent and autonomous individuality manifests itself," and further: "The highest human interests are often linked to problems of arithmology. The arithmological worldview indicates that final causes also play a role in the world's manifestations." Bugaev refers to Leibniz, as a source of inspiration for such questions. He explains why until present times only the analytical point of view was used in the scientific and philosophical considerations on the world and nature. The problem, he says, is that until now it was assumed that any scientific question assumes only one answer. But in arithmology, one finds functions that are multiple-valued, and sometimes these values are infinite. Such functions, he says, arise in nature, and he gives examples from sensation theory. He is led then to talk about antinomy. From the mathematical point of view, it is impossible to reconcile the concepts of continuity and discontinuity. But to have a complete understanding of facts of nature, we have to take equally into account the two notions. He says that in logic, biology, psychology, history of philosophy, and sociology, the universal and the individual, the concrete and the abstract, and person and society mutually complete each other. These thoughts are very much within the cosmic Russian stream of that epoch, according to which man and the cosmos are in harmony; this is why they called man a microcosmos, a terminology that was used in Ancient Greece by Anaximander, Plato, the Stoics, and others.

The use of the idea of discontinuity and its necessity in the description of nature, in Bugaev's teaching, did not escape Florensky. The title of the dissertation he presented at the Faculty of Mathematics and Physics in 1904, first under the supervision of Bugaev and, after the latter's death, under that of Egorov, is informative: *The idea of discontinuity as an element of a worldview*. He quotes this work several times in his later writings; see in particular Note 183 of the *Pillar* (Florensky 1975, p. 485), where he mentions the numerous existing works "in the domain of the formal investigation of the idea of discontinuity, i.e., in mathematics and in logic," referring to the bibliography given in the above manuscript. He then refers to the "works of the Moscow mathematical school," and in particular to Bugaev's *Introduction to the theory of numbers* and *Mathematics and the scientific-philosophical worldview* (Bugaev 1898b). In the same note, Florensky talks about the idea of discontinuity in thermodynamics, leading to the construction of the discontinuous thermodynamic surface, and in the works of Gibbs on phases, of Korzhinsky on heterogenesis, and of neo-Lamarckian and neovitalist researchers in biology, "opening broad horizons of the discontinuous evolution of organisms and their discontinuous adaptation." He also mentions researches in psychology and on the subconscious and superconscious psychic life, where one analyzes discontinuous changes in consciousness, in creativity, in inspiration, etc. In a note to Letter X of his *The pillar and ground of the truth*, titled *Sophia*, Florensky refers again to two papers by Bugaev, *Geometry of arbitrary quantities* and *Discontinuous geometry*.

In Sect. 2, I mentioned a passage from Florensky's autobiographical notes (Florensky 2007) where, talking about his 1899 crisis, he declares that the notion of continuity "suffocated him." This shows the importance of this topic for him, and at the same time, it shows how he experienced mathematics physically, in the same way he experienced sound – we shall talk about that in Sect. 8.

With Florensky, the notion of discontinuity also entered the realm of theology, which is the main subject of *The pillar and ground of the truth*. In Letter V, titled *The Comforter*, Florensky talks about "the discontinuity of the metahistorical revelation of the Spirit" (Florensky 1975, p. 101). In Letter VI, titled *Contradiction*, talking about the Apostle Paul, Florensky writes: "His brilliant religious dialectic consists of a series of discontinuities; it jumps from one affirmation to another, where each successive affirmation is antinomic with respect to the preceding one. Sometimes an antinomy is even embodied in a stylistic discontinuity of exposition, in an external asyndeton.[45] Rationally contradictory and mutually exclusive judgments have their sharp edges directed against each other." Antinomy and discontinuity are present in all of Florensky's theological works; I will say more about this in Sect. 10. Regarding the philosophical implications of the concept of discontinuity in Florensky's works, and, more generally, in Russian philosophical thought, let me mention the article (Oppo 2022) by Andrea Oppo, titled *Conceptualising discontinuity: Pavel Florenskii's* Preryvnost' *as a universal paradigm of knowledge*, in which the author discusses, among other things, Florensky's interpretation of Shakespeare's *Hamlet* in his essay (Florensky 2006a), and Florensky's passage on Dante in the *Imaginaries* (Florensky 2016).

To conclude this section on Bugaev, and talking again about the ideas of continuity and discontinuity beyond mathematics, let me mention a paper by Yuri Manin titled *Time and periodicity from Ptolemy to Schrödinger: paradigm shifts vs. continuity in history of mathematics* Manin (2019), in which the author discusses the idea of "scientific revolution," central in Thomas Kuhn's philosophy, opting rather to a theory of continuity for what regards the history of pure mathematics. In the same article, Manin mentions Ptolemy's system, also dear to Florensky.[46]

[45] By the word *asyndeton*, Florensky refers to a form of speech in which coupling conjunctions are dropped or replaced by commas, in order to speed up speech. An example, in the writings of Saint Paul to whom Florensky refers, given by F. Godet in (Godet 2002), is the following passage (*2nd Epistle to the Romans*, v. 9 and 10): "Tribulation and anguish, upon every soul of man that doeth evil, of the Jew first, and also of the Gentile; but glory, honour, and peace, to every man that worketh good, to the Jew first, and also to the Gentile." Godet comments: "As always, the asyndeton indicates a more energetic reaffirmation of the preceding idea." The notion of *asyndeton* is present at several places in the explanations that Godet gives in his book (Godet 2002).

[46] For a related discussion, the interested reader is also referred to the article on Manin in the present Handbook (Papadopoulos 2023). For a recent point of view on (the philosophy of) continuity and discontinuity in mathematics and in the relation between mathematics and physics, let me mention Plotnitsky's article *Continuity and discontinuity in, and between, mathematics and physics* (Plotnitsky 2023). Let me also take this opportunity to mention another paper by Plotnitsky, titled *The Image of time and the specter of the clock, from modernist literature to cinema* (Plotnitsky n.d.), in which he discusses continuity and discontinuity in Belyi's famous symbolist novel *Petersburg* (1913), and in cinema, in particular in the work of Andrei Tarkovsky, who was very close spiritually speaking, and also in his films, to Florensky, as we shall recall in Sect. 13. Plotnitsky tells me that Belyi's novel *Petersburg* is not only a founding novel of symbolism and of modernism in general, but it is also a novel about anarchism. In fact, the action takes place during the 1905 revolution. Plotnitsky points out the following passage from this novel which makes a relation with cinema, which in those times was one of the rising arts, seen by some (Lenin was among them) as the most important communist art: "We [our brains] are the unrolling of a cinematographic film subject to the minute action of occult forces; should the film stop, we will be fixed forever in an artificial pose of terror."

We have mentioned Bugaev's influence on Florensky. If, in another direction, we want to name a mathematician on whom Florensky had a definite influence, the first name that comes to mind is Luzin, of whom I will talk in the next section.

7 Luzin: Spiritual Crisis, Function Theory, Luzitaniya, and Disgrace

Nikolai Nikolaevich Luzin and his mentor, Dmitri Fedorovich Egorov, are usually considered as the founders of the Moscow school of functions of a real variable. Demidov, in his paper *On an early history of the Moscow school of theory of functions* (Demidov 1999), writes that this school was born with Egorov's *Comptes Rendus* note *Sur les suites des fonctions mesurables* (On the sequences of measurable functions) (Egorov 1911). In this paper, Egorov proves that any convergent sequence of measurable functions is uniformly convergent up to neglecting a set of measure ε, where ε may be chosen arbitrarily. The theorem was stated without proof by Lebesgue in his paper (Lebesgue 1903) and in his book (Lebesgue 1904).[47]

The development of the theory of functions of a real variable relies in an essential way on set theory, and more precisely, on the field known as "descriptive set theory," whose goal was to set up firm foundations for the topological and set-theoretical methods used in the theory of functions. Descriptive set theory may be considered as a subarea of mathematical logic, to a large extent based on the works of Georg Cantor (1845–1918), whose name is closely associated with the use of infinity in mathematics and who, incidentally, was Russian born.[48] Luzin was one of the architects of this emerging area, and an extensive development of this theory is contained in his 1930 book *Leçons sur les ensembles analytiques et leurs applications* (Lectures on analytic sets and their applications) (Luzin 1930). The French mathematicians that were thoroughly involved in this field include Emile Borel (1871–1956), René Baire (1874–1932), Jacques Hadamard, (1865–1963), Henri Lebesgue (1875–1941), Arnaud Denjoy (1884–1974), and Paul Painlevé (1863–1933). Florensky was a mathematics student at the time of the development of the foundations of function theory, with set theory in the background, the theory which remained for him a constant subject of reflection.

Luzin became familiar with the main problems of set theory and measure theory during a stay he made in Paris after the first Russian revolution and the bloody events in its aftermath (1905–1906). In Paris, he attended lectures on function theory by the leading mathematicians there. Functions were classified in terms of set-theoretic properties and limit operations. New sets emerged and were given names. Since open and closed sets are not stable under simple operations involving infinity, G_δ and

[47] Egorov attended Lebesgue's course at the Collège de France in 1903; see (Kuznetsov 1971).

[48] See the article (Sinkevich 2015) for a concise biography of Cantor, together with notes on Florensky, Mlodzievsky, and other actors of the Silver Age.

F_δ-sets were introduced as countable unions (respectively, intersections) of open (respectively, closed) sets. *Borel sets* are obtained from open or closed sets under the operations of countable union, countable intersection, and taking complement. Among the other classes of sets that appeared, we mention *A-sets* (A stands for "analytic"), later called *Suslin sets*, whose existence arose with a remark that Suslin[49] made, saying that a continuous image of a Borel set is not necessarily Borel, correcting a mistake made by Lebesgue on this metter.[50] Suslin introduced the class of *analytic sets* in his note (Suslin 1917). Luzin, who gave Suslin the impetus for the introduction of these sets, continued the latter's work on this topic after his death. *Baire functions* arose, as functions obtained from continuous functions by a transfinite repetition of simple limits. Baire first and second category sets[51] and *Luzin sets*[52] were introduced. Luzin introduced the notion of *projective set*, that is, a set obtained from a Borel set in *n*-dimensional Euclidean space by operations of projection and taking complement. The notion of *effective sets* (a set whose definition does not use the axiom of choice) was born. Lebesgue introduced the notion *of nameable set*, a set that can be "named." Luzin presents this notion, in his *Mémoire sur les ensembles analytiques et projectifs* (Luzin 1926). He writes:

> One of the fundamental ideas that we owe to Mr. Lebesgue is the precise distinction between the two notions of a nameable set and unnameable set. We already know what, according to Mr. Lebesgue, is meant by a nameable set: it is the set of points that can be named, i.e., characterized without possible confusion, by means of a suitable definition. "Nameable" sets are precisely those which, according to Mr. Lebesgue, are the necessary object of Mathematical Analysis. As we know, in the current state of Science, unnameable sets are those that can be obtained by means of Mr. Zermelo's Axiom or similar reasoning. It is these unnameable sets that Mr. Lebesgue considers doubtful: they can only be introduced into Science under the necessary condition that they show their interest, applicability, usefulness and efficiency in solving some classical problem. But, in general, it is the domain of nameable beings that is, par excellence, the content of Mathematical Analysis. This is the conception of Mathematical Analysis proposed by Mr. Henri Lebesgue.

Luzin was aware of the difficulties which affected the theory of functions that arose from set theory, including the use of transfinite constructions and the continuum hypothesis, the discovery of hierarchies between infinities, etc. Lebesgue refused the use of the axiom of choice, considering it as counterintuitive. He considered that in order for a mathematical object to exist, one has to be able to

[49] Mikhail Yakovlevich Suslin (1894–1919) was Luzin's student. He died at age 25 from typhus, an epidemic that followed the Russian Civil War.

[50] The story is recounted by Lebesgue in his preface to Luzin's monograph *Leçons sur les ensembles analytiques et leurs applications* (Luzin 1930).

[51] A *Baire first category set* is a subset of a Baire topological space contained in a countable union of closed subsets which all have empty interior. A *Baire second category set* is a subset of a Baire topological space which is not a Baire first category set.

[52] A *Luzin set* is a subset of the real numbers which is uncountable but whose intersection with every set of the first Baire category is countable.

explicitly "name" a property that defines it in a unique way. Bourbaki in (Bourbaki 2007, p. 53ff) has an interesting passage on this matter:

> For Lebesgue, who broadens the debate, it all boils down to knowing what we mean when we say that a mathematical being "exists"; for him, we have to "name" explicitly a property that defines it in a unique way (a "functional" property, we would say), and already the question of choosing a single element in a set seems to him to raise difficulties: we need to be sure that such an element "exists", i.e., that we can "name" at least one of the elements in the set. Can we then speak of the "existence" of a set in which we do not know how to "name" each element? Already, Baire has no hesitation in denying the "existence" of the set of parts of a given infinite set; in vain does Hadamard observe that these requirements result in abandoning even the idea of talking about the set of real numbers: it is indeed this conclusion that E. Borel eventually rallies to. With the exception of the fact that the countable seems to have acquired the right to exist, we have pretty much returned to the classical position of the opponents of "actual infinity."[53]

On the questions of existence and nonexistence of certain mathematical objects, Lebesgue, in the preface he wrote to Luzin's book, *Leçons sur les ensembles analytiques et leurs applications* (Luzin 1930), recounts the following story: "When I was a student, we used to have coffee and talk about general ideas; the discussion was getting hot and seemed bound to go on forever, when one of us shouted: 'First of all, you, do you exist? I say *you* for convenience, but even, do I exist?'. . . ."

In France, like in Russia, a group of religiously inclined mathematicians[54] raised questions such as how, and to what extent, infinity – which is an attribute of God – can be used in human and mathematical contexts. It was a period where mathematicians realized that the theory of transfinite numbers and the use of the axiom of choice may lead to contradictions. Lebesgue did not exclude the existence of sets that are neither finite nor infinite.[55] This indicates again the fact that the notion of infinity, in the mathematical context, must be used with care. It was natural that Florensky, even after he quitted the Mathematics Department of Moscow University, given his interest in all areas of science, and especially mathematics, kept abreast of all these developments which involve at the same time science, philosophy, and religion.

Luzin was also tormented by philosophical and religious thoughts. At the time he was a mathematics student, he underwent, like Florensky a few years before him, a spiritual crisis that shook what he called his "materialistic worldview," an expression which, at that time, meant atheism. Eventually, his relation with Florensky became an important factor in the resolution of this crisis and his return to mathematics. C. E. Ford, in his article *The influence of P. A. Florensky on N. N. Luzin*, writes (Ford 1998, p. 332–333): "The early history of the Moscow school has been greatly illuminated

[53] The clear distinction between actual and potential infinity was made by Aristotle. According to Aristotle, actual infinity cannot exist because it is paradoxical. Only potential infinity exists.

[54] In Russia, these mathematicians include Bugaev, Luzin, and Florensky. In France, the religious tendency among mathematicians is represented by Cauchy, Hermite, and Appell.

[55] Lebesgue writes in a letter to Borel: "Although I very much doubt that we will ever name a set that is neither finite nor infinite, the impossibility of such a set does not seem to me to have been proved"; see (Hadamard 1905). The same sentence is quoted in Luzin's ICM talk (Luzin 1929).

by the recent discovery that a close relationship had developed between Luzin and Florensky.. . This enabled Luzin to launch his career as a mathematician." The article (Ford 1998) is based on the correspondence between Luzin and Florensky which has been preserved, and I would like to quote some passages from it. This will confirm the fact that Florensky had a definite influence on one of the main founders, if not *the* main founder, of the twentieth-century Moscow mathematical school.

In a letter to Florensky sent from Paris, dated May 1, 1906, quoted in (Ford 1998, p. 335), and translated from (Demidov et al. 1989), Luzin writes:

> Life is too depressing for me, sometimes agonizingly depressing. I am left with nothing, no solid worldview; I am unable to find a solution to the "problem of life." My self-image is so frequently changing that life has become pure torment....You would not believe how precious your letter and your concern for my inner life were to me. It is horrible, horrible, infinitely horrible to feel yourself surrounded by egoism, nothing but unrelieved egoism.. .. By now you will have understood how precious to me, against the background of the vast and empty night that oppresses the soul, the heart, and the brain to madness, how precious to me is your concern for my inner life....I cannot be satisfied any more with analytic functions and Taylor series. To see the misery of people, to see the torment of life, to wend my way home from a mathematical meeting, to wend my way through the Aleksandrovsky Garden, where, shivering in the cold, some women stand waiting in vain for dinner purchased with horror – this is an unbearable sight. It is unbearable, having seen this, to calmly study (in fact to enjoy) science... . Then came the terrible days for us all [the 1905 revolution], for me in particular...I could not work in science, and I seem to have begun to lose my mind as a result of the impossibility of living quietly and understanding where, where the truth is. Yes, I now understand that "science," in essence, is metaphysical and based on nothing. The scientific quest for "differential resolvents for equations of degree six" is absolutely incomprehensible...At the moment my scholarly interests are in principles, symbolic logic, and set theory. But I cannot live by science alone. . . I have nothing, no worldview, and no education. I am absolutely ignorant of the philological sciences, history, philosophy...It is painfully clear to me that it makes no sense to settle for a "scientific" education.

Luzin's crisis lasted 3 years and was eventually resolved with the decisive help of Florensky, who persuaded Luzin to return to mathematics (Ford 1998). Upon his return to Russia, Luzin frequently visited the Sergiyev Posad monastery and valued his meetings with Florensky. In a letter to his wife, dated June 29, 1908, talking about Florensky's *Pillar*, of which he read a preliminary version, he writes (Ford 1998, p. 337):

> I read it all at once in a single day—skipping a lot, but the impression was overwhelming. As I read it, I was STUNNED the entire time by blows from a battering ram against a stronghold...Our life, the life of the XIX and XX centuries, is full of confusion, full of contradictions. The work of Florensky is one solution to this impossible situation.

Luzin was interested in all of Florensky's writings. In a letter dated June 19, 1919, he asks him: "I would like to have, if possible, all your published works. I do have many, but do not have your big works, the latest lectures on philosophy (it is said that they are already published) and above all, I do not have your thesis *The Pillar and Foundation of Truth*."

On his return to Moscow, Luzin joined the Faculty of Mathematics of Moscow University. He was appointed professor there in 1917, just before the revolution.

A few words on Luzin's mathematical interests are in order. Luzin was strongly influenced by French mathematics. In 1911 and 1912, Egorov and Luzin published a series of papers in the *Comptes Rendus* which confirmed the French school's support for the Russian (Egorov 1911; Luzin 1912; Luzin 1914). In particular, Egorov's result in (Egorov 1911) on sequences of measurable functions was a substantial improvement of previous works by Borel and Lebesgue. This result says that any sequence of measurable functions is uniformly convergent up to a set of arbitrarily small measure. Luzin's result in his paper (Luzin 1914), titled *Sur un problème de M. Baire* (On a problem of Mr. Baire), answers a question raised by Baire. Precisely, Luzin proved that under the assumption that the cardinality of the continuous is aleph one, there exists in the interval (0,1) a set E having the cardinality of the continuous such that any perfect set which is non-dense in (0,1) contains at most a countable set of points of E.

Luzin was an atypical teacher. Mikhail Alekseyevich Lavrentieff, who was his student, in a memorial article on his teacher (Lavrentieff 1974), writes that around the years 1922–1926, Luzin introduced to the mathematical division of Moscow university a new style of unprepared lectures, far from the standard "good lecture," and that the result was a brilliant, deep, and fascinating way of teaching, encouraging the development of originality and independent thinking. Lavrentieff also writes that the essential characteristic of the school founded by Luzin was "the fostering of independent thought, the capacity to crack problems, to find new methods and to pose new problems." He reports that Luzin prepared his lectures only in outline, that he was often late to his class, and that he believed that having a strict schedule was not compatible with doing mathematics.

Luzin's 1926 *Mémoire sur les ensembles analytiques et projectifs* (Memoir on analytic and projective sets) (Luzin 1926) starts with the words:

> The current state of mathematical analysis provides ample proof of the desirability of establishing a precise demarcation between mathematical beings regarded as "existing" and others whose reality is only apparent. . . .This distinction was the subject of the famous *Five letters on set theory*[56] by Messrs. Hadamard, Baire, Lebesgue and Borel, on whose necessity Mr. Emile Borel insisted with extreme exactitude in his later writings. This distinction between mathematical beings that are truly real and others that appear to be real, but which have no substratum and to which no intuition corresponds, is currently very necessary, but its imminent realization seems unlikely in the present state of Science.

In 1927, Luzin was elected corresponding member of the USSR Academy of Sciences. The following year, he was elected full member, but, surprisingly, at the Department of Philosophy. In 1928, he was Vice-President of the ICM (Bologna). He presented there a communication titled *Sur les voies de la théorie des ensembles* (On the paths of set theory) (Luzin 1929) in which he discussed the problems that arose in the theory of functions as a consequence of the questions that were raised in set theory regarding infinity and the definition of real number. He used in this communication the philosophical tone that Bugaev had, 31 years before him, in

[56] Luzin refers to the letters reproduced in (Hadamard 1905).

his ICM communication. The problems he addressed are the same as those that have preoccupied Florensky. In the introduction, Luzin writes:

> In order not to get bogged down in metaphysical discussions on the meaning of the word infinite, I shall confine myself here to discussing a particular point that no doubt attracts the attention of all mathematicians: this is an attempt to satisfactorily resolve the so-called continuum problem, posed by Georg Cantor some sixty years ago.

In the conclusion of the talk, after a tour of several problems concerning the foundations, Luzin ends with the sentence: "Over the centuries, the great debate between d'Alembert and Euler on the notion of arbitrary function now becomes the debate on arbitrary real numbers and even arbitrary positive integers."[57]

In 1930, Luzin published his monograph *Leçons sur les ensembles analytiques et leurs applications* (Luzin 1930), with an appendix by Sierpiński and a preface by Lebesgue. The book was published in Paris.

Lebesgue is full of praise for Luzin in the preface. At the end of this preface, he writes:

> [Luzin] has philosophical worries, and he admits this. For him, mathematical and philosophical imperatives are constantly associated, one might even say merged. Although his book is a mathematical work, written by a mathematician for mathematicians, this intimate association of philosophical and mathematical thought is clearly evident on almost every page, giving the volume exceptional importance and appeal.

At Moscow University, Luzin was a charismatic figure. A mathematical community was formed around him, affectionately called Luzitaniya, whose members were linked not only by mathematics but also by culture. S. S. Demidov and V. D. Esakov write in (Demidov and Lëvshin 2016, p. 3) that Luzin was "the acknowledged leader of the Moscow School of function theory, the heart and soul of the famous Luzitaniya, [. . .] a true brotherhood united around their adored teacher." They add (Demidov and Lëvshin 2016, p. 10) that "[Luzin] had a charismatic personality that was attractive to young people" and that "[he] felt most in his element when working in a tight circle organized like a family gathered around an adored father-teacher." Alexey Sossinsky tells me that no such mathematical community has ever existed since, except perhaps for the early Bourbaki members. Let me add that from what we know, Pythagorean communities were the same.

Luzin's last years were saddened as he became persecuted by the state and rejected by most of his former students. His fate was not comparable in severity to that of his old friend Pavel Florensky, but still, he was betrayed, he fell into depression, and he never recovered. I will say a few words on this now.

The violent campaign against Luzin started in the summer of 1936. The purpose was to expel him from the Academy of Sciences. The period was that of a relative political quiteness, just preceding Stalin's Great Purges, which started a year before

[57] Luzin refers to a controversy which involved some of the brightest mathematicians of the eighteenth century, among whom are Euler, d'Alembert, Lagrange, and Daniel Bernoulli, on the question "what is a function?" I have surveyed this question in §10 of the article (Papadopoulos 2017).

Florensky was shot. A document reproduced in the book (Demidov and Lëvshin 2016) shows that, as early as in 1931, a confidential letter signed by Ernst Yaromirovich Kol'man (1892–1979),[58] who became president of the Moscow Mathematical Society after Egorov was arrested in 1930, was sent to the divisions of the Central Committee, in which he accuses Luzin of several offences, among them, that of being closely connected with Emile Borel, "an active member of the military [French] establishment."[59] In the same letter, Luzin is accused to be an idealist militant, and as a proof of that, Kol'man quotes a passage from a report in which Luzin writes: "The series of natural numbers does not seem to be an absolutely objective structure. It seems to be an artifact of the brain of the mathematician who happens to be speaking about the natural numbers. There seem to me, among the problems of number theory, some that are absolutely unsolvable" (Demidov and Lëvshin 2016, p. 12).

The official public campaign against Luzin started with two anonymous articles in the *Pravda*, with the titles *Answer to Academician N. Luzin* (July 2, 1936) and *On enemies in Soviet masks* (July 3, 1936). The same year, a "Committee concerning N. Luzin" was created at the Presidium of the Academy of Sciences of the USSR. The committee was headed by the Vice President of the Academy, G. Krzhizhanovsky, and its members included several well-known mathematicians, among them I. Vinogradov, L. Shnirelman, S. Sobolev, P. Aleksandrov, and A. Khinchin. Kolmogorov and Lyusternik, without being members of the Committee, were invited to attend the meetings. Most of the committee members were Luzin's former students or students' students.

The academic accusation claimed that Luzin, by the end of the 1920s, showed a lack of interest in the mathematical schools that were emerging in the Soviet Union, and was only interested in his own field. The prosecution also claimed that he was putting pressure on his students to include his name in their publications, or to make them acknowledge his help in their work. We already mentioned that Luzin continued the work of his student Suslin, after the latter's death. In fact, he was accused of stealing this work. No one will ever know if there is any truth in this, because no one will ever know to what extent Suslin shared unpublished ideas with Luzin. I learned from Sossinsky that some of Luzin's students tried to appropriate Suslin's results after the latter's death. In any case, the claims that Luzin stole others' ideas contradict what Lebesgue wrote in the preface to Luzin's book (Luzin 1930): "Mr. Luzin is perfectly happy only when he has managed to attribute his own discoveries to someone else," adding that this is a "strange mania, forgivable, it seems, since it is hardly to be feared

[58] Kol'man was a virulent Marxist who, in his own way, brought order to Moscow's mathematical community in the 1930s. He is among those who attacked Florensky's *Imaginaries*, ridiculing "mathematics in the service of religion," "mathematics in the service of priestcraft," and "mathematics in the service of obscurantism" it contains (Demidov and Ford 2005, p. 608). He published an article in the Moscow journal *Bolchevik* titled *Against the recent revelations of bourgeois obscurantism*. See pages 114 ff. of (Florensky 2016).

[59] Borel had been the Minister of Naval affaires, between April 17 and November 28, 1925, in the government of Paul Painlevé, the French mathematician who became prime minister (in those days this function was called Président du conseil).

that Mr. Luzin will be a model in this respect." Luzin was also blamed, by the Academic court, for the fact that he published his papers in French rather than Russian journals, which was claimed to be a disloyalty to his country.

In the end, and surprisingly, Luzin was not condemned as an "enemy of the people," as was planned by his detractors. The common explanation is that the physicist Piotr Leonidovich Kapitsa[60] (1894–1984), who was the head of the Physics section of the Russian Academy of Sciences, wrote a letter to Stalin, saying that Luzin might yet be useful to the government; see (Hoffman 2009) where the author comments: "It is not clear why Stalin listened, but his whim ensured the future of a discipline." Still, after this affair, Luzin remained rejected by an important part of the mathematical establishment and the case left a deep wound in the Russian mathematical community.[61] He continued working, but in isolation.[62] In 1946, Luzin published a 900-page textbook on calculus for technological universities. In 1953 (the year Stalin died), 300,000 copies of the book were already sold.

This so-called "Luzin case," a combination of a generation dispute and personal interests, is considered to be one of the darkest episodes of the history of Soviet mathematics, if not the darkest one; see the details in (Demidov and Lëvshin 2016). Discussion of these events remained a taboo in the Soviet Union, until their reexamination several decades later. In 2012, the Russian Academy of Sciences reversed the decision that was taken against Luzin in 1936. A reconstruction of the minutes of the various trials that took place is carried out in book (Demidov and Lëvshin 2016) by Demidov and Lëvshin. The reader may also consult Demidov's article *The Moscow school of the theory of functions in the 1930s* (Demidov 1993) which constitutes an excellent concise report on the school founded by Luzin. The Lavrentieff memorial book (Dobretsov et al. 2000) contains a chapter dedicated to the Luzin case.

Today, it is clear that the reason behind Luzin's persecution was his religious convictions. The same thing had happened to Egorov. The latter, who had not been politically active, fell into disfavor with the Soviet authorities 6 years before Luzin. Demidov and Esakov write in (Demidov and Lëvshin 2016, p. 10) that "[Egorov] disliked the new regime and made no attempt to hide his negative attitude." The

[60] Kapitsa was awarded the Nobel prize in physics in 1978. In 1946, he refused to work on the Soviet atomic weapons, and this led to his dismissal from the Academy, a position he took up again in 1955, 2 years after Stalin's death. At his death in 1984, Kapitsa was the only member of the Russian Academy of Sciences who was not a member of the Communist Party.

[61] In an email I received on April 29, 2019, Alexei Sossinsky writes: "When the Committee concluded its work, it was expected that it would declare that Luzin is 'an enemy of the people', which meant that he would be sent to the camps or even be given the death penalty. But it didn't! Until a few years ago, we did not know why this happened. The publication of certain documents now gives us the correct story, which involves Kapitsa's letter, Kol'man's falling into disfavor, Krzhizhanovsky, Molotov, and Stalin, the final decision apparently being taken in a tête-à-tête between Krzhizhanovsky and Stalin."

[62] I learned from Yuri Neretin that in 1937–1939, Luzin published an ingenious work on some types of bendings of two-dimensional surfaces, solving a problem that had been discussed during 50 years; see (Luzin 1939). Unfortunately for him, the solution was negative and his work closed the topic and had no direct continuation. Sabitov wrote a review of this problem in (Sabitov 2016), in which he says: "a truly dramatic end to this direction of geometry came with Luzin's paper (Luzin 1939)."

campaign against him started in 1929 when Egorov, at the first All-Union Congress of Mathematicians in Kharkov, opposed a proposal to send greetings on behalf of the Mathematical Congress to the Sixteenth Party Congress; see (Demidov and Lëvshin 2016, p. 11). The same year, after having been President of the Moscow Mathematical Society for 7 years, he was dismissed from his position at the University. The next year, he was jailed for being a "religious sectarian." About Egorov's religiousness, see (Kolyagin and Savvina 2010). In fact, Egorov was accused of being part the so-called Catacomb Church (Demidov and Lëvshin 2016, p. 12).[63] Little is known about this sad story, and the information about Egorov's last years contains contradictions. Most probably, he died after a hunger strike. According to Demidov, he died in the hospital of the Institute for the Continuous Education of Doctors (a branch of Kazan University) (Demidov 1999). I learned from V. N. Berestovskiĭ that Egorov was buried in the same cemetery as N.I. Lobachevsky, in Kazan.

On the Luzin case, I have benefited a few years ago from correspondence with Yuri Neretin and Alexey Sossinsky. There are many comments on this in Neretin's article (Neretin 1914). Let me end this section by a last information about Luzin, which I learned from Sossinsky. The year before his death, Luzin thought he had a counterexample to the Goldbach conjecture. He sent his result to the *Doklady Akademii Nauk*. The example was numerical, with huge numbers involved. It took a large amount of time for the persons in charge of checking the result to find an error in the calculations.

The book *Naming infinity: A true story of religious mysticism and mathematical creativity* by Graham and Kantor (Graham and Kantor 2009), despite many historical, mathematical, and theological inaccuracy,[64] contributed in the rising of interest among Western readers in the history of Soviet mathematics.

[63] The "Catacomb Church" is a generic name for underground Christian communities in the Soviet Union who no longer felt part of the official Orthodox Church after the state took over its activities. The name makes reference to the Christians worshipping in the catacombs of Rome during the period of the Roman persecutions against Christians.

[64] Regarding the inaccuracy, see the corrective reviews by Hoffman (Hoffman 2009), Trimble (Trimble 2021), and Katasonov (Katasonov 2009), to mention just a few. See also the interesting bachelor thesis by Eriksson (Eriksson 2009). Katasonov (Katasonov 2009) argues against the claim which is repeated all over the book that Name Worshippers consider that naming things create them, whereas these worshippers never associated naming with creating. Trimble (Trimble 2021) notes that Graham and Kantor have no knowledge and a false reading of Orthodox theology. For instance, they conflate the hesychastic tradition as a whole with Name Worshippers. Eriksson writes that the book by Graham and Kantor with, "lamentably, very narrow view of the cultural context, attempts to analyse the connection between culture and mathematics." She adds that in their treatment, "Bugaev is left out, and in this way the mathematical roots of the tradition are cut. Graham and Kantor even seem to be unaware of Bugaev's contributions, as Bugaev is not mentioned at all in the discussion about continuity and discontinuity in Florensky's work." Personally, I do not see any reason for Graham and Kantor's insistence on homosexuality in the Russian mathematical community they describe, and for me their suggestion that Florensky was homosexual is bewildering. I think that it is based on a misinterpretation of his religious style of writing and a misunderstanding of his personality. In any case, homosexuality was severely condemned in Russia during the Soviet era, and Florensky was being very closely monitored. If there had been the slightest hint of his homosexuality, this would have been known and recorded by the KGB, but there seems to be nothing to suggest this in the documents found and published in (Chentalinsky 1993) and elsewhere.

8 Silver Age: Mathematics, Symbolism, Art, and Poetry

They call it "Silver" Age, but it is comparable to the Renaissance in Europe
(Valentin Poénaru told me).

In the chapter *The Practice of Mathematics in a Totalitarian Society* (Sossinsky 2023a) published in the present Handbook, Alexei Sossinsky talks about his past as a student at Mekhmat, the Faculty of Mechanics and Mathematics of Moscow State University, and then as a mathematician at this faculty, during the period called the "Golden Age of Russian mathematics." This is the epoch of an unprecedented development of mathematics in the Soviet Union, and it involves fields such as geometry, topology, number theory, function theory, probability theory, mathematical logic, and others. With this period are associated the names of Pavel Sergeyevich Aleksandrov (1896–1982), Mikhail Alekseyevich Lavrentieff (1900–1980), Andre Nikolaevich Kolmogorov (1903–1987), Israel Moiseyevich Gelfand (1913–2009), Yuri Ivanovich Manin (1937–2023), and several others, forming at least two generations of first-rank Russian mathematicians. The impact of their work on the development of mathematics worldwide was enormous. The reader interested by the history of this period of Russian mathematics may refer to the book (Zdravkovska and Duren 2007).

The Golden Age of Russian mathematics was preceded by another, sometimes referred to as the "Silver Age of Russian mathematics," which has been the subject of much attention in recent years among historians of mathematics; see the articles (Demidov 2021; Demidov 1993; Demidov 1999), and (Ford 1998). This is the period dominated by the figure of Luzin, which we presented in Sect. 7. Luzin mentored and had a significant impact on several of the key players of the Golden Age. This Silver Age of mathematics overlaps, by a few years, with a period also known as the "Silver Age," for poetry, literature, and art. It is a period which saw the birth of the Russian Symbolist movement, one of whose main protagonists was Andrei Belyi (Bugaev's son), whom we mentioned in Sect. 6. In 1910, Belyi published an important collection of articles bearing the characteristic name *Symbolism*, to which Florensky refers in several writings and in particular in his major theological work, *The Pillar and ground of the truth* (Florensky 1975).

Let me add that Andrey Andreyevich Markov (1856–1922) the outstanding Russian mathematician who worked in Saint Petersburg, best known for his work on stochastic processes, and Andrei Kolmogorov, the student of Luzin whom we already mentioned and who became the world leader of probability theory, algorithmics, complexity, and information theory, were both interested in the statistical approach to verse analysis in Russian poetry, a topic which was started by Andrei Belyi. Both Markov and Kolmogorov applied this approach to Pushkin's poetry; see (Markov 1913). More recently, Sossinsky wrote a paper on this topic, titled *Belyi–Kolmogorov theory* (Sossinsky 2023b).

Florensky, who belonged to the group of mathematicians of the Silver Age, was connected at the same time with the Russian symbolist movement, with its renewed interest for classical literature and for the significance of language. Since the times he was a student at Moscow University, he had close relations with Moscow's Symbolist literary circle. He published several articles in symbolist periodicals such as

Novyi Put' (New Way) and *Vesy* (Scales). In 1903, he published in *Novyi Put'* an article titled *Superstition* (Florensky 1903), which is concerned with supernatural phenomena and the psychology of their perception. In 1904, he published in the same journal an article titled *On symbols of infinity: Sketch of the ideas of G. Cantor* (Florensky 1904a), to which he referred later in the *Pillar*. This article is the first essay ever published in Russian on Cantor's ideas on infinity. In the same year, Florensky published in *Vesy* a series of poems, and an essay titled *On a certain premise of a worldview* (Florensky 1904b). In 1905, he wrote the essay we mentioned, with symbolist inclinations, *Hamlet*, on Shakespeare's play which many have seen as a work in which the author anticipates in several ways the modern world. This essay was meant to be published in the symbolist journal *Vesy* but was never published before it was included in Volume I of Florensky's Collected Works published in Moscow in 1994. It was recently translated into French, in the form of a booklet; see (Florensky 2006b).

Talking about symbolism in the Russian Silver Age, one should mention the names of some leading symbolist poets of that period: Vyacheslav Ivanovich Ivanov (1866–1949), a very complicated figure with a long and serpentine biography, Valery Bryusov (1873–1924), and Aleksander Blok (1880–1921). I like the following description of symbolism by Ivanov who, according to Sabaneeff (Sabaneeff 1961, p. 314), knew Florensky and had a high esteem for him: Symbolism is "a cult of eternity and all-embracing unity of the multicolored reflections of the moments" (Strakhovsky 1959).[65] Finally, in referring to the Russian Silver Age in art, one may mention the names of Chagall, Kandinsky, Stravinsky, Prokofiev, and Skriabin, to name but a few of the best known figures.

Florensky described symbolism as "the necessity of seeing the concrete incarnation of the soul." In his autobiography dedicated to his children, he writes: "All my life I have pondered a single problem, that of the symbol. [...] Positivism repelled me, but abstract metaphysics repelled me just as much. I wanted to see the soul, but I wanted to see it incarnate. Someone will say that this is materialism, but it is not materialism that is at stake, but the necessity of the concrete, of symbolism." In the same autobiography, we can read: "I have always been a symbolist. Symbols are created by the mind according to precise laws, and with an inner necessity, and this happens whenever certain aspects of the mind begin to function in a particularly lively way. What symbolizes and what is symbolized are not fortuitously interrelated." With all this, it is not surprising that Florensky's major theological and philosophical work, *The Pillar and ground of the truth*, is written in the language of symbols. He writes there, in the Xth letter (Florensky 1975, p. 236): "I am compelled to use a metaphysical terminology, but in my speech these terms have not a strictly technical sense but a conventional or rather a symbolic one. They have the significance of colors by means of which inward experience is painted." The language he uses is also the one of the *Imaginaries*.

[65] In this sentence, Strakhovsky in (Strakhovsky 1959) is translating Ivanov, from his article *Of the Merry Craftsmanship and Smart Revelry*, published in the ephemeral periodical *Zolotoe Runo* (1906–1909) (Ivanov 1907, p. 54).

Speaking of art and poetry, I would like to mention Florensky's inclination toward poetry and music. Sabaneeff writes, in an article I have already mentioned several times, that Florensky "was too far removed from music and from art in general." I think Sabaneeff was wrong.[66] In his autobiography and correspondence, Florensky regularly talks about music and poetry. As a child, he received a musical education, and everybody in his family listened to and played music. Let me quote a small passage from his recollections (Florensky 2007, p. 80): "As a child, my musical inclinations also led me to poetry. I was less interested in the meaning of verses than in their sound and rhythm. Endowed with an almost absolute memory, I was able to memorize everything that interested me, especially poems, instantly and with total precision." Florensky's writings are so full of musical references, thoughts on music and poetry, that one could write a book on the subject: *Music and poetry in the works of Pavel Florensky.*

Florensky also wrote poetry. Many of his poems were confiscated and are still lost, probably forever, but the volume of correspondence (Florensky 2021) contains an unfinished 60-page poem, ORO, which he wrote during his exile. It is translated into French by Françoise Lhoest.

Regarding sound and music, let me quote a passage from Florensky's correspondence (letter addressed to his mother dated 28–29.VII.1936) (Florensky 2021, Letter no. 70, p. 447):

> An acquaintance of mine asks me why I never write about the sounds of Solovki, but only about colors and shapes. This is because everything here is soundless, like a dream. This is the realm of silence. Not in the literal sense, of course; there is more than enough unwanted noise, and one would want to get away from it. But you cannot hear the inner sound of nature, you cannot perceive the inner words of beings. Everything glides along, in a shadow theater, and sounds are added from outside, like an appendix or a disturbing noise. It is hard to explain why nothing produces sound, why there is no music in things and in life, and I do not really understand, but all the same, there is no music.

Finally, talking about sound and music, I would like to quote another passage, this time from Florensky's autobiography, in which he describes how he experiences, in both a physiological and symbolic way, Chladni's figures, the acoustic lines formed on a plate rubbed by a bow[67] (Fig. 7). He writes (Florensky 2007, p. 66):

> I was feeling almost physically like a string, or rather like a Chladni plate, over which nature passes like a bow: in my soul, or rather in my whole organism vibrated, almost audible to the ear, a pure, high, elastic sound, and in my thoughts were ordered schematic figures, like Chladni figures, like symbols of worldly phenomena. I write and I am almost certain to be misunderstood. People will want to hear in these words comparisons and poetic essays, whereas I want to express, to draw from myself, the soberest and most literal description

[66] Sabaneeff based his opinion on the fact that when the poet Vyacheslav Ivanov introduced Florensky to the world of Aleksander Skriabin, Florensky did not fit in there; see (Sabaneeff 1961, p. 315).

[67] Ernst Florens Friedrich Chladni (1756–1827) was a German physicist, sometimes considered as the founder of modern acoustics. He conducted experiments consisting in making a plate vibrate by scraping it on the side with a bow, after covering it with a layer of fine sand, and observing the patterns the sand produces: geometric figures, always regular, but very different, depending on where and how the plate is excited. These are the *Chladni figures* mentioned by Florensky in the passage.

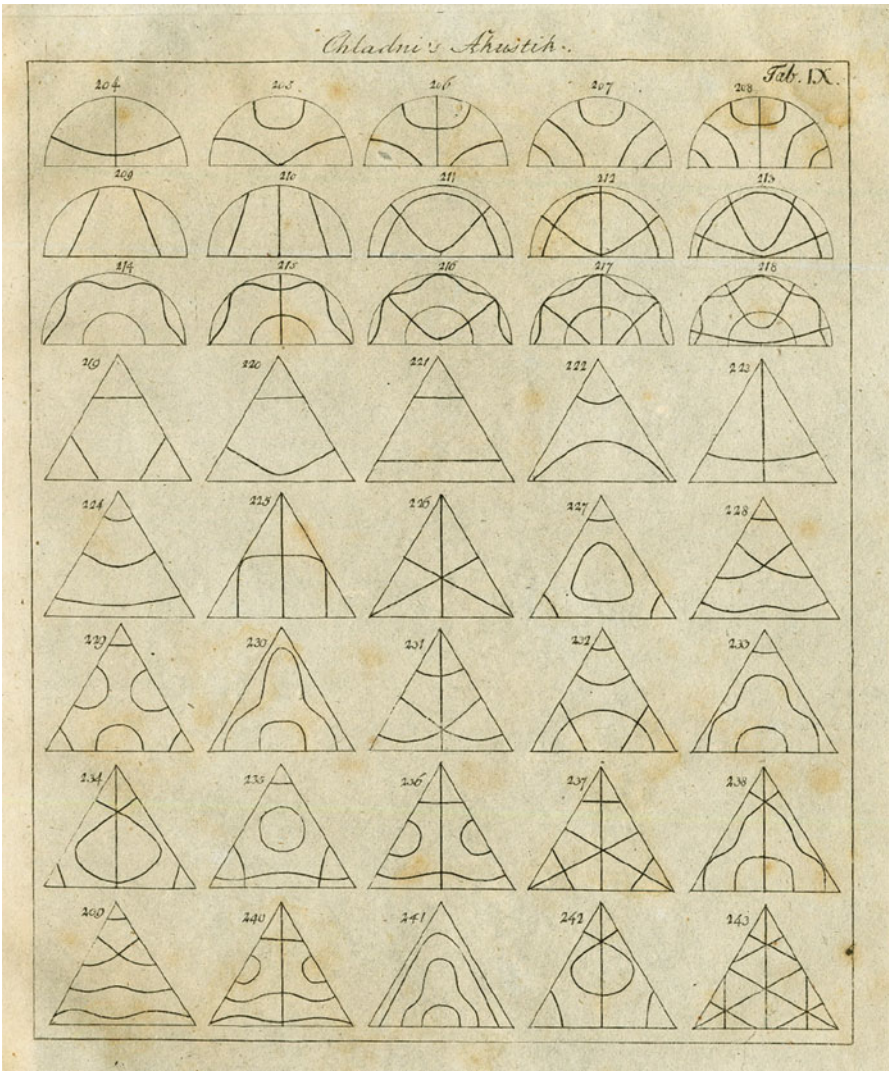

Fig. 7 Chladni acoustic figures, from Chladni's *Akustik* (Chladni 2015)

> possible, a kind of physiological picture. It consisted of this: everything in me, every vein, was full of an ecstatic sound that concentrated within itself *my* knowledge of the world, generating patterns of a rather mathematical order: my categories of knowledge.

Talking about poetry, let me mention Pasternak again. Chentalinsky, in (Chentalinsky 1993, p. 164), quotes him describing Florensky as a "hostage of eternity; captive of time." Arkady Plotnitsky tells me that the line comes from a well-known and much quoted poem from the 1950s by Pasternak, and that this poem is addressed to an artist in general, and not particularly to Florensky. But the poem fits Florensky very well. Let me quote here the corresponding stanza and the one before:

Don't sleep, don't sleep, work
Don't interrupt your labor,
Don't sleep, struggle with a slumber,
Like a plain pilot, like a star.

Don't sleep, don't sleep, artist
Do not submit to sleep,
You are a hostage of eternity,
In time's captivity.

In this section, I have talked about poetry in the Silver Age. In the next section, I will continue with, arguably, the greatest poet of the Silver Age.

9 Florensky and Akhmatova

While the expression "Silver Age of Russian mathematics" is used in reference to the Golden Age that followed it, the expression "Silver Age of Russian poetry" is used in comparison with the Golden Age that *preceded* it, that is, the age of Pushkin and Lermontov. Some consider that the expression "Silver Age of poetry" was coined after certain verses in Akhmatova's poem *Poem without a hero*, namely,

And the silver month is bright
Frozen over the Silver Age.

Akhmatova, who was dubbed "the Soul of the Silver Age," was close to Florensky in many respects, and I will talk about this in the present section. Let me start by quoting a poem she wrote on Dante (Akhmatova 1997):[68]

From death there will be no return
To the old Florence he adores.
And leaving, back forever turned,
For him I sing this song, this lore.
Dark night, fire, torches, last embrace,
Beyond the Gate, the howl of Fate.
From Hell he sent his final curse,
In Heaven Florence he will not forget.
And barefoot, wearing shirt of shame,
With flaming candles lightly carried,
He walks in Florence all the same,
So trech'rous, base, but so desired.

In the middle section of her *Poem without a hero*, Akhmatova has the following epigraph:

[68] The following translation is by Alexei Sossinsky.

. . . a jasmine bush that bloomed
Where once Dante walked and the air is mute.

These two lines by Akhmatova are a variation on (and a truncation of) the following lines in a poem about Akhmatova's silence during several years, by Nikolai Klyuev:[69]

Akhmatova—a jasmine bush,
Scorched by asphalt and gray pitch—
Is she lost on the path through the dark pits
Where Dante passed and the air was parched,
Or is she a nymph spinning flax into crystals?
Among Russian women, remote and subtle
Anna is a cloud at sunset, she reflects
Streaks of gray light like rockets!

Dante was for Akhmatova, like for Florensky, a source of inspiration and reflection. They both regarded the fourteenth century Florence *Podestà*, which condemned Dante to an exile with no return, as a prelude for the twentieth century brutal Soviet regime. The long journey that Dante recounts in the *Divine Comedy* symbolized for Akhmatova all the exiles she had known, people she loved who emigrated to Europe, and those who were sent to the Gulag. Among the latter, there were poets, writers, and her son.

The resemblance with Florensky is striking. Akhmatova had Eurasian origins: Her father, like Florensky's, was an engineer, of Greek descent, and her mother was of Tatar descent. Those who knew her personally described her as a strange woman: shy, gentle, sad, indifferent to worldly things, and with an acute taste for contemplation. All this coincides with what we know of Pavel Florensky. Contradictions were noted in her social behavior. Her first husband, the prominent poet Nikolai Gumilev, called her an enchantress. It was said that she was both a saint and a harlot, and that she had diabolical charisma.[70] Apart from the harlot part of it, Florensky's social image was similar. I already quoted Sabaneeff, who wrote that there was in him "something of black magic, dark, devoid of divine grace." In the same article, we read (Sabaneeff 1961): "Beyond any doubt, there was a demoniac element in him, and as indubitably he was an extraordinary man, an outstanding personality,

[69] The symbolist poet Nikolai Alekseevich Klyuev (1884–1937) was arrested and sent to the camps in 1933 (the same year as Florensky). He was shot to death in 1937 in Tomsk (2 months before Florensky) and rehabilitated posthumously in 1957 (1 year before Florensky). The translation here is from the article (Mager 2005). Although the details would take us far beyond the scope of this chapter, let me mention that I learned from Plotnitsky that Akhmatova's truncation and the change of meaning of Klyuev's passage was likely to be mediated by Mandelstam (with Klyuev's poem still as the original source), and that there is a controversy about this because Akhmatova changed her poem several times; see the article (Leving 2009).

[70] On August 14, 1946, the decree signed by Andrei Zhdanov, who was Stalin's minister of culture, which banned Akhmatova from publishing, accused her (in the present case, with an outright malice) of mixing debauchery with prayer, describing her as a "bourgeois lady gone mad, tearing between her boudoir and her altar . . . half nun, half harlot, or rather both nun and harlot."

quite beyond comparison with any other prominent man of his time... . Lucifer was closer to him than Christ." Sabaneeff adds: "This increased rather than diminished his fascination for me."

Detached from everything, Akhmatova was trying to understand life through poetry. Like Florensky, she refused emigration, even though she had friends in Italy and France. For this, let me quote the opening of her *Requiem*[71]:

> No, not far beneath some foreign sky then,
> Nor with foreign wings to shelter me, —
> I was with my people then, close by them,
> Where my luckless people chanced to be.
> 1961

Akhmatova was neither exiled nor shot like Florensky, but she experienced exile and execution within herself: Her first husband, Nikolai Gumilev, accused of conspiration, was shot in 1921. Her son, Lev, endured the Siberian camps. Her lover, the art historian and critic Nikolai Punin, died in the Stalin camps, and one could continue this gloomy list.[72] We already talked about Florensky's very insecure position regarding publication: He was deprived of the opportunity to publish in scientific journals, and his notes and manuscripts were confiscated. Akhmatova's writings were judged by the authorities, but also by the Writers' Union, as "socially too irrelevant," and her poetry was banned from publication, starting in 1922, for over 30 years. She was led to recite her poems secretly to close friends, asking them to memorize them. Thus, it was her works that were deported instead of her.

Akhmatova had a religious soul. Korney Ivanovich Chukovsky dubbed her "the unique and last Orthodox poet" (Chukovsky 1999).[73] Like Florensky, she was

[71] Transl. Robin Kemball.

[72] An exception to this "gloomy list" is her last lover, Isaiah Berlin, an English diplomat and academician, born in Riga, which belonged to the Russian Empire, who was 20 years her junior and who came to see her in Leningrad while he was completing an internship at the British Embassy in Moscow. Reportedly, when Stalin learned of this affair, he said: "Now the nun is receiving foreign spies at night!" Akhmatova was deeply moved by Berlin, whom she dubbed the "Guest from the future," and to whom she dedicated four cycles of poems. In one of her conversations with him, she declared, "I have only darkness and Rus' by my side" (Victoroff 2016). Berlin was also deeply moved by Anna. On his return to England, he arranged for her to be made Doctor Honoris Causa of Oxford University.

[73] Korney Ivanovich Chukovsky (1882–1969) was a journalist, poet, translator, literary critic, and professor of Russian literature. With Akhmatova, he belonged to the same artistic and intellectual circles, before the revolution. Chukovsky was the illegitimate son of Emmanuel Solomonovich Levinson, whose (legitimate) daughter, Henrietta Emmanuilovna Levenson, was the mother of the outstanding Soviet mathematician Vladimir Abramovich Rochlin (1919–1984). Rochlin was the doctoral advisor of M. L. Gromov, A. M. Vershik, V. G. Turaev, O. Y. Viro, Y. M. Eliashberg, and several other bright mathematicians. Chukovsky's daughter, Lydia Korneyevna Chukovskaya (1907–1996), was a Russian and Soviet author and literary critic. Her second husband, Matvei Petrovich Bronshtein (1906–1938), was arrested as part of Stalin's Great Purge and was shot on February 18, 1938. Bronshtein was an outstanding Soviet theoretical physicist, working on quantum theory, astrophysics, semiconductor theory, cosmology, and quantum gravity theory. His doctoral dissertation, *Quantization of gravitational waves*, defended in 1935, was the first serious work on quantum gravity. He indicated there the main difficulties in this theory. In 1965, Lydia Chukovskaya

steeped in Orthodox culture, even though this culture was forbidden. Her poem *Requiem*, dedicated to "seventeen months waiting in prison queues in Leningrad,"[74] includes whole lines that are variations on Orthodox liturgical texts.

> Do not weep for me, Mother, when I am in my grave.
> A choir of angels glorified the hour,
> the vault of heaven was dissolved in fire.
> Father, why hast Thou forsaken me?
> Mother, I beg you, do not weep for me.

Each line here is taken from a liturgical text; Florensky has a poem on the same theme, titled *Lament of the Mother of God*, which he wrote in 1907; see (Oppo 2022, p. 89]. Akhmatova's poem continues:

> Mary Magdalene beat her breasts and sobbed,
> His dear disciple, stone-faced, stared.
> His mother stood apart. No other looked
> into her secret eyes. No one dared.

This is a faithful description of the Orthodox icon of the crucifixion.

Akhmatova was a twin sister of Florensky. The comparison and the close relationship between them could be the subject of another book.

There would still be a third book to write, about the relationship between Florensky and another twin sister: Simone Weil. In this respect, I would like to quote a passage from her book *La pesanteur et la Grâce* (1947), the chapter titled *Mystique du travail* (Mysticism of work) (Weil 1948): "The spirituality of work. Work makes us experience in a harassing way the phenomenon of finality bouncing back like a ball; working to eat, eating to work. . . If we look at one of the two as an end, or at both taken separately, we are lost. The cycle contains the truth."[75] This passage also contains another incarnation of the idea of eternal return, dear to Florensky, which I discussed in Sect. 5 above. Among the strong ties between Simone Weil and Pavel Florensky are a love of mathematics, a strong sense of self-observation, a passion for history and especially for Greek antiquity, extreme mysticism, and an intense religious feeling.[76]

published a novel, *Sophia Petrovna*, in which the son of the main character, Sophia Petrovna, was imprisoned in Leningrad's jail and later shot. In fact, Sophia Petrovna repeated in many respects the fate of Lydia Chukovskaya. (I learned most of the content of this note from V. N. Berestovskiĭ.)

[74] The dedication is to the people waiting for hours, often with no result, in this mile-long line to get any information about their relatives in prison or in a Gulag. Akhmatova was among these people waiting.

[75] Spiritualité du travail. Le travail fait prouver d'une manière harassante le phénomène de la finalité renvoyé comme une balle; travailler pour manger, manger pour travailler. Si l'on regarde l'un des deux comme une fin, ou l'un et l'autre pris séparément, on est perdu. Le cycle contient la vérité.

[76] I would like to thank S. Tanabé who suggested to me several relations between Pavel Florensky and Simone Weil.

10 Contradiction and Antinomy in Mathematics, Philosophy, and Theology

So far, I have tried to allude to Florensky's philosophy, and I shall try to say more about it in this section.

The Russian Silver Age, besides referring to mathematics, poetry, and art, was a period of fusion between philosophy and theology. The representatives of this alliance include Sergei Nikolaevich Bulgakov (1871–1944), Lev Isaakovich Shestov (1866–1938), Aleksei Fedorovich Losev (1893–1988), Nikolai Aleksandrovich Berdyaev[77] (1874–1948), and Dmitry Sergeyevich Merezhkovsky (1866–1941). The latter was one of the founders of the symbolist movement, to whom Florensky belonged. The others are also connected to this movement in various ways.

Florensky's philosophical worldview is based on antinomy, and I will mostly talk about this now.

Florensky considered that the world of ideas is based on antinomy rather than on logic as one intends it usually; in fact, truth, for him, is grounded on contradiction, and this holds in particular for the truths of theology. He considered that contradiction and paradoxes are unavoidable in theology. He believed that religious truth is beyond any formal logic, and more generally, beyond any formal categorization. He considered that the Holy Scriptures, including the Old and New Testament, contain contradictory statements that are nevertheless all true, and that these contradictions do not need to be resolved but on the contrary they are an integral part of Christian teaching. In Letter VI of the *Pillar*, he reviews some sources of antinomy, in Greek Antiquity, passing by Heraclitus, the Eleatics, and Plato. To understand Florensky's background, it is good to recall first a few facts about contradiction in mathematics, the first field that he studied in depth.

At the beginning of the twentieth century, at the time when Florensky was suffering his existential crisis, mathematics was traversing a *foundational crisis*. A strong indication of this crisis is Hilbert's "second problem," formulated in 1902 at the second congress of mathematicians in Paris, asking whether one can prove the coherence of arithmetic, i.e., whether one can demonstrate that the axioms of arithmetic are not contradictory. In reality, it was a question not only about arithmetic but also of geometry, and, by extension, of all mathematics, because it was shown before (notably, by Hilbert) that the coherence of the axioms of geometry depended on the coherence of the axioms of arithmetic. For the answer to Hilbert's Problem II, one had to wait for the work of Kurt Gödel, who demonstrated that the answer is negative. Gödel published his famous *Incompleteness Theorem* in (Gödel 1931), while Florensky was already in the glaciers, far away from it all. In any case, mathematicians who had thought about these questions had always felt that there might be problems of coherence in formal logic, and this had been so since Greek antiquity. (Even though formal logic did not exist yet, it was formally the same logic.) The paradoxes of Zeno

[77] It has been suggested that the term "Silver Age," in relation with Russian philosophy, derives from Berdyaev's work *The Brightest Lights of the Silver Age* (Berdyaev 2015).

of Elea are generally quoted in this respect. Let me recall here that Zeno was considered by Aristotle as the father of dialectic, that is, the art of asking questions and defending successively opposite theses with the aim of finding the truth. Florensky mentions Zeno in the *Pillar* (see p. 345 and p. 574), in relation with the continuous and the discontinuous, with references to his paradoxes of motion. He quotes classical paper on Zeno's aporias, by the French mathematician and historian of science Paul Tannery (Tannery 1885). As a matter of fact, Zeno's arguments are not contradictory; they are only paradoxical, and based on the paradoxes that are possible in mathematics. But these paradoxes are presented in Florensky's writings in a philosophical language that makes them appear practically contradictory. Regarding antinomy in theology, Florensky refers to the philosophical system of the monk Serapion Mashkin, from the Optina monastery.[78] In Note 837 (p. 574) of the *Pillar*, talking about Zeno's antinomies, Florensky writes: "It is precisely on these antinomies, and their overcoming that the entire philosophical system of Father Serapion is built." Antinomies, but also discontinuity: In the same page (note 836), Florensky writes that "one cannot fail to mention Father Serapion Mashkin's attempt to conceive space and time as composed of finite, further-indivisible elements."[79]

Mathematics since at least Euclid is based on definitions and postulates/axioms. The axioms are assumed to be internally consistent, not containing a contradiction. In case an axiomatic system contains a contradiction, the simple rules of logic (*Modus Ponens*) imply that every statement formed in the language of the system is a formal consequence, thus rendering the system most powerful but useless and mathematically unacceptable. Consequently, if a contradiction is detected within a system, then the system is rejected. Frege's foundation of set theory was famously found to be contradictory because it contained the rule of comprehension, from which Bertrand Russell constructed his paradox. However, it is a consequence of Gödel's Incompleteness Theorem (Gödel 1931) that internal consistency cannot be proved within the system if the system is reasonably strong. Let me refer here to a paper by Farmaki and Negrepontis, titled *The paradoxical nature of Mathematics*

[78] Father Serapion was a former naval officer. The name *Optina* refers at the same time to a small village and a monastery, in the Kaluga region, 250 km to the South-West of Moscow. The monastery is linked to episodes in the lives of several Russian writers and philosophers. In the summer of 1878, Vladimir Solovyov brought Fedor Dostoyevsky to the monastery following the tragedy of the latter's son's death. Dostoyevsky stayed at the monastery for 3 days. Several details of his novel *The Brothers Karamazov* appeared following this visit to Optina. The list of the other visitors of the Optina monastery includes Vasily Zhukovsky, Nikolai Gogol, Ivan Turgenev, Vasily Rozanov, and Leo Tolstoy. After the October Revolution, Soviets closed the Optina monastery and the monks of the monastery were asked to choose between deportation in the Solovki Archipelago or working in a secular agricultural cooperative. The monastery itself was declared a Gulag, and various kinds of prisoners were sent there. After these events, Florensky launched a campaign to "Save Optina"; see (Demidov and Ford 2005, p. 607).

[79] For a modern treatment of Zeno's aporias and of contradiction in mathematics from the historical point of view, let me mention the paper *Zeno's arguments and paradoxes are not against motion and multiplicity but for the separation of true Beings from sensibles* (Negrepontis 2023) by S. Negrepontis.

(Farmaki and Negrepontis 2021), in which these authors stand that in a sense all of Mathematics can be considered as a (hopefully) consistent approximation of the truly contradictory. It is not clear whether Florensky has in mind, even in some very intuitive sense, such a view of Mathematics; it would indeed be fascinating if he did.

In any case, the fact that *truth* is antinomic is one of the main themes of *The pillar and ground of the truth*. Florensky explained quite simply in his work that reason alone is sufficient to accept or not accept what is not antinomic, and that if faith is needed, it is precisely because truth is antinomic. Letter VI of the *Pillar* is titled *Contradiction*. In this letter, Florensky analyzes different occurrences of antinomy, in philosophy, theology, logic, mathematics, ethics, linguistics, and other fields. In short, he develops the thesis that contradiction and antinomy are the basis of knowledge. As a matter of fact, each of Florensky, Bulgakov, and Losev developed elaborate philosophical and theological systems based on antinomy.

At the time he was writing his book, Florensky was witnessing a renaissance in Russian theology, which found its sources in the Jewish Kabbalah and in the writings of the Desert Fathers, a theology which came to be known as *apophatic* theology, or *negative* theology. According to this theology, every time one tries to say something positive about God and the transcendent is inevitably led to contradictions or absurdities. Here, let me quote again Sabaneeff on Florensky:

> His mind was complex, many-storied, and to some extent even hostile to simplicity. One might even call it a cabalistic mind. . . . His extravagant and excessively luxuriant thoughts often contradicted one another, but this did not embarrass him in the least. . . . He even asserted that every perceived law "generates" its own negation, inasmuch as every law discerned by the logical apparatus of man is but a part of a real, comprehensive synthetic law embracing "all that exists" and "all that is possible and thinkable."

Let me talk now about the notion of infinity.

Florensky was fascinated by the idea of actual infinity which was highlighted by Cantor, and he saw in it a symbolic vision of God. He proposed a philosophical and symbolic interpretation of this concept based on Bugaev's mathematical theory of discontinuity. In 1904, he published the pamphlet titled *Symbols of infinity: Sketch of the ideas of G. Cantor*, which we already mentioned, dedicated to the analysis of Cantor's ideas on set theory and infinity. According to I. H. Anellis, Florensky's essay was the first article in Russia written on Cantor's set theory (Anellis 1994). In some sense, Florensky was a disciple of Cantor, who had already declared in his 1883 work, *Grudlagen einer allgemeinen Mannigfaltigkeitslehre*, that everything that has to do with the infinite has theological, mathematical, and philosophical connotations that cannot be separated. N. Misler writes in (Misler 2006, p. 35) that Florensky's proposed philosophy of symbol was in accordance with the wish of the editors of *Novy put'* to promote the relation between the intelligentsia and the Church. The logic of symbols is used by Florensky in his theological arguments. In his writings, the issues about contradictions in formal logic become issues about contradictions in theology. He declares in Letter VI of the *Pillar* (Florensky 1975, p. 106): "Truth is an antinomy. . . . . What is needed is a formal logical theory of

antinomy," and he goes on explaining a way to obtain such a theory. In Letter X, titled *Sophia*, he declares: "faith clothes its knowledge of dogmatic truth in a symbolic garment, in figurative language, which covers the higher truth and depth of contemplation in consistent contradictions" (Florensky 1975, p. 244). In Letter II, titled *doubt*, he writes that "[the rational mind] desires self-contradiction" (Florensky 1975, p. 17) and that "contradiction is everywhere and always" (Florensky 1975, p. 23). We can read in the same letter: "At the same time we get: A is A; A is not A" (Florensky 1975, p. 29). In Letter VI, titled *Contradiction*, he writes: "For rationality, truth is contradiction, and this contradiction becomes explicit as soon as truth acquires a verbal formulation. . . . truth is an antinomy, and it cannot fail to be so." (Florensky 1975, p. 109).

Florensky's references include Heraclitus, Zeno, Plato, and Origen. Regarding Plato, Florensky writes: "The majority of his dialogues are nothing but a gigantic antinomy, developed with all care and artistically dramatized. Plato's very predilection for the dialogic form of exposition, i.e., the form of the contraposition of convictions, already hints at the antinomic nature of his thinking" (Florensky 1975, p. 116).

Let me make a remark here. It is difficult to be certain of what Florensky had in mind when he referred to Plato. According to Stelios Negrepontis,[80] one might reasonably assume that Florensky had in mind, at least in part, Plato's most contradictory-looking statements of the dialogue *Parmenides*, especially in the second hypothesis (*Parmenides* 142–155). These statements are indeed scandalously antinomic/contradictory in their appearance. For instance, Plato's intelligible Being (i) is infinite and finite, (ii) is One and Many, (iii) is in motion and at rest, etc., and even worse: is older and younger than itself and the others, and is neither older nor younger than itself or the others! However, it would be a rush conclusion that these statements are in fact contradictory. They have a fully rational and mathematically consistent interpretation. According to an interpretation proposed by Negrepontis, Plato exploits in these passages the paradoxical, but fully consistent, nature of the infinite but periodic anthyphairesis and describes it employing what might be considered an abuse of language, to cause surprise and amazement. But Plato is always safe within consistent noncontradictory mathematics. The same remarks apply to Zeno's scandalous and fascinating paradoxes since they are of the same nature as Plato's paradoxes, and in fact form the primary source for Plato's paradoxical arguments. I refer the reader to the interpretation of Zeno's paradoxes by Negrepontis in (Negrepontis 2023). In the same page (Florensky 1975, p. 116), Florensky declares: "Knowledge of contradiction and love of contradiction, along with ancient skepticism, appear to be the highest achievement of antiquity." In the same chapter, he gives a detailed list of dogmatic antinomies. "The Holy Scripture, he says, is full of antinomies." The Apostle Paul's epistle to the Romans, he writes, is an "antinomy-charged bursting bomb against the rational mind." The paradoxical method of reasoning is justified by symbolic logic (Florensky 1975, p. 112). In

[80] Personal communication.

Chapter XIV of the *Pillar*, he writes: "There are an uncountable number of antinomies. There are as many of them as there can be acts of the rational mind. But, as we have already noted, antinomies are essentially reducible to the dilemma: 'finiteness or infiniteness'" (Florensky 1975, p. 344). We are back to mathematics. We already quoted Lebesgue saying that there might exist a set which is nameable and which is neither finite nor infinite (Footnote 55.)

In Letter VI (*Contradiction*), Florensky makes a list of 11 theological antinomies.[81] In this list, we find for example:

- *Retribution* – Thesis: Retribution applied to all according to their works (Rom. 2: 610; 2 Cor 5:10). Antithesis: Free forgiveness of the redeemed (Rom. 4:4, 9:11, 11:6).
- *Grace* – Thesis: "Where sin abounded, grace did much more abound" (Rom. 5: 20). Antithesis: "Shall we continue in sin, that grace may abound? God forbid" (Rom. 6:12). "If we say that we have no sin, we deceive ourselves, and the truth is not in us" (1 John 1:8).
- *Faith* – Thesis: Faith is free and depends on the free will of man (John 3: 1628). Antithesis: Faith is God's gift and is not found in human will but in the will of the Father Who draws us to Christ (John 6:44).

There are eight other such theological themes in his list, with antinomic approaches. I refer the interested reader to the detailed list together with Florensky's commentary in p. 121–123 of the *Pillar*.

Antinomy is found in Yahweh, the supreme order of the world. The God of the Old Testament, who punishes severely and looks very cruel, has two entirely antinomic faces. Florensky writes in Chapter VI of the *Pillar*: "The Book of Job wholly consists of such a concentrated experience of contradiction. This book is wholly constructed on the idea of antinomialness."[82] C. F. Jung, in his book *Answer to Job* (Jung 1952), reached conclusions similar to those of Florensky.[83]

What can we conclude?

Mathematics is the most exact science, and with the actual axioms, there is no proof that there is no contradiction in mathematics. If ever we find contradictions in mathematics, then there would be contradictions in all the other sciences. In theology, we already live with contradictions. This is expressed in a most dramatic style in *The Pillar and ground of the truth*, which is Florensky's major theological written work. The *Pillar* is a treatise on contradiction and antinomies.

From the more recent period, let me mention that the French philosopher and epistemologist Jules Vuillemin (192–2001), who was a professor at Collège de France, dedicated his course there, during 7 years (in the 1960s–1970s), to the

[81] "I deliberately exclude certain antinomies that I intend to examine in a future book," he writes.

[82] I am using the wording of the English translation (Florensky 1975).

[83] I owe this remark to S. Tanabé.

notion of mathematical antinomy,[84] after which he wrote a book on antinomy in the concept of God (Vuillemin 1971).

11 The Philosophers

There is a famous canvas, owned by the Moscow Tretyakov Gallery, representing Pavel Florensky with the philosopher Sergei Bulgakov, painted in 1917 by Mikhail Nesterov (1862–1942), a brilliant representative of the Russian symbolist movement. The painting is known under the name *The philosophers*. It is represented here in Fig. 8. The quiet landscape in the background is the countryside near Sergiev Posad. The contrast between the two philosophers is manifest in their face expressions and in the colors of their clothes. Bulgakov became priest in 1918 and was expelled from Russia, together with 160 other intellectuals, in 1922, on one of the *Philosophers' boats*. Florensky decided to stay in Russia. Nicoletta Misler wrote a remarkable article on this painting in the Tretyakov Gallery Magazine to which I refer the reader (Misler 2007). In this article, she quotes a passage by Bulgakov, from a Russian version of (Bulgakov 1989). I reproduce here an extended passage which I translated from the French version:

> A recollection, and with it the foreshadowing of events and achievements to come, never leaves me. It is the portrait of the two of us, painted by our common friend Nesterov on an evening of May 1917 in Father Paul's garden. For the artist, it was not just a portrait of two friends by a third, but a spiritual vision of the times. For the painter, the two faces expressed the same understanding, but for one as a vision of horror, for the other as peace, the joy of overcoming hardship. The painter himself had doubts as to whether he should portray the *first* character, and tried to remake the portrait by replacing the horror with idyll and the tragedy with placidity. But he immediately felt the unbearable falseness of this substitution, and returned to his first vision. On the other hand, he immediately found Father Paul's face, its artistic and spiritual evidence, which he had no need to modify. This was the clear artistic vision of two figures of the Russian apocalypse, of one and the other face of earthly existence, the first in struggle and disarray (and in my heart it was about the fate of my friend), the second in the victorious fulfillment we are now contemplating.

[84] The titles of Vuillemin's courses at the Collège de France include the following: 1962–1963: La notion d'antinomie: analyse des doctrines de Kant et Hegel; 1963–1964: La notion d'antinomie: l'origine des antinomies dans les mathématiques modernes; 1964–1965: La notion d'antinomie: les solutions de Russell en 1905; 1965–1966: Sur la notion d'antinomie: Découverte des antinomies "épistémologiques"; 1966–1967: Sur la notion d'antinomie (1890–1910): Conséquences des antinomies pistmologiques pour la conception du principe d'induction complète, logicisme, formalisme, intuitionnisme; 1967–1968: Sur la notion d'antinomie: Analyse de l'article de Russell "Mathematical Logic as based on the Theory of Types"; and 1968–1969: Sur la notion d'antinomie: Analyse de Russell: Préface de la première édition des "Principia mathematica" (1910), "On the Relation of Universals and Particulars" (1911–1912).

12 Reverse Perspective Again

Andrei Tarkovsky was close to Florensky, philosophically, spiritually, and also in his way of making films. Beatrice Barbalato writes about Tarkovsky: "Inspired by Florensky's thinking (*Reverse Perspective*, 1916), his filmic visual focuses radiate from the minute detail, both as seen in a dream and as occurs in experiential reality" (Barbalato 2021). Jaromír Blažejovský writes, on the same subject (Blaejovsk 2008):

> Tarkovsky used in what we have called—following Pavel Florensky—"reverse perspective," typical for Russian Orthodox icons: narration from various points of view and completed from relatively independent parts of time and space. The effect of this pattern is a feeling of infinity of the narrative world.

The Trinity icon – Abraham's hospitality – which is shown in the film's finale, is an epitome of inverted perspective. I have reproduced in Fig. 9 two paintings, in which the drawing is done in reverse perspective. In such a portrait drawing, the back of the face appears larger than usual, as does the hair.

Fig. 9 Two paintings drawn in reverse perspective. Left: The Archangel Michael, by Andrei Rublev, ca. 1414, egg tempera. Tretyakov Gallery, Moscow. Right: Portrait of Pavel Florensky, by Vladimir Alexeyevich Komarovsky. Oil on canvas, 1924. The Pavel Florensky Museum, Moscow

Tarkovsky quotes Florensky at several occasions. In chapter IV of his book (Tarkovsky 1987), titled *Cinema's destined role*, he makes some observations on reverse perspective in Florensky's writings, pointing out relations with his own works:

> I am reminded of a curious observation of Father Pavel Florensky's in his book, *The iconostasis*. He says that the inverted perspective in the works of that period was not the result of Russian icon-painters being unaware of the optical laws which had been assimilated by the Italian Renaissance, after being developed in Italy by Leon Battista Alberti. Florensky argues, convincingly, that it was not possible to observe nature without discovering perspective, it was bound to be noticed. For the time being, however, it might not be needed—it could be ignored. So the inverted perspective in ancient Russian painting, the denial of Renaissance perspective, expresses the need to throw light on certain spiritual problems which Russian painters, unlike their Italian counterparts of the Quattrocento, had taken upon themselves. (One account has it, incidentally, that Andrei Rublev had actually visited Venice, in which case he must have been aware of what Italian painters had been doing with perspective.)

Florensky writes in his book on reverse perspective, regarding the children's drawings (Florensky 1992, p. 219 of the English translation):

> The children's drawings, in their lack of perspective and especially their use of reverse perspective, vividly recall mediaeval drawings, despite the efforts of educators to instil in children the laws of linear perspective. It is only when they lose their spontaneous relationship to the world that children lose reverse perspective and submit to the schema with which they have been indoctrinated

In my article on Manin which appears in the present Handbook (Papadopoulos 2023), I mention Tarkovsky several times, especially from his diary (Tarkovsky 1993). Reverse perspective appears on several occasions in Manin's writings. It describes a world where there is no predetermined logic. Manin, like Florensky, notes that children draw, before they are formatted by the adults' reason, in reverse perspective. I refer to chapter III.4 of the French version of his book *Mathematics as a metaphor* (Manin 2007), titled *Spontaneous artistic activity, the origin of logograms and mathematical intuition*.[85] Let me add that the Swiss biologist, psychologist, logician, and epistemologist Jean Piaget (1896–1980) has an article titled *Le développement des perceptions chez l'enfant* (The development of perception in children) (Piaget 1960) whose first section is titled *Structures projectives (perspective)*. Piaget discusses there the evolution of the notion of perspective in child development. He states in particular that, from the study of children's drawings, it appears that they are unable to reproduce perspective until around the age of 9 or 10, which is the stage when children draw "what they know about an object, not what they see of it."[86]

Finally, let me mention a theory developed by R. K. Luneburg (Luneburg 1947) according to which objects in the region of binocular vision (which differs substantially from monocular vision only for nearby objects) are perceived in terms of Lobachevsky geometry. This is developed by B. V. Rauschenbach in his book (Rauschenbach 1980) and in his paper (Rauschenbach 1983) titled *On my concept of perceptual perspective that accounts for parallel and inverted perspective in pictorial art*.[87]

13 In Guise of a Conclusion

I wrote at the beginning of this chapter that Florensky has been compared to Leonardo and Pascal. The comparison is amply justified. I would like to add to this list two mathematicians of recent times, René Thom and Yuri Manin, for whom, like Florensky, mathematics, besides being the language of nature, is that of philosophy, linguistics, poetry, and magic. To conclude, let me quote some verses of a poem by Manin titled *Péniches sur le Rhin (élégie)* in which he mentions Florensky's name (Manin 2007, p. 523):

[85] The French version of this book is much more complete than the English.

[86] I learned about Piaget's article by S. Tanabé.

[87] I learned this from V. Berestovskiĭ. Rauschenbach's theory is commented on and used in Berestovskiĭ's paper on Lobachevsky geometry (Berestovskiĭ 2022).

Dieu est inconnaissable mais nommable,
Le nom de Dieu, c'est Dieu,
croyaient les adorateurs du Nom.
Le Starets Hilarion, Pavel Florensky ...
L'infini non plus n'est pas connaissable, mais il est nommable.
Qui connaît les péniches ? Qui leur donne un nom ?
On ne sait pas si c'est Lui — si c'est Elle ...

Acknowledgments I would like to thank V. N. Berestovskiĭ, Stelios Negrepontis, Ken'ichi Ohshika, Victor Pambuccian, Arkady Plotnitsky, Valentin Poénaru, Galina Sinkevich, Alexei Sossinsky and Susumu Tanabe for useful comments and suggestions on previous versions of this chapter. Abstract

The author, who came to the Soviet Union in 1957 from the West, describes his own experience in the totalitarian regime in the USSR and the attitudes of the leading Russian mathematicians of his generation to the regime in the period from 1957 to 1987.

In this essay, I will try to describe my own experience as a student, a researcher, and a teacher of mathematics in the Soviet Union in the 30-year interval 1957–1987, and analyze the different behavior patterns of several outstanding mathematicians of the times.

I came to Moscow in July 1957 from the United States, where I had received my BS from New York University with all kinds of honors and had been accepted to a PhD-track program at the Courant Institute, but did not take that program. Thus, my personal background and experience differ from that of Russian students, teachers, and researchers practicing mathematics in the USSR during that period, so that my account is perhaps more objective and certainly more understandable to the Western reader than the accounts that were, or could have been, written by my Russian colleagues stuck behind the Iron Curtain in 1957–1987.

From my very first years in the USSR, I was often asked by Western visitors what I felt as a mathematician in the repressive regime of Soviet Russia, and quickly developed a joking answer that usually ended conversations on that topic: "Well, any Russian boy who is smart and honest, cannot perform on the violin or play ice hockey, has only one career choice – to do theoretical physics or mathematics. I can't play the violin or ice hockey, yet I feel fine doing mathematics here."

This joking answer should be taken seriously – it is in fact the secret of success of mathematical creativity in that repressive society: only the smartest and most honest persons did mathematics. This key point will be developed in more detail below, but let me begin at the beginning.

My undergraduate years in Moscow. In September 1957 I became a second-year undergraduate at *mekhmat* (the Mechanics and Mathematics Faculty (or Department) of Moscow State University) as a transfer student from NYU. At that time, the following people were also mekhmat undergraduates: Yura Manin, Sasha Kirillov, Dima Arnold, Mitya Fuchs, Sasha Vinogradov, Galya Turina, Borya Mityagin, Serezha Novikov, Dima Anosov, Igor Girsanov, Gena Henkin, Tolya Karatsuba, Vitya Palamodov, Yasha Sinai. I did not realize it at the time, but one can safely say that no university before or after can claim a similar amount of undergraduates who eventually became world famous, or simply great, mathematicians.

At my arrival, I already knew that I would specialize in algebraic topology, but it turned out that no courses in the subject were available at *mekhmat* at the time, except Boltyansky's course, which I felt was not up to the level – at NYU, I had studied an algebraic topology course based on the deep lecture notes of Lipman Bers, published in 50 copies in a "rotaprint" edition and not included in his Selected Works.

Had I become a third-year rather than a second-year student, I would certainly have connected with the group of third-year students (Fuchs, Turina, Novikov,

Arnold) who were studying the latest research papers on the subject, but this did not happen.

But I did meet Fuchs, Turina, Novikov, Arnold in my first undergraduate years in Moscow, not in one of the lectures or seminars, but in camping expeditions outside the city – in the taiga forests, on white-water kayak trips, in the Ural or Caucasus mountains. At the time, none of us was allowed to leave the country, so the search of new vistas and adventures, sometimes dangerous, took place within Soviet Russia.

The photograph below shows six of us standing on the Mura mountain pass (3500 meters) in the Caucasus in June 1967. The group consisted of four mathematicians and three colleagues from the chemistry faculty (Mochigin, Chapovsky, Uskov). The third chemistry professor, Uskov, does not appear in the picture: he took the photograph.

A. Sossinsky, I. Girsanov, D. Fuchs, E. Mochigin, G. Turina, Yu. Chapovsky (l.-r.)

The picture is beautiful, expressive, and in a sense tragic: Girsanov, Mochigin, Chapovsky were killed in an avalanche in the Ural mountains the same year, and Turina, in a white-water expedition in 1968.

Returning to mathematics and 1958 – I began studying and working in geometric topology under Lyudmila Keldysh, having rejected the advances of Academician P.S. Alexandrov, the head of the Chair of Topology and Geometry, who was willing to become my scientific advisor. For the next few years, my academic carrier continued smoothly, unhampered by the totalitarian regime.

But I have wandered in this digression from the subject matter of this essay, so let me move to the analysis of the behavior of several of my contemporaries listed above.

1 The Unusual Case of Yuri Manin

Manin differs from all the other mathematicians in the list above in that he was the only one with whom I was not on a first-name basis (addressing each other, we both used the second person plural **vy** rather than **ty**), and although I have heard many of his talks, I have never spoken to him at length. Besides, unlike all the other people in the list, he never participated in olympiads and other mathematical contests, he did not take part in math circles, he did not have an inspiring math teacher in high school. He is the perfect example of a Russian youngster "who is smart and honest, cannot perform on the violin or play ice hockey," and so has only one career choice – to do mathematics or theoretical physics. Manin did both.

Not knowing Manin well, I cannot assert that he never expressed, orally or in written form, his opposition to the regime. However, it is clear that he favored democracy and was strongly opposed to the communist bureaucracy – as soon as it became possible, he emigrated (1987) to Germany, traveled all over the world, but would regularly return to Russia to give talks.

2 The Opposite Case: Anatoly Vershik

When I became a mekhmat student, Tolya Vershik was an undergraduate at the Leningrad *matmekh*. Unlike Manin, he participated in olympiads and other math competitions, in math circles, he had excellent high school teachers, and chose mathematics because of his love for the subject itself, rather than because he had no other choice.

Also unlike Manin, he opposed the regime, became an active dissident, published an illegal "anti-Soviet" newspaper, and remained a very vocal opponent of the regime all his life. Even today, Vershik continues to live and work in Saint Petersburg, strongly expressing his attitude to the Putin regime.

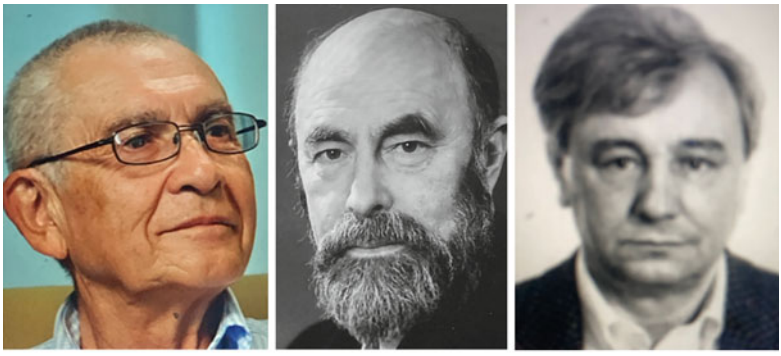
3 The Ambiguous Case of Sergey Novikov

Sergey Novikov comes from a scientific family, his father was the logician and algebraist Academician Petr Novikov, and, more importantly, his uncle was Mstislav Keldysh, President of the Soviet Academy of Sciences and head of the soviet space program. He participated in math Olympiads only once, in seventh grade, "only" got the second prize. His love of mathematics was inherited from his parents and from

his half-brother Leonid Keldysh. Novikov obtained world-class results in algebraic topology and its applications as an undergraduate and was awarded the Fields Medal in 1970, but his uncle's support was not sufficient for him to be allowed to leave the Soviet Union to participate in the ICM in Nice and accept the medal.

Sergey Novikov had very strong family feelings, and regarded the leading students of his mother (Lyudmila Keldysh) as part of the family. I will always be grateful for his help at various moments of my life. I have used the term "ambiguous" in the subtitle above only because some colleagues have a negative attitude to several of his brash statements about the work and personalities of other mathematicians.

As far as I know, while living in the Soviet Union, Novikov did not openly criticize the regime. But when leaving the country became possible (1987), he was one of the first to "choose freedom" and emigrate to the US. In the States, he continued his outstanding work in mathematics and mathematical physics, and placed in the internet various texts about his colleagues and their work that some people consider misleading. Novikov often returns to Russia, where his seminar (which he heads jointly with V. Buchstaber) remains one of the leading research platforms in Moscow.



Yu. Manin A. Vershik S. Novikov

4 The Most Typical Attitude

Here I will not describe the attitude of a concrete mekhmat professor, but that of a "generic" one, the attitude of the vast majority of my colleagues. It was quite simple. The generic professor strongly disapproves of the regime, but expresses his disapproval only among trusted friends, usually at home in the kitchen. At university, he pretends to agree with the authorities – not from lack of courage, but because of the basically correct understanding that one's serious actions against the regime would produce, at best, the loss of one's position, or, at worst, a stay at the Gulag.

5 A Paradoxical Principle

Very soon after my arrival in Moscow, I was contacted by the KGB. Two of its agents attempted – unsuccessfully – to make me an informer. This attempt was repeated by different agents – also unsuccessfully – a year later. A more detailed description of these meetings, as well as of a third meeting in the 1970s, appear in my article "In the other direction" in Golden Years of Moscow Mathematics, AMS Publ. (2007). It was during these meetings that I first applied a new principle concerning how I should talk to different categories of people.

The principle, which is absolutely perpendicular to the most typical attitude described above, is very simple:

Whoever you speak to, be it your best friend or someone you suspect of being a KGB informer, you tell him the truth about yourself and refuse to say anything (good or bad) about any other concrete person.

For instance, I would say:

"Last night I had the opportunity to read *The Cancer Ward*, it is really a great book," instead of saying: "So-and-so gave me *The Cancer Ward* to read, it's a great book."

The logic behind that attitude is that the KGB already knows enough bad things about me anyway, and what I don't want to happen is to give them any information about others.

The application of that principle invariably led to a dead end in any line of questioning, be it by secret service agents in an official meeting or by a prosecutor in a court of law.

6 Fighting the Regime: My Resignation from Mekhmat

I now return to my own relationship with the authorities. Up to the end of the 1960s, things moved ahead without serious difficulties: I passed my diploma examination without any troubles worth reporting, and obtained the diploma (the Russian version of a Western MS degree), was recommended for graduate work by the topology chair, successfully passed the graduate exams, defended my candidate's thesis (equivalent to the Western PhD) in 1965, and obtained the position of Assistant Professor at the mekhmat topology chair. The trouble began later, in 1974, when I was already promoted to the position of Associate Professor.

It was a difficult period of my life, my wife was in hospital seriously ill, I had a heavy teaching load at the university, two children to feed and clothe and take to school. On March 3, 1974, the Communist Party member of the topology chair, responsible for the ideological attitudes of its members, called me aside and told me that it was my turn to take the one-semester Marxism-Leninism course. I replied that it was impossible for me in the coming semester, and that I would think about taking it next year, but my colleague replied that the course has become obligatory, I would automatically lose my job if I did not take it, and that it was really not much trouble at all.

"You just come to the class once a week, you can sit somewhere in the back and read a book or correct papers, choose a topic in Marxist philosophy and copy some (slightly modified) excerpts from approved textbooks, that's all there is to it," he said.

Swallowing my pride, I agreed to take the course. My colleague gave me an application form. I read:

> I, the undersigned |. . . ..| .... | ask the Mechanics and Mathematics Party Organisation to kindly recommend me for a one semester course at the University of Marxism-Leninism beginning in |. . . . . |. . . .|19. . . ..|.

I took a pen to sign, but my hand was physiologically incapable of putting my name on that document! I tore up the form, seized a blank piece of paper and wrote the resignation from my position at the department effective in a month's time. Several people of the topology chair, including the chairman (P.S. Alexandrov), tried to make me change my mind, but succeeded only in part: I agreed to finish my lectures on a novel course called "Analysis on Manifolds" that no one else at Alexandrov's chair could continue.

Thus, I had lost the first battle with the authorities: its result was that I had been forced to exchange my prestigious mekhmat position for a modest editor position at the popular science magazine "Kvant." And yet I felt that I had scored a moral victory. In subsequent months, I had the following poignant experience several times: walking along the corridors of mekhmat, I would meet one of my colleagues, who, after furtively looking around, would come up to me and silently shake my hand. I would also enjoy demonstratively not shaking hands with those of my colleagues who actively supported the wrongdoings of the party bureaucracy.

7 After Solzhenitsyn's Exile

This episode also occurred in 1974, but later in the year, when Solzhenitsyn was exiled from Soviet Russia. Together with Maxim Khomyakov, my former classmate and best friend, we wrote a strongly worded letter in support of the novelist. At the time, Soviet newspapers were publishing letters by eminent personalities and by ordinary people supporting Solzhenitsyn's banishment. In particular, such a letter signed by P.S. Alexandrov and A.N. Kolmogorov appeared in Pravda.

We made a dozen copies of our letter and addressed it to the street number and street of the International Herald Tribune, the addressee being one of the editors, with his name misspelled, and mailed it from mail boxes in different parts of Moscow. But we had underestimated the efficiency of the KGB: none of the letters reached their destination. The result was that Maxim Khomyakov was forced to resign from his job, while I, being briefly unemployed at the time, was left alone.

In this connection, an important little episode occurred in January 1975: walking in the corridors of the department, I saw Kolmogorov coming in my direction from the other end of the hall. I quickly moved toward him and firmly shook his hand.

I clearly remember the expression of relief in his face and the silent sigh that he was unable to suppress just before the handshake. After that we discussed some questions concerning *Kvant* magazine as if nothing had occurred in our lives.

8 Bella Muchnik's People's University

Bella Subbotovskaya-Muchnik was a student, then a graduate student of mekhmat, defended her candidate dissertation (PhD) in mathematical logic in 1963 and, surprisingly, became a school teacher. In 1978, she founded an informal educational institution, often called The Jewish People's University, for those students who had been flunked the Moscow University entrance examinations in the framework of the shamefully famous "Jewish auditoria." This ended tragically in September 1983, when Bella was killed by a truck late at night in what everyone regarded as a KGB assassination.

A lot has been written about this unusual institution, so I will mention only two important facts, not clearly indicated in the literature. First, it was Alexander Vinogradov (more about him below) who was the first to lecture at the People's University and who invited many colleagues to work there, including the present author. Further, in 1979, during a visit to Moscow, Fields medalist John Milnor was invited by Vinogradov and myself to give a lecture to the students, which took place at Bella's overcrowded apartment, with me doing the translation.

9 Aleksandr Esenin-Volpin and the Letter of the 99

EseninVolpin, son of the famous Russian poet Sergey Esenin, was himself a poet, a human rights activist and dissident, as well as a mathematical logician. He obtained his candidate degree from mekhmat MSU in 1949, was arrested several times for "anti-Soviet activities." In 1968, just before the arrival of Nixon to the Soviet Union, he was forcibly placed in a psychiatric institution. This led to the appearance of the now famous "Letter of the 99," which asked, in very mild terms, for his release from that institution, and was immediately published in the West. The number 99 indicates the number of people (mostly mekhmat professors) who signed it. Esenin-Volpin's life story is well documented, so here I will simply say that he eventually emigrated to the U.S.

But I would like to add three remarks that connect this story with the main subject matter of this essay. First, many (if not most) of my colleagues listed at the beginning of this text, in particular Fuchs, Novikov, and Kirillov, signed the letter. Secondly, P.S. Alexandrov and A.N. Kolmogorov did not sign the letter, but wrote their own (even milder) letter asking for Esenin-Volpin's release. Finally, I did not sign the Letter of the 99, although the Wikipedia articles about me say that I did. The fact is that I would have signed it, but it was circulated for only 2 days, during which I was out of Moscow.

10 Yuri Shikhanovich and the Chronicle of Current Events

Like Esenin-Volpin, Yuri Shikhanovich was a dissident, an inmate of political labor camps and doubtful psychiatric institutions, as well as a mathematical logician and a graduate of mekhmat. Perhaps his main achievement in the human rights movement was related to his role in the creation and functioning of the anti-Soviet journal *The Chronicle of Current Events*.

I met Shikhanovich and became friends with him in my graduate years, when he invited me to do the exercise class in his Calculus course at the newly created Department of Mathematical Linguistics of MSU. I knew from the start that he was a dissident and read some issues of his Chronicle, but was never directly involved in human rights activities.

Unfortunately, I was unable to find any serious publication about Shikhanovich other than a short obituary. There is, surprisingly, no Wikipedia article about him, although there is a detailed Wikipedia article about the *Chronicle* (the article contains several inaccuracies). Let me just add that many interesting events in Shikhanovich's life occurred outside the time span of the present essay, and the last years of his life were happy and productive.

11 My Late Friend Sasha Vinogradov (Before Italy)

Unfortunately, I did not get to know Aleksandr Vinogradov in my undergraduate and graduate years – I would have learned a lot of useful mathematics from him, and possibly my research would have proceeded along different lines.

I became friends with Sasha soon after I left the department (in 1974). His seminar in Algebraic Topology and Differential Equations, followed by a seminar in Mathematical Physics, took place on Wednesday afternoons, but in fact the entire day was devoted to joint activities. It began with an outdoor soccer game (in any weather), followed by a shower, lunch at the professor's cafeteria, the two seminars, and was concluded by a walk to the Moscow University metro station. Perhaps the main result of this activity was the book "Smooth Manifolds and Observables," of which I am very proud to be a co-author.

Sasha was strongly opposed to the communist ideology, but his position re the authorities was to avoid any conflict. He emigrated to Italy in 1990, but returned to Soviet Russia every year for a summer school in Differential Equations, again avoiding any conflict with the authorities. Sasha adapted beautifully in Italy – learning Italian well enough to write excellent poetry in the language – created an important seminar and a school of young Italian researchers.

But all this lies outside the time interval of this essay, so I will conclude this section by saying that Alexandre Vinogradov passed away in 2019 in the process of heroically writing the second edition of the book "Smooth Manifolds and Observables" while fighting a terminal cancer.

12 My Friend Mitya Fuchs (Before California)

Dmitry Fuchs became my friend in the early 1960s in the context of several hiking expeditions. I used (not to say abused) this friendship in order to learn contemporary Algebraic Topology from him.

The tragedy of his life was the unexpected death of his first wife. Galya Turina drowned in a white-water kayak expedition in the Urals in 1970. It took him nearly a year to recover from that shock, and it was Izrael Gelfand who brought him back to life by suggesting that he take up painting.

When he returned to mathematics, Fuchs constructed, jointly with Gelfand, the so-called Gelfand-Fuchs cohomology. His work is precisely summarized in Wikipedia articles, his life, in an article written by S.Tabachnikov, myself, and others.

To return to my own relationship with Fuchs and Gelfand, let me mention that in 1974 Gelfand invited Mitya and me to leave the topology chair to work in his Biology Laboratory. Fuchs accepted, while I turned down the invitation.

Later, my wife Elena Efimova in the role of matchmaker invited Mitya to a seat in a play, next to Irina Kloumova, editor at Kvant magazine: Irina eventually became Mitya's second wife.

Mitya Fuchs "chose freedom" in 1990, and is now professor emeritus at the University of California at Davis.

13 The Older Generation

I have decided not to write extensively about the great mathematicians of the older generation – P.S. Alexandrov, A.N. Kolmogorov, I.M. Gelfand, A.D. Alexandrov – although I knew all of them quite well. For a good reason. Who am I, being several levels below them as a researcher, to assess the value of their work, and who am I, a person who never experienced life in the Stalin regime, to judge their behavior with respect to the communist authorities?

P. Alexandrov L. Keldysh A. Kolmogorov

14 Conclusion

Rereading this text, I have the feeling that I have written too much about myself, and not enough about the general situation and the attitudes of other, more important, persons. I ask the reader for forgiveness – I have neither the strength, nor the time, to rewrite this essay.

Abstract

In this chapter, we look at how philosophical standpoints widely held by mathematicians, conventionalism, and logical positivism were brought about through works of mathematicians. Starting from Poincaré's philosophical ideas, we try to understand philosophical ideas of two mathematicians in the Vienna Circle, Hans Hahn and Karl Menger, through their mathematical works. After that, we also touch upon a problem about the relationship between natural science and mathematics, which the Vienna Circle left unsolved.

Keywords

Vienna circle · Conventionalism · Logical positivism · Poincaré · Hahn · Menger · Popper

1 Introduction

In studying mathematics on a daily basis, most mathematicians today are aware of neither the philosophical foundations of mathematics nor the philosophical significance which their mathematics may have. Still they have some philosophical tendencies which are brought about from their mathematical work, and at the same time uphold their research activities. Such implicit philosophy appears on the surface only occasionally, but if we look back on the history of mathematics from the end of the nineteenth century to the first half of the twentieth century, we find that there was very fruitful interaction between mathematics and philosophy then. In this chapter, we are going to look at two important philosophical views which are closely related to mathematics, and how they were born through mathematicians' work. The first is "conventionalism," and the second is "logical positivism."

The conventionalism is a term contrived to stand for the philosophical standing of a great and versatile mathematician, Henri Poincaré. As we shall see in the following section, the conventionalism expresses Poincaré's flexible thinking, particularly his quite radical anti-Kantian attitude concerning non-Euclidean geometry and the universe. In the "Vienna Circle," this attitude would be extended to more general geometry and even to axiomatic systems of mathematics. Logical positivism is a philosophical trend dating back to the beginning of the twentieth century. It started and flourished in particular in Vienna before the culture of this city was brutally destroyed by the political disaster leading to the Anschluss. It is the name of Wittgenstein that is usually associated with this term. Still, we should note that logical positivism is a way of thinking somehow commonly shared by Viennese philosophers, scientists and mathematicians, in particular those who participated in the Vienna Circle. After the destruction of intellectual freedom under the Nazi rule, some of the people in the circle had a luck to flee from continental Europe, and started new academic lives in other worlds, mainly in the USA and the UK. These émigrés contributed to the foundations of the modern philosophy in the Anglo-Saxon world, which is referred to as analytic philosophy.

After examining in the first section Poincaré's conventionalism with regard to geometry and space, and his rather Kantian attitude towards mathematical formalism, we shall look at how these two philosophical views, conventionalism and logical positivism, were combined and developed by mathematicians in the Vienna Circle, Hans Hahn and Karl Menger. Both are not only first-rate mathematicians, but also had deep knowledge and insight of philosophy. Through their works, we can understand how the development of modern mathematics freed us from old Kantian apriorism, both in geometry and logic.

In the last part of this chapter, we shall look at a problem which was not fully solved by the conventionalism and the logical positivism espoused by the Vienna Circle: the relation between natural science and mathematics. Another Viennese philosopher, Karl Popper, did pioneering work, criticizing some traits of the Vienna Circle, but the problem remains far from being solved.

2 Poincaré: Conventionalism

We start by looking at Poincaré's conventionalism in geometry and apriorism in logic before turning to the work of mathematicians in the Vienna Circle.

Henri Poincaré (1854–1912) is a versatile mathematician whose works extend to so many branches of mathematics, but to understand his conventionalist standpoint, it is indispensable to look at his work in geometry (and topology). (We note that some of the description here overlaps with Ohshika (2019).) From the days of Euclid up to the eighteenth century, it had been believed that the only possible geometry is Euclidean geometry, a system of geometry where the parallel postulate holds, or in other words, where the sum of interior angles of any triangle is equal to π. If we consider geometry on a sphere, then by defining great circles to be straight lines, we can consider non-Euclidean geometry, where there are no disjoint parallel lines. Spherical geometry was known even to ancient Greeks, and in the modern era, it was studied by Euler comprehensively, but it was regarded as a part of Euclidean geometry. It was through the work of Bolyai and Lobatchevsky that non-Euclidean geometry really began. Their geometry, in which for any straight line ℓ and a point P outside ℓ, there are infinitely many straight lines disjoint from ℓ that pass through P, corresponds to hyperbolic geometry where the sum of interior angles of any triangle is less than π. Beltrami and also Poincaré constructed a model of hyperbolic geometry, realizing it as either the upper half-plane or the interior of the unit disc, making use of Riemann's idea to describe geometry using infinitesimal metrics.

In several of his essays contained in Poincaré (1902, 1908, 1911, 1917), Poincaré talked about the epistemic consequences of the invention of non-Euclidean geometry. According to Kantian epistemology, it is a synthetic a priori judgment that our space is Euclidean and has three dimensions. Poincaré rejected this view by (a) analyzing how we construct the notion of space around us from sensations we get from outside, and then (b) by showing that Euclidean geometry is just a possible choice which looks convenient to us. The first part (a) of Poincaré's idea is shared by positivists such as Mach whose view we shall look at in the next section. Poincaré's real originality lies in part (b), which should be called the geometric conventionalism. He explained convincingly that there can be no possible observations which verify Euclidean geometry, rejecting the non-Euclidean one. It is well known that Einstein was influenced by Poincaré's conventionalism in the process of accomplishing his general relativity.

Poincaré's view on the relation between the real world and geometry, based on his conventionalism, is anti-Kantian and was very revolutionary at the same time. Compared to this, his view on the foundations of mathematics was more intuitionistic, anti-formalistic, and rather close to the Kantian standpoint. We now turn to looking at his view on the latter topic.

For geometry, its axiomatization was already started at its beginning in ancient Greece, in Euclid's "Elements." Also the rules of logic, such as syllogism and the law of excluded middle, were formulated explicitly in ancient Greece, especially by Aristotle. In contrast, in other parts of mathematics, in particular in analysis, most notions, including those using infinity above all, had been used without precise

definitions, relying on intuition. Georg Cantor, the founding father of set theory, formulated the notion of set rigorously, and found that we can define that two sets have the same number of elements, or to be more precise, have the same cardinality, if and only if there is a bijection between them. Making use of this, he showed that there are more than one kind of infinity, in particular that the cardinality of natural numbers (countable infinity) is different from the cardinality of real numbers (uncountable infinity).

Based on Cantor's new notions, Richard Dedekind and Giuseppe Peano tried to axiomatize the natural numbers. While the possibility of mathematical induction had been considered to be derived from some property of the set of natural numbers before their work, in Peano's axioms, it is rather a part of the axiomatic definition of natural numbers. In the same vein, Ernst Zermelo tried to axiomatize set theory. His system of axioms made it possible to save set theory from the famous Russell's paradox, and also includes a controversial one, the axiom of choice.

Poincaré was not so enthusiastic about this trend of axiomatizing mathematics. Analyzing axiomatic approaches attentively, he thought that although they tried to eliminate contradictions by axiomatization, there is no guarantee that this would not introduce a new contradiction. In Poincaré (1917), he says

> Mais s'il a bien fermé sa bergerie, je ne suis pas sûr qu'il n'y ait pas enfermé le loup.
> But if he surely closed his sheep pen, I am not sure if he did not lock up the wolf inside.

As for the axiom of choice, Poincaré took a transcendental position to claim that it should be valid, a position which we can call Kantian. (See Cassinet (1983); Longy (2001) for a detailed analysis.) It seems that what Poincaré had in mind when he talked about the axiom of choice was its use for a countable family of sets whereas what is really problematic is its application to an uncountable family of sets. In fact, a later development of the foundations of mathematics tells us that it is possible to construct a system of axioms without the axiom of choice for uncountable families of sets.

To sum up his view toward mathematical formalism or logicism, he says in Poincaré (1908):

> Si même ils y avaient entièrement réussi, les Kantiens seraient-ils définitivement condamnées au silence? Peut-être pas, car en rduisant la pensée mathématique une forme vide, il est certain qu'on la mutile.
> Even if they had totally succeeded (in axiomatisation), would the Kantians be damned to silence for good? Probably not, for, by reducing the mathematical thinking to an empty form, they would certainly mutilate it.

It is rather amazing that Poincaré took a Kantian position with regard to the foundations of mathematics whereas he was clearly anti-Kantian in geometry. We surmise that this choice has something to do with the facts that his mathematics has a quite geometric flavor even when the subject is neither geometry nor topology, and that the geometric intuition was very important for his research.

3 Mathematicians in the Vienna Circle I: Background and Hans Hahn

As we mentioned in the Introduction, we shall next focus on mathematicians in the "Vienna Circle" (Wiener Kreis), Hans Hahn and Karl Menger in particular, and the trend of philosophy, called logical positivism, which flourished in Vienna before the Anschluss. The University of Vienna is known to have a tradition of philosophical studies on the foundations of science. The name of Ernst Mach (1838–1916), who held a chair at the University of Vienna from 1895 to 1902, comes to mind when we look at the beginning of this tradition. In fact, the people in the Vienna Circle can be regarded as philosophical successors of Mach, and some of them founded the "Ernst Mach Society" (Verein Ernst Mach) and organized public conferences under its name in the 1920s. Mach, as a physicist, is well known in particular for his work on acoustics and optics. He wrote influential works in philosophy, "Die Analyse der Empfindungen und das Verhältnis des Physischen zum Psychischen" and "Erkenntnis und Irrtum : Skizzen zur Psychologie der Forschung" among them. His philosophical position, often dubbed "empirio-criticism" along with that of Richard Avenarius, can be regarded as another departure from orthodox Kantism with Poincaré's conventionalism. At the same time, his philosophy is a precursor of the Viennese logical positivism combined with conventionalism, which is the topic of this section.

In the books which we mentioned above, Mach tried to analyze how our notion of the existence of objects is constructed from senses which we receive from outside. Naïve materialism, as was expounded by Vladimir Lenin in his criticism of the empirio-criticism Lenin (1909), presupposes the existence of things independent of human recognition. In a sense, this position regards the epistemology as being superfluous. In the other extreme, there is a position of solipsists such as George Berkeley. The latter denies the existence of external world, that is, things independent of and outside us, and admits only the existence of minds and ideas, and of course of God. Kant's transcendental idealism, set forth in his main work Kant (1781), is an attempt to justify the existence of things outside minds, by distinguishing "thing-in-itself (Ding an sich)" from its appearance. Mach's philosophy expounded in these books can be regarded as a different way to bridge the gulf between existence and recognition, which rejects both naïve materialism and Kantian thing-in-itself. He starts with our sensations, such as colors, sounds, pressures, spaces, and times, and analyzes how the external world and the existence of things outside us are deduced from them. In this way, he can explain how things outside us turn up without assuming the existence of Kantian thing-in-itself. We note that this argument is quite similar to Poincaré's analysis of our recognition of space, which we explained in the preceding section.

Thus Mach tried to consolidate the foundations of the external world based on our sensations. This can be regarded as a precursor of the modern worldview of physicists after the birth of quantum dynamics, in particular Heisenberg's uncertainty principle. Mach's philosophy had a big influence on Russian Marxists such as Alexander Bogdanov, Anatoly Lunacharsky, and Nikolai Velentinov among others.

This made Lenin, in exile in Geneva and London, write a disparaging criticism of the empirio-criticism Lenin (1909) from the viewpoint of naïve materialism, which can be barely called Marxism: Marx, who had a deep Hegelian philosophical background would not have adhered to such simple-minded materialism. Although this rough work of Lenin, in which he identifies the empirio-criticism with Berkeley's solipsism, has minor value as a philosophical work, it was canonized in Stalin's era and served as heavy shackles on Soviet philosophers (see Valentinov 1968; Bakhurst 2018).

Now we return to the topic of this section and the next: the Vienna Circle. The Vienna Circle was initiated by Hans Hahn (mathematician, 1879–1934), Moritz Schlick (physicist, philosopher) who inherited the chair of Mach from Ludwig Boltzmann, and Otto Neurath (sociologist, economist). (Before this, there had been what should be called the proto-Vienna Circle founded by Hahn, Neurath, and a physicist, Frank Philipp. See Introduction by Karl Menger of Hahn (1980) and Haller (1991).) The circle held seminars, lectures, and above all meetings in Viennese cafés. The existence of first-rate mathematicians, Hahn at the beginning, and Karl Menger and Kurt Gödel later, made the circle easy to absorb the most recent progress in mathematics and to make use of it for philosophical thinking.

In the years during which the Vienna Circle was active, problems concerning the foundations of mathematics, upon which we have touched in the preceding section, were intensely studied. This led to the consolidation of the axiomatic systematization of mathematics, which became common knowledge of mathematicians later. In this field, the impact of Gödel's (first) incompleteness theorem, his work during his Vienna years, is enormous. Another important aspect of mathematics in these years is the debates and antagonism between "formalists" and "intuitionists." Roughly speaking, the former, represented by David Hilbert, claimed that mathematics is just a series of logical manipulations, which obey rules of logic, starting from non-defined terms and axioms, whereas the latter, represented by L. E. J. Brouwer, tried to base mathematics on construction and intuition, and not on logical manipulation, rejecting in particular the law of excluded middle. The standpoint of the Vienna Circle is closer to the formalist, as we shall see soon.

The name of one of the founders of the circle, Hans Hahn, appears in contemporary textbooks on measure theory and on functional analysis which we usually refer to. In measure theory, the Hahn decomposition theorem appears in most textbooks. It states that for any signed measure μ defined on a $\boldsymbol{\sigma}$-algebra $\boldsymbol{\sigma}(X)$ on a set X, there is a decomposition of X into two disjoint $\boldsymbol{\sigma}(X)$-measurable sets, on one of which $\boldsymbol{\mu}$ induces a positive measure and on the other of which $\boldsymbol{\mu}$ induces a negative measure. This work was completed before Hahn came back to Vienna. He returned to Vienna, after taking a position at the University of Czernowitz and then serving for the army, to succeed the chair of his mentor, Gustav von Escherich. In Vienna, Hahn's interest was focused on what is now called "functional analysis." Hahn is regarded as one of the founding fathers of this field of mathematics, and he is known for fundamental results such as the Hahn-Banach theorem and the uniform boundedness principle. It is noteworthy that Hahn used the axiom of choice (or its equivalent) to prove these

theorems. This should be noted as an example of non-triviality and usefulness of the axiom of choice for uncountable families, which Poincaré did not realize.

Hahn's philosophical standpoint is clearly and succinctly expressed in his pamphlet titled "Superfluous entities or Occam's razor" which is reprinted in Hahn (1980). There he declares that his philosophical standpoint is that of empiricism and shows his sympathy toward British philosophers such as John Locke, David Hume, and Bertrand Russell, whereas he puts himself against Plato and German metaphysics, and above all, Kant. He distinguishes two ways of thinking: one is "world-denying" and the other is "world-affirming." According to Hahn, Plato is a typical world-denying philosopher. Distrusting the world of our senses, which is not constant and sometimes deceiving, Plato considered that outside and above this world, there is a world of true being, ideas. He declared that the things which we sense in this world are just projections of ideas. Hahn says that the history of western philosophy from ancient Greek age through medieval theology until French rationalism and German idealism is dominated mainly by the world-denying philosophy, possibly except for Democritus and the Epicureans. For Hahn, it is the British empiricists such as Locke, Hume, and his contemporary Russell that liberated us from this tradition.

William of Occam is a Franciscan in the fourteenth century England. Occam's razor refers to the proposition saying that "entities must not be multiplied beyond necessity," which he repeated in his works and which we can regard as expressing his view of nominalism against mainstream scholasticism of his day. Hahn says that Occam's razor should be used to cut away the world-denying philosophy such as Plato's "ideas" and Kant's "things-in-themselves." Hahn believes, along with Mach, that we should start from observations obtained by our senses as the only foundations of our knowledge. What distinguishes his philosophy from that of Mach is his belief that logical deduction and mathematics are tautological and hence do not add anything new but logically equivalent contents. This understanding of mathematics is shared by most people in and around the Vienna Circle at that time (see for instance Neurath (1973)), with an exception of Karl Menger, whom we are going to talk about in the next section, and who was not totally in agreement with this idea. This view that mathematics is a tautology was first formulated in the form of philosophy by Wittgenstein (1922), and this book was highly praised by Hahn, although there was a subtle difference in the use of the word "tautology" between Wittgenstein and Hahn, Uebel (2005). We note that Karl Popper, whom we shall talk about later, was quite antagonistic towards Wittgenstein and his work, and had quite different views on natural science from Wittgenstein, but still shares this view on mathematics.

The above summary of Hahn's pamphlet may give an impression that his standpoint would be close to that of naïve realism, for instance, that of Lenin, but Hahn's philosophy is not that simple. First, Hahn did not assume things prior to and outside our senses, but started from our observations as the foundations of our knowledge following Mach's philosophy. Secondly, Hahn clearly distinguished the real world from logic-mathematics, and said that there is no unequivocal correspondence between the two.

Hahn died in 1934. This was 4 years before the Anschluss, but Austria already fell into the hands of fascists that year, and the Social Democratic Party of Austria would be banned 2 years after then.

4 Mathematicians in the Vienna Circle II: Karl Menger

Now we turn to the second protagonist of our study of the Vienna Circle, Karl Menger (1902–1985). He studied mathematics at the University of Vienna. (See Golland and Sigmund (2000), (Menger 2002, Sigmund's chapter) for an academic biography of Karl Menger.) A fairly detailed description on Menger's encounter with Hans Hahn and his first original work in mathematics can be found in his own memoir (Menger 1994, Chap IV). Menger was a first year student of the university when Hahn returned to Vienna as a professor in 1921. Menger participated enthusiastically in the seminar organized by Hahn titled "Neueres über den Kurvenbegriff," which dealt with the problem of how to give a mathematically precise definition of curves.

A traditional intuitive understanding of curves was turned into a mathematically precise definition for the first time by Camille Jordan. He defined a curve on a plane to be a continuous image of an interval. Peano constructed in Peano (1890) a continuous image of an interval filling up a plane, which is not injective but finite-to-one. Based on this construction, Hahn proved that more generally, every compact, connected and locally connected metrizable set in a Hausdorff space can be a continuous image of an interval, Hahn (1914). This result of Hahn showed that the definition of curves as continuous images of intervals is too general. On the other hand, if we impose the condition that the map is injective, then we can regard neither a graph nor a figure-eight closed curve as a curve. Therefore, to define mathematically what we intuitively regard as curves, more work would be necessary. Menger, learning this state of difficulty in defining curves, tried hard to solve this problem, and reached a conclusion that curves should be defined by considering neighborhoods of the points lying there and their boundaries. He also used the notion of continuum, that is, compact connected metrizable space, under the restriction that it is embedded in a Euclidean space. We note that the notion of continuum had already been introduced by Cantor. This result of Menger was published as Menger (1929) much later, only in 1929, in which he says:

> Wir nehmen Kurve ein Kontinuum K von der Eigenschaft daß, wenn p ein beliebiger Punkt von K und U_1 eine offene Umgebung von p ist, eine offene Umgebung von P $U_2 < U_1$ existiert, mit deren Begrenzung K keinen zusammenhängenden Teil gemein hat.
>
> We call a continuum K (in a Euclidean space) a curve when it has the property that if p is any point of K and U_1 is an open neighbourhood of p, then there exists an open neighbourhood $U_2 \subset U_1$ of p such that the intersection of the boundary of U_2 and K contains no connected subset (except for singletons). (Phrases in parenthesis are added to explain the context of this definition.)

He also tried to define the dimensions of sets inductively based on this line of idea. First, a zero-dimensional set is defined as follows:

> Wir nennen nulldimensional eine nichtleere Menge, welche keinen zusammenhängenden Teil enthalt.
> We call a non-empty set zero-dimensional when it contains no connected subset (which is not a singleton).

Then an n-dimensional set is defined inductively as follows:

> Wir nennen n-dimensional eine Menge M mit der Eigenschaft, daß zu jedem ihrer Punkte p und zu jeder offenen Umgebung U_1 von p eine offene Umgebung von p $U_2 < U_1$ existiert, mit deren Begrenzung M eine höchstens $(n - 1)$-, mindestens für einen Punkt aber auch tatschlich eine $(n - 1)$-dimensionale Menge gemein hat.
> We say a set M (in a metric space) to be n-dimensional when it has the property that for any point $p \in M$ and any open neighbourhood U_1 of p, there exists an open neighbourhood $U_2 \subset U_1$ of p whose frontier has at most $(n - 1)$-dimensional intersection with K, and at least for some point p, such a neighbourhood actually has $(n - 1)$-dimensional intersection with K.

The mathematical notion of dimension was first defined for linear spaces, as can be seen in the work of Hermann Grassman. Riemann introduced a generalized space equipped with what is now called a Riemannian metric, which is the origin of the notion of manifold, and its dimension was defined to be equal to the dimension of the Euclidian space on which it is modeled. Although there is a phrase as follows in (Poincaré 1917, Chapitre III), where he tried to define dimension for a more general space, based on the notion of cuts, originally due to Dedekind, it is not formulated rigorously. (Menger himself remarked that he found this work of Poincaré after completing his work, in a footnote of (Menger 1929, note 15).) After observing the properties of curves and surfaces using cuts, Poincaré defines an n-dimensional continuum as follows:

> Un continu a n dimensions quand on peut le décomposer en plusieurs parties en y pratiquant une ou plusieurs coupures qui soient elles-mêmes des continus à $n - 1$ dimensions. Le continu à n dimensions se trouve ainsi défini par le continu à $n - 1$ dimensions; c'est une définition par récurrence.
> A continuum has n dimensions when we can decompose it into several parts, by performing one or more than one cuts which are continua of $n - 1$-dimensions themselves. Thus the continuum of n-dimensions is defined by the continuum of $n - 1$-dimensions; this is a definition by induction.

We can easily see an analogy between this definition and Menger's. Still, by "continuum," Poincaré meant something like a submanifold embedded in a Euclidean space or a union of submanifolds intersecting transversely each other. Since Poincaré did not use the theory of general topology developed by Hausdorff, he could not make the definition mathematically rigorous. In fact, it is easy to see that this definition will break down if we apply it to objects with cone-like singularities.

Menger's definition relies on general topology and deals with quite general topological objects, although they must be assumed to lie inside a metric space.

Menger had worked out these results while he was still a student, but they were not completed as a paper immediately since he fell ill with tuberculosis soon after. He wrote his thesis based on this idea after his recovery. After obtaining a doctoral degree, he was offered a job under Brouwer, a Dutch topologist who is famous as a proponent of mathematical intuitionism.

Although his relation with Brouwer got tense during his stay in Amsterdam because of a problem of priority for the definition of dimension, Menger got a serious interest in Brouwer's idea of intuitionism. He returned to the University of Vienna as an associate professor in 1927. Soon after his return to Vienna, Menger wrote two books, one on dimension theory, Menger (1928e), and the other one on curve theory, Menger (1932), which summarize his work on these two subjects started in his student years. At the same time, Menger was invited to join the Vienna Circle by Hahn.

Menger introduced new findings (his own and also others') on the foundations of mathematics to the circle. Besides his works in topology and geometry, Menger himself wrote several papers on logic and the foundations of mathematics during these years while he actively participated in the circle. For instance, in his paper in 1930 (see (Menger 1979, Chap 2)), he gave a clear explanation on mathematical intuitionism, which was propounded mostly by Brouwer at that time, but in a very obscure way. In the 1920s, there were debates between proponents of intuitionism, first advocated by Kronecker, and represented by Brouwer at that time, and those of formalism, represented by Hilbert. The intuitionists, against the formalists, claim that when one proves a theorem, the logical inference alone is not enough, and that mathematical constructions should be accompanied. This in particular implies, in Brouwer's version of intuitionism, the rejection of using the rule of "excluded middle" (i.e., the logical rule that $p \vee \overline{p}$ *is* always true), hence proofs by reduction ad absurdum, and existential propositions. Brouwer further tried to construct a set theory free of the rule of excluded middle in Brouwer (1919).

Brouwer's papers on this topic are reputed to be very difficult to read. Menger deciphered this work of Brouwer and showed in Menger (1928a, b, c, d) that Brouwer's intuitionistic set theory can be interpreted within the framework of ordinary set theory. Also in his public lecture in 1932 (see (Menger 1979, Chap 1)), Menger demonstrated that mathematical intuitionism can be kept within formalistic mathematics only by changing the axioms of logic, once the element of value judgment is removed from the intuitionists' claim. For instance, one can consider axioms of logic such that there are more than two possibilities for the validity of a proposition p, that is, by admitting the possibility that neither p nor $\overline{p}$ holds. By changing axioms in this way, some theorems which were already proved using reduction ad absurdum might not be proved any more, but the formalistic foundations of mathematics is preserved.

Menger's standpoint expressed in these works can be regarded as an extension of conventionalism to logic and the foundations of mathematics. As we saw in Sect. 2, Poincaré, who was the founder of conventionalism with regard to space and time,

took rather Kantian view for the foundations of mathematics. It should also be emphasized that Gödel, who was 4 years younger than Menger, was also a student of Hahn, and that his first incompleteness theorem, evidently one of the most important work in the foundations of mathematics, was first presented in Menger's colloquium. Menger not only had first-hand information on the fast developments of the foundations of mathematics but also wrote himself several papers on this topic.

Another philosophically important aspect related to Menger's mathematical work is that he dealt with very general geometric objects compared to his predecessors, above all Poincaré. Even in his first work, he considered very general objects, continua, to define dimensions. As was explained above, only objects Poincaré had in mind when he tried to define dimension are manifolds or a union of manifolds with the same dimension intersecting transversely.

Later, from the 1940s on, Menger developed the theory of statistical (or probablisitic) metric space, Menger (1942, 1951a, b, c). For two points p, q in a space X, instead of an ordinary distance function $d(p, q)$ which defines a structure of a metric space, he considers a monotone non-decreasing function F_{pq} defined on the set of real numbers which takes values in [0,1], with the properties $F_{pq}(t) = 0$ for every $t < 0$ (the positivity), $F_{pq} = F_{qp}$ (the symmetry) and $F_{pq} * F_{qr} \leq F_{pr}$ (a substitute of the triangle inequality), where * denotes the convolution. (The last condition using convolution is originally due to Wald (1943).) The intuitive meaning of this function is that $F_{pq}(t)$ is the probability that the distance between p and q is less than or equal to t. In particular if $F_{pq}(0) > 0$ for $p \neq q$, then this means that p, q are indistinguishable with the probability $F_{pq}(0)$. As this observation shows, this theory of Menger is a precursor of the fuzzy set theory.

In Menger (1979, Chap 20), Menger explains the philosophical significance of this work. If we try to construct our notion of space, as did Mach and Poincaré, including its geometric/topological property, starting from our senses, then we need to take into account the fact that if two points are too close then we cannot distinguish them. Poincaré also noticed this and repeatedly described it in his essays Poincaré (1902, 1908, 1911, 1917, 2002). In Poincaré's description which appeared in (Poincaré 1911, Chap 3), in our senses, we may perceive that $A = B$, $B = C$, $A < C$, that is, pairs of points A, B and B, C are undistinguishable for us, whereas we can distinguish A from C. This rather confusing expression can be interpreted clearly using Menger's probabilistic metric: $F_{AB}(0) > 0$, $F_{BC}(0) > 0$, whereas $F_{AC}(0) = 0$.

Poincaré's geometric conventionalism made it possible to consider non-Euclidean spaces, or more generally Riemannian manifolds as models of our space. Still if we look at them microscopically, for instance, if we look at their tangent spaces, they have a Euclidean geometry. Therefore, we can call Poincaré's conventionalism "global conventionalism." Menger's work above shows that we can also consider "local conventionalism" or even "infinitesimal conventionalism." Modern theoretical physics is founded on general relativity and quantum mechanics. It was Riemann's work extending the geometric objects enormously and Poincaré's geometric conventionalism combined with Mach's positivism that paved the way for general relativity. On the other hand, there had not been a new notion of space which supports quantum mechanics. Menger was aware of this situation, and tried to

construct a model of space which is compatible with quantum mechanics. Later there appeared many geometric theories which support the worldview of quantum mechanics, but it should be remembered that Menger tried to construct a geometric model relying on his deep philosophical thinking well ahead of his time.

5 Natural Science Versus Mathematics

By choosing a rather formalistic position towards mathematics, people in the Vienna Circle consolidated the foundations of mathematics, and overcame Kantian mindset both for geometry and logic. On the other hand, they tended to project the integrity and logical strictness of mathematics onto natural science, trying to eliminate imprecise, non-mathematical elements from science. (This is not exactly Menger's attitude though.) Naturally, this was not readily acceptable for natural (or even social) scientists in general.

There is a typical picture of a mathematician put against natural science in a passage of Brecht's piece "Lebens des Galilei" (Brecht 1952, 1998), where Galilei tries to demonstrate his finding of satellites of Jupiter (via his telescope) to court scholars of Florence.

> PHILOSOPHER: Thank you my boy. I am afraid it is not as simple as that. Before we use your celebrated instrument, Mr. Galilei, we beg the favour of a discussion - subject: can these moons exist?
> MATHEMATICIAN: Of a formal discussion.
> GALILEO: I strongly suggest you take a look first. You will find that a discussion would have wasted your time.
> ANDREA: *indicating stool*: Here please.
> MATHEMATICIAN: Surely! You know your proposition that there is no support in the heavens in contradiction to the wisdom of the ages? . . .

This is from the English adaptation performed in New York, based on the translation by Laughton. In the Berlin version Brecht (1998), the corresponding passage is a bit different from the English version as follows. The last line by the mathematician, a bit longer than the New York version, contains geocentrism:

> DER PHILOSOPHER Danke mein kind. Ich fürchte, das alles ist nicht ganz so einfach. Herr Galilei, bevor wir Ihr berühmtes Rohr applizieren, möchten wir um das Vergnügen eines Disputs bitten. Thema: Können solche Planeten existieren? / DER MATHEMATIKER Eines formalen Disputs./ GALILEI Ich dachte mir, Sie schauen einfach durch das Fernrohr und überzeugen sich?/ ANDREA Hier bitte./ DER MATHEMATIKER Geweiß, Geweiß.- Es ist Ihnen natürlich bekannt, daß nach der Ansicht der Alten Sterne nicht möglich sind, die um einen anderen Mittelpunkt als die Erde kreisen, noch solche Sterne, die im Himmel keine Sttze haben?

A mathematician is thus depicted, alongside a philosopher, as someone who starts a discussion within the framework of the "wisdom of the ages," ignoring the

evidences before their eyes. Of course this is not the role played by mathematicians in modern age, but there remains a doubt among natural scientists that what is important for mathematicians is theories, not facts.

Logical positivism is clear in pointing out the tautological character of mathematics, but it did not answer the question of why natural laws can be aptly described by mathematics. Karl Popper's "philosophy of science," which can be found in his first book published in Vienna (Popper 1935, 1959) took an approach quite different from the Viennese logical positivists. In the book, he tries to solve the problem of justifying the validity of natural laws. Positivists tried to solve this problem by introducing the "inductive methods," which says that by accumulating many observations and experiments, and by induction, we have a scientific law. This is obviously logically untenable, for we have only finitely many observations and experiments whereas any scientific law is a universal proposition. Popper's solution to this problem is very clear: he claims that scientific laws are nothing but hypotheses which are not negated by observations and experiments. He also gave an answer to the problem of demarcation between a scientific theory from a nonscientific one. Popper claims that a scientific theory must be falsifiable, that is, it must be possible to conceive a result of an experiment or an observation which would falsify the theory if it happened. As we can easily see, mathematics was not regarded as a scientific theory by Popper. As we mentioned before, he shared with the Vienna Circle the view that mathematics is a tautology.

There is an issue in Popper's view of a scientific theory that it did not reflect what really happened in the process of scientific discoveries, in particular when really new theories such as general relativity or quantum theory appeared. This type of criticism was put forward, among others, by Kuhn, in his very famous epoch-making work, Kuhn (1962). Another issue in Popper's view is that although he regarded a scientific theory as a system, he did not take into account the effect of the theory on the observations/experiments. This second issue is more important for mathematicians.

Scientific theories are frequently formulated in a form of mathematical formulae. Although Newton invented for himself the mathematical theory which he needed for his theory of dynamics, in the modern era, natural scientists usually make use of mathematics which already exists to formulate their theories. Even such a great physicist as Einstein would not have been able to formulate his general relativity without relying on the differential geometry originated by Riemann. Since observations and experiments are always theory-laden, they are affected by what kind of mathematics we have in our hands.

If the Vienna Circle had existed for longer than it really does, and if they could go on to discuss such things with Popper or other philosophers, mathematicians, and physicists, then they could have dug into such problems, and a new view on the relationship between mathematics and science might have been born. Unfortunately, after the Anschluss, they fled to far-flung parts of the world, and this prospect was never realized.

6 Conclusion

In works belonging to recent philosophical trends such as structuralism and post-structuralism, modern mathematical notions and arguments appear frequently. Some of them are serious applications of mathematics, but there are some in which the significance of introducing mathematics seems to be hard to justify. For instance, Lacan talked about automata in his famous lecture on "la lettre volée" and Borromean rings in his lectures titled "R. S. I." (see Lacan (1974–1975, 1978)). It is fairly easy to realize the relevance of the notion of automaton in the first, whereas in the second, it is rather dubious if Lacan really understood the mathematics which he was trying to use (knot theory).

The book written by Bricmont and Sokal (1997), which reveals inexact, or worse, nonsensical use of mathematics by French post-modern thinkers, had a devastating effect among mathematicians and scientists on the reputation of fashionable trends of French philosophy. Although their analysis is well documented and adequate in many ways, what they took as examples are only parts of contemporary philosophy, even if we restrict our attention to the French one. The present author believes that there still remain both philosophical problems in mathematics and mathematical problems in philosophy, and serious discussions as were done in the Vienna Circle are still possible between mathematicians and philosophers and should be desirable for both.

Some Disillusioned Thoughts About School and Teaching

Valentin Poénaru

Abstract

This is an outline of my experience, from philosophy, to physics and then to mathematics, and my personal view on today's important philosophical problems. This leads me to some critical thoughts concerning high-school teaching, particularly in France, related to religious or political fanaticism.

Keywords

High-school teaching · High-school programs · Religion · AMS classification: 97D30

Since a few years, I sometimes write, occasionally, nonmathematical texts too and call them literary, mostly in English. Occasionally, I might also write in French. So, it happens that sometimes I am a writer. But I must confess that, to my regret, I never managed to create, out of nothing, characters who can jump out of the written prose, with a life of their own, like Cervantes, Dostoevski, or Balzac were able to do. The only thing I can do is to put down on paper impressions or fleeting thoughts, which sometimes cross my mind in a night of insomnia. Because it can happen that I may have insomnia, usually of a mathematical kind, but then also, of a literary nature. And in that case, the story unfolds all by itself, with me as a mere spectator, and words get organized all by themselves. And when there is a matter of maths, then there are no words at all, but rather abstract images, with their own life.

Note. The first version of this essay was written in French, a first part in October 2014, in Bures-sur-Yvette, France, and a second part in February 2015, in Vuda Point Fiji.

When I grew up, as a child or a teenager, in that Balkan country where I happen to have been born, I hated the school where I had to go. With rare exceptions, elementary school teachers, or high-school teachers, were never endeared by me, neither then nor now, neither there nor here.

There were exceptions, of course. For a number of years, in high school which in Romania lasted from the age of 10–18, I had a remarkable history teacher. He was the son of a priest; we were in an Orthodox country where priests, unless they are monks, have to be married. And that particular priest, the father of my teacher, had been himself a professor of ancient languages at the Theological faculty, which existed there before Communism. And this father had insisted that his son, at home, should speak living languages, old Greek and the Latin of Cicero, in addition to Romanian, of course.

The lectures of my teacher were brilliant, nothing to do with the official programs concocted by the high authorities of the Ministry of education, of that country. And what he told us was so interesting that even the worst pupils listened to him, fascinated. I love to think that, had we not lived in a communist country, my teacher would have made a big university career.

It is that particular teacher, and also my father, who gave me a big taste for history, which I practice as a hobby, when I need to relax. And, in that particular domain I am today knowledgeable enough to be able to identify the sources of my teacher from long ago, and even sometimes to disagree with him, concerning those things he told us. When it comes to reading history, I can do that in several languages. And it is from an Italian author, actually a former professor of nuclear engineering at the university of Milano, and also former boss of the Italian version of NSF, who later became a remarkable historian, that I learned something which I cannot resist telling you now. Toward 1900, Charles Péguy, that big hero of both Catholics and the French left, tells a friend: “Yes, the war will certainly come, and then the first thing we should do is to shoot Jaurès.” As you may know, Jaurès was shot the very first day of the war, in August 1914. Not by Péguy, of course, but then Péguy certainly suggested it big. And it is not here in France that these things were ever taught in school.

Mario Silvestri, my nuclear expert turned historian, wrote the best pages I have ever read on Fascism, Italian, or from elsewhere, and also on the mechanisms of the big economic crisis from 1929 to 1933. And he is also one of the rare historians to give a good account of the impact of science and technology on history.

To change topic, maybe not quite, I was always puzzled by how close friends can have very different memories concerning things they went through together, and have such radically different judgments about the same events. Already when I was seven, in elementary school, Mircea became a close friend, and he stayed so until he died of lung cancer, in Paris, in 1987. And for him, our elementary school, which we went through together, was a beautiful thing, very important for his future career as medical doctor and biologist. But for me, it was a black jail: That is how I felt about it. In my memory, the worst moments of my life were that school (4 years), the military service which I did under the shadow of Stalin, and my first marriage. Of

course, there were other unpleasant moments in my life, but those left the biggest mark in my memory.

I certainly disliked school, but I was very far from being a bad pupil. Year after year, I had the best grades in all the subjects. But I rarely did my homework, neither at home nor in school, and I very often missed the lessons. Surreptitiously, together with a chum who incidentally also became a mathematician, we left the school building and went to the boxing school instead.

But I know how to manage, and here is a typical example. One day, there was a rumor in my high school class that for once our teacher of Romanian was going to control our homework. I never did that homework at home, and so during the break I wrote quickly a little text. When the teacher started checking, he noticed that I was presenting something much shorter than the other pupils. Of course, I had not had the time to do something longer. And then some friendly voices started mumbling: "He just wrote it, Ha!Ha!Ha!" So my teacher asked me to read aloud my effort. I expected some punishment, but I was actually congratulated for my elegant prose. In fact, when necessary I can write fast and well. I was even offered once a fancy job as editorial writer for a weekly magazine. But I am not in the mood of telling you now about that. I am just a mathematician, a bit of a physicist too, but neither a journalist nor a historian, although history interests me a lot.

The only thing that I learned in that high school was to live in society, together with other people of my age. But concerning the big philosophers, mathematics or physics, I had to learn all that alone, not in school. I still remember that when I was 13 or 14 my maths teacher realized that I knew already calculus, and then he got very cross. He said that I did that just in order to challenge him, and he started disliking me big. It is certainly not under the guidance of my various maths teachers that I became a mathematician. Actually, maths as such did not interest me much then. It is physics I wanted to understand, and mathematics was needed there.

I got to physics via philosophy. And then, why philosophy, and how does one get from philosophy to physics?

My father loved to take long walks with me in the nearby beautiful parks and talk to me about all sorts of things. And when I was about 9 or 10, there was an issue which bothered me a lot and I told him about it. How is it possible that something moves, when at any given moment it stays still? It seemed to me then that this meant that movement was impossible, and this thought tormented me. My father was very puzzled by my worries, which he did not understand; he did not know what to tell me.

But at home, there was a big library, the books of my parents, filled with interesting things. I started to read the Greek philosophers, and very soon I found out that Zeno of Elea, 24 centuries before, had already shared my worries. That was the beginning of my philosophical adventures. And for a while at least, my great hero was Immanuel Kant, the Kant of the "Critique of pure reason" (*Kritik der reinen Vernunft*).

There were also other books in my parental library. I found physics books, and although I could not understand exactly what they said – they were written in the

language of mathematics, opaque to me then – I still grasped that they could get much farther than the philosophers.

There is here, in this story, a matter of personal taste too, of course. Both physics and mathematics I had to learn all by myself, maths in order to be able to understand physics. And then, with their strange beauty, these two topics marveled and excited me, in a breathtaking way. And I have continued to be fascinated by them, ever since. Things concerning life I found much less attractive, and the questions of organizing human society even much less so.

Actually, moral philosophy and ethics I found frankly boring. I know, of course, quite well that we are directly concerned by the organization of society and interaction between human beings; our everyday life depends on that. But then so is good plumbing, of course. There are all sorts of things, essential for our survival, but they have nothing to take away your breath with excitement, nothing to marvel you, nor to clinch your thirst for universality and the absolute. And, intellectually speaking, I am not at all attracted by those things; they leave me ice cold.

I have just described you my personal road to philosophy, from philosophy to physics, and then quite naturally from physics to mathematics. But being brilliant in maths in school was never an attractive thing for me.

All these things notwithstanding, there were still some good things in that Balkan high school of mine. One had to attend classes only half-day, sometimes in the morning, sometimes in the afternoon, depending on the years. So, I had plenty of free time. I never did my homework, but I read all the books I wanted to read, and very importantly, I could think, think, and think.

I find that nothing is more important than free thought, when you can play around with mathematical objects or philosophical ideas, without any preestablished plan or schedule, just wander through the magic forest of abstract thought. And this way, I became the person I am.

Here in France, through my children, I discovered a school even more repressive than mine, although I come from the third world of the Balkans and here we are in civilized land. No question of free time, no possibility to read what you want, or even to think freely. No question of letting your mind explore that far away land of ideas.

And then, the ridiculous way in which various topics are put together in school, here. Why the Devil should history and geography be lumped together? Geography fits well with geology or geophysics, but not with history. Of course, historical atlases are useful, but that is not geography. I suspect that some big brain, some high civil servant in the Ministry of education, had the stupid idea that space and time correspond to geography and history, and hence the two should go together. Or, maybe, there is here some ultranationalistic idea about ancestral blood and sacred soil of our mother country (theirs, not mine!).

And then, why lump physics and chemistry together, rather than maths and physics, like in the more intelligent educational systems of Germany or Russia? All this, I think, is not unrelated with the lack of visibility surrounding theoretical physics in this land, which lasted so long. Until late, well into the first half of the twentieth century, big topics like Boltzmann's statistical mechanics or Maxwell's great synthesis electricity-magnetism-optics were totally ignored here in France. Of

course not really by everybody: There was also Henri Poincaré, the solitary genius. But then, he was a mathematician, and mathematics has always fared very well in this country.

Then, what can one say about how quantum theory was received here in France? This all-important breakthrough was totally ignored by the university, until the 1950s. Between the two wars, there were important voices claiming that it was just some Germanic metaphysical speculation. My friend Pierre Cartier told me that toward 1950, when as a young student he attended a physics course, in Paris, the professor started by saying: "Ladies and gentlemen, the so-called atomic hypothesis will never be mentioned in my course." Five years after Hiroshima, atoms were still hypothetical for this disciple of Marcellin Berthelot (not only the well-known chemist, but also minister of education, who banned atoms from high school in the beginning of the last century).

Concerning physics in high school, that is total disaster. A friend of mine, a famous physicist, told me that while around 1950, physics taught in high school was at least 40 years old; now it is about a 150.

To crown all this, why should philosophy in high school go together with the political-ideological doddering of those guys who call themselves the intellectuals? Concerning this, I still remember that at a party, after a painting exhibit of my friend Hermann Braun-Vega, a lady who had heard that I was a mathematician turned to me saying: "But you are a scientist, you sir you are not an intellectual!"

And I do not talk here about the teaching of biological sciences in high school, because I am less competent there. When I went to high school, in Romania, that was in Stalin's time, and biology was completely controlled by a certain Lysenko. Very few people still know about him today. Anyway, genetics was banned, and its practitioners went to jail. So, when I escaped from Romania, in August 1962, I was totally ignorant in biology. And I can tell you now a little funny story. In the Summer of 1964, I attended a big topology conference, in Cambridge, England, organized by my friend Christopher Zeeman, soon to become my cousin by marriage, and a bit later, Sir Christopher too. And one day, he invited me to a little lunch party with Francis Crick and an Anglican bishop. And my ignorance was such that I had never heard about DNA and I totally ignored who Crick was. The bishop was, actually, not much better. He kept calling him Mister Watson Crick, to the big annoyance of Crick and the great amusement of Christopher. But there I stood and did not understand a thing.

Coming back now to those intellectuals from above, the most important figure of the Enlightenment was Kant, who had started his career as a scientist, as a great astronomer actually, but I will not tell you here about what he achieved. Then, at a certain point, Kant started pondering, why and how did Newton succeed in understanding the world, while for more than 2000 years the philosophers hat failed to do so. And out of this came the Critique of pure reason, already mentioned, from which much of what is interesting and serious in philosophy proceeds. And if one looks at things, before and after that, a lot of philosophers were scientists too. I will quote here, at random, Descartes, Pascal, Leibniz, Mach, Poincaré, Bertrand Russel, Ludwig Wittgenstein, the members of the Vienna Circle *(der Wiener Kreis*), Popper,

and Tom Kuhn; the list is long. And then, some towering physicists of the twentieth century were imbued with philosophy, like Einstein, Bohr, Heisenberg, or Schrödinger. And I could add to the list the mathematicians Hermann Weyl and Kurt Gödel.

Why then lump together philosophy, in the classroom lessons, with the political doddering of a character like Sartre, the man who treated his conscience problems on par with the liver ailments?

Can one talk seriously about philosophy today without Gödel's undecidability and without the Turing machine and its cousins?

I will tell you now some personal opinions, for which I take full responsibility. I can only see two really important philosophical issues today: on the one hand, the foundations of mathematics, the big open gap between mathematical truth and what one can prove (see here Gödel and company), and on the other hand, the interpretation of quantum mechanics, the problem of measurement, and its incidence on the existence of objective reality (see here John Bell and company). Those two problems touch deeply the fundamental relation between thought, i.e., what goes on in our mind, and what is outside, physical reality and mathematical reality, both of them, to me, with the same ontological status. And, connected with all this is also the ontological status of the laws of nature.

Coming back to those intellectuals, with their blatant lack of depth and knowledge as soon as they leave their very narrow horizon, they should better learn from Voltaire, who from his English exile brought back in his luggage Newton's *Principia.* And he gave it to his girlfriend the marquess Emilie du Châtelet, who produced a beautiful translation, the first of its kind in France, with beautiful comments. And this was an important thing, but I do not intend to deliver you here a lesson in the history of science.

And I should not forget here that little gang of intellectuals called by some, rightly so, "the impostors." I am thinking here, of course, of Sokal's hoax and the "Science Wars." These impostors tell all kinds of phony things concerning the scientific topics I have been mentioning here. And they present their stuff bathing in a very heavy, highly undigestible, scholarly pedantic, sauce. They believe that if you quote Gödel or quantum uncertainty, this is good excuse for telling, afterward, all kinds of phony stuff.

Coming back to my starting point, I do not like school, but at least I had the good luck to be submitted to it in the third world Balkan country where I come from, and that gave me what I needed most, much much free time.

The pages you just read were written toward October 2014, but then a bit later a bloody terrorist attack was unleashed against a Paris satyrical magazine; that was in January 2015, and that triggered in my mind the text which follows now.

Religion can be a very serious challenge today; I am thinking about the fundamentalist and radical Islam, but before we had the challenge of Communism and then, even earlier in time, when the Catholic creed was intolerant and uncompromising, that was a challenge too.

Concerning Islam, in its days of glory, the Ottoman empire was relatively tolerant. My "tolerant," to be taken with quotation marks, refers to the general

climate of yore, when religious wars were creating bloody havoc in Germany, France, and England. But then, when the Ottoman empire was, later on, in the throes of death, then it became really murderous, like any wild beast in such throes, and then we had those Bulgarian atrocities, much bemoaned by Gladstone, or the 1915 Armenian genocide.

Of course, in their long history, the Ottoman Turks did other murderous deeds, but to get something comparable to our present Islamic terrorism, one has to go back 800 years, to the times of the Old Man of the Mountain and to his assassins, stuffed with hashish. I believe the same Arab word covers both things.

And it is only the radical Islam which, these days, assassinates satyrical draftsmen in France or Denmark or elsewhere. It is radical Islam which pronounces death sentences against writers like Salman Rushdie.

From our present vantage point, the other traditional religions have quieted down long ago. Of course, that is not the case with political movements like Fascism, Nazism, or Communism, which somehow replaced them. But I will not talk about them now.

You will have probably already guessed that I am very fond of Enlightenment, and concerning our present topic, here are two typical heroes of it. Toward 1700, John Locke wrote his book "On Tolerance," where he preaches great tolerance in religious matters, with one exception: no tolerance for the fanatic Catholics, very intolerant then. At least, this is how they were in these times; they calmed down big, since.

And few years later, Voltaire came with his famous "Ecrasez l'infâme !" meaning religious fanaticism.

As far as I am personally concerned, I do not believe in God; more exactly, I fail to understand what the whole issue of His existence or inexistence means. But would I be a believer, which I am not, I would not do what the good Christians daily do, pray God for my health or my little problems; I would think that is sacrilege. Besides, believers tell me about Creation, the creation of the world, something I cannot understand; I am already at pains making sense of the existence of the world, so when it comes to its creation . . .

Comes to my mind a comment by Steve Weinberg, the great physicist, in one of his essays for the New York Review of Books; he says something like this: There are many people who do horrible things, but when a nice person does that, then religion is somewhere there. Yes, at least under its radical, fundamentalist, and uncompromising form, religion is a problem.

I have talked here a lot about Islam and Catholic creed, but I was born in an Orthodox country, and when I was a young man I got to know Orthodoxy quite well. I had then strong links with Orthodox monks, something which earned me, some years ago, an invitation to a theology conference, at the Vatican. But since I thought I was out of place there, I refused very politely.

Coming back to Orthodoxy, one of its basic ideas is the existence of a vertical direction, toward transcendence, an idea which still appeals to me, and then also a horizontal direction, this world. And I was always told that this is what interests, mostly, the Catholics.

All this might be so, but then Orthodoxy is quite arch-conservative and can be even more antisemitic than Catholicism. And then, Romanians are too ultra-nationalistic, believing that one should always do as the grand-grand-fathers have done, so Romania never knew Humanism, Renaissance, Reformation, Baroque, Scientific Revolution, or Enlightenment. The country stayed too long outside of the European civilization, and that is still very feelable today.

To come back to those bloody events from 2015, when the French minister of education suggested that one should introduce more courses of civic education in school, I do not know whether I should laugh, weep, or get angry. Why the Devil make school even more boring! We do not need more courses on civic morality, pure annoying doddering, but rather courses on science, something which could interest and excite the young minds, thirsty for the absolute, and develop their curiosity too.

History teaches us that there is nothing better than science, for cutting that branch on which the fundamentalist, uncompromising religious fanaticism sits. Remember that while the Vatican did some long due excuses for Galileo, it never did so for Giordano Bruno. I believe this is because Bruno's idea of an infinite universe, with infinitely many inhabited worlds, puts dynamite under the belief in a special unique destiny for humanity, which God the Son came specially to save, on our modest planet. And Bruno conceived this idea as a direct consequence of his reading of the breakthrough of Nicolas Copernic. The Church can never forgive this kind of ideas.

One hears a lot of talk these days about Revolution. But how many people know that the origin of the word is the Latin verb "revolvere," and the noun is "revolutio," which means circular movement, hence a backward one, certainly not a linearly forward one. Remember that Copernic talks about revolution of celestial bodies. And during many centuries, all European revolutions, starting with the Hussites of Bohemia, all the way to the puritan revolution in England, were made not for a "shining future" (the French leftists say "l'avenir radieux"), but in the name of a mythical past, for going back to Paradise on Earth. All this in the name of God and for the salvation of the eternal soul. Of course, this was no longer true for the next revolutions, starting with the American and the French one.

And this is because, in the meanwhile, came the TRUE revolution, the scientific one, and that brushed away all that talk about the God on the image of Whom man is made, or about the eternal soul and its salvation. Of course one can be scientifically minded and not cut the bridge with transcendence, with the individualistic mysticism. But that kind of religious spirit is totally foreign to the traditional, highly organized, and structured religion, too often fundamentalist and uncompromising. There is no contradiction between the kind of individual and individualistic religion I was talking about before, and "laïcité," a French word which I may translate as secular spirit, something which humanity needs so much today.

A little prentice, here. In the 1920s, when Kemal Atatürk decided to modernize his country, Turkey, and get it out of underdevelopment, he identified religion as the main thing in the way. And since the word "laïcité" did not exist in Turkish, he imported it from French.

Just before ending, I feel I still have to tell you some personal ideas of mine. I think there were only two important revolutions, the scientific one and the

technological-industrial one, each coming in several successive waves. All the other revolutions might have had, here and there, some reasonable, pragmatic ideas, but most times they were beds of Procust, brutal attempts to impose a rigid grid on top of a complex and complicated humanity. That always brought a lot of suffering and misery. Nothing appealing to me, here.

I love scientific revolutions, but I dread like hell political ones, and everything they come with. About a 100 years ago, the Russian philosopher Nicolas Berdiaev wrote a book "The new Middle Ages." And there, he writes that if once people have cherished Utopias, now the time has come when those Utopias might fall on our heads, and, in that case, God have mercy on us. That is what he said.

1 Introduction

What characterizes twentieth-century mathematics? Twenty-first-century mathematics? As opposed to mathematical practices? The former is too broad and subject to different answers depending on the individual or the group being addressed. Hilbert's 23 problems published in 1900 would probably be mentioned because they influenced generations of mathematicians in the ensuing 123 years. Many names could also be mentioned such as Hardy, Ramanujan, Kolmogorov, Arnold, Poincaré, Grothendieck, the Bourbaki, the Langlands program, and numerous others as shaping the agenda of twentieth- and twenty-first-century mathematics.

In the twentieth century, among the external factors that influenced mathematics, one could say that pure mathematics (topology, algebraic geometry, and analysis) were essentially a continuation of mathematics of the nineteenth century; the influences came essentially from Riemann, Klein, Poincaré, and the Italian school of algebraic geometry. Mathematical logic was influenced by philosophy. The influences to mathematical physics came primarily from physics: quantum mechanics and relativity. Applied mathematics certainly had external influences: physics, the wars of the twentieth century, industry, medicine, computer science, etc. Discrete mathematics emerged in its own right.

2 Mathematical Practice

Mathematical practice, on the other hand, is a broader arena than mathematics per se. It is broader because it includes not only mathematicians making original contributions to the field but also others that use mathematics in other contexts. These can vary from applications of mathematics in the real world, revisiting historical sources, (auto) biographical and metamathematical accounts, to making mathematics more accessible through textbooks. Felix Klein's classical book *Elementary Mathematics from a Higher Standpoint* is an example of a textbook aimed at making mathematics accessible to school teachers over a century ago. It still remains a classic today. Textbooks (and teachers) can inspire people toward the study of mathematics. Others could simply view mathematics as a recreational

activity (e.g., Bhaskara's Lilavati, Victorian Mathematics, etc.). In this section of the Handbook, a selection of chapters serve as examples of mathematical practice in a broader sense. The perspective conveyed provides a balance between Western and non-Western contributions to practice. The contributions explore Greek, Indian, Levant, Javanese, Victorian, and Western contributions to mathematical practices culminating in twenty-first-century financial mathematics. The arrangement reveals a progression of thought and practice starting with the Greeks, suggesting mathematics as a cultural practice across time and place.

3 Mathematics as a Cultural Practice

Diophantine arithmetic is regarded as a difficult area of mathematics (and mathematical practice). Questions are easy to pose but difficult to answer. Modern number theory textbooks relegate Pell equations toward the back even though the history of mathematical practice in number theory suggests otherwise. Negrepontis, Farmaki, and Brokou provide a reinterpretation of Plato's philosophy in terms of periodic anthyphairesis. They focus on one of the most difficult and profound books of Euclid's Elements, namely, Book X, and examine palindromically periodic anthyphairesis through the lens of *Politicus*. One learns of the remarkable contributions of Theaetetus in his work on the general Pell equation. This chapter also points to connections and similarities to work on Pell equations done by Brahmagupta.

Ancient Indian mathematics has been subject to all sorts of interpretations, appropriations, and misappropriations in the literature ranging from speculations on the computational nature of Vedic mathematics to nationalistic discourses in twenty-first-century India. The view of ancient Indian mathematics today stands in stark contrast to denigrating views during colonial times expressed by the likes of W.W. Rouse Ball who wrote:

> The Hindoos, like the Chinese, have pretended that they are the most ancient people on the face of the earth, and that to them all sciences owe their creation, But it is probable that these pretensions have no foundation; and in fact no science or useful art (except a rather fantastic architecture and sculpture) can be definitely traced back to the inhabitants of the Indian peninsula. . .. (Ball 1908, p. 146)

Dani in his chapter on Ancient Indian mathematics provides a detailed review of the Sulbasutras. The Sulbasutras are a striking example of mathematical practices embedded in cultural contexts and provide us a unique window to the mathematics in India from the millennium BCE. Engagement with performance of yajnas (sacrificial fire worship) with elaborate and intricate structures led to knowledge of geometry, in particular the statement of what is called Pythagoras theorem, well ahead of the latter, and also several interesting constructions. There are four major Sulbasutras, Baudhayana, Manava, Apastamba, and Katyayana, that have been studied, to varying degrees, from an historical perspective, starting from about the 1870s, with Thibaut's translation and editing of Baudhayana Sulbasutra. Many authors, from

around the world, and from India, have contributed to the study over the years. Knowledge on the topic nevertheless remains patchy and limited, with many unanswered questions. In this overall context, Dani's chapter aims to present a comprehensive review of the mathematical contents of the Sulbasutras, together with a critical evaluation of various claims that have been made about them.

Mathematics as a cultural practice is also revealed in Karjanto and Beauducel exploration of the intricate relationship between number theoretic congruence formulas and the Javanese calendar, especially how this type of arithmetic permeates the daily lives of Javanese in Indonesia. The Javanese calendar which combines the *Saka* Hindu, lunar Islamic, and western Gregorian calendars is used for cultural and spiritual purposes.

4 Historiography of Mathematics: Who Has the Prerogative?

Who has the prerogative in writing the historiography of mathematics? Is it mathematicians or historians of mathematics? History of mathematics is a typical undergraduate course taken by students in North America and other parts of the world. Burke's account of the mathematics of three ancient cultures Thebes, Babylon, and Alexandria brings episodes from the history of measurement – some of which are found in textbooks today. These cultures have also been a legitimate area of study within the community of historians of mathematics who were more attuned to the context of the cultures that created this mathematics. Colonization played a role in creating "access" to western historians to artifacts in the greater Levant. Mathematicians, on the other hand, are able to telescope forward from origins and changes of notation into research advances in the field of mathematics. One could trivialize the history of mathematics as simply being the "wait" for the right notation to come along which encapsulates cumbersome attempts of the past in a more efficient manner. But is it okay to trivialize the mathematics of the past? Narratives in textbooks shape the worldviews of students on the origins, nature, and trajectory of the development of mathematics. Issues of precedence, the influence of colonial narratives such as the deplorable quote (one of many) by Ball earlier in this introduction, can portray the development of mathematics by nonwestern cultures in a negative or skewed light.

Blasjö argues that "presentist historiography is not the natural outlook of the mathematician, but rather a direct antithesis of the mathematician's most fundamental reason for studying history. To study past mathematics precisely as it appeared to active researchers at the time is not foreign to the mathematician, but a direct corollary of the mathematician's core conviction that only those with first-hand research experience in a field of mathematics truly understand it." In other words, the hope is that more mathematicians today become interested in shaping the narrative of mathematics instead of casting it aside as the purview of historians.

5 From Natural Philosophy to the Present

No account of practices in twentieth- and twenty-first-century mathematical practices would be complete without acknowledging the impact of Newton. It was only in the second half of the nineteenth century that expressions such as "scientist" and "mathematician" began to replace "natural philosopher." Britton and Sriraman provide a chapter on Newton's Opticks where they describe his insights into developing a theory of color through his experiments on light. Donnelly, Dunkum, and McCoy delve into the original source of enumerating integer sequences with alternate parity entries, through an 1839 paper by Olry Terquem. Their chapter makes remarkable connections between Terquem's "forgotten" problem, the Fibonacci sequence, a one-player game of numbers, continuant polynomials (an extended version of), the Euclidean Algorithm, and Bezout's Lemma.

Does mathematics have/make a social impact? Ernest's chapter examines the interaction of ethics with mathematical practice. His chapter analyzes resistances from the community of mathematicians that simply said that mathematics can be pursued for its own sake. To wit, G.H. Hardy studied pure mathematics unapologetically (!) because it had little or no applications to real life during his time period. In fact in Victorian times, pure mathematics was mostly viewed as a recreational activity with various periodicals tailored toward circles of the gentry, who enjoyed doing mathematics for its own sake. Bertrand Russell started out with the infamous Mathematical Tripos in Cambridge and pursued it for its own sake despite his disenchantment in the way it was taught. Russell not only turned to philosophy but also wrote about the ills of war and the social responsibility of Science. Similarly, Ernest reviews ideas of social responsibility since mathematicians increasingly are in the background of media communications given the data-saturated world we find ourselves in – and media increasingly shapes worldviews of the population.

One finds numerous personal accounts from mathematicians on events that shaped their worldviews and practices. Norbert Wiener's accounts of how he learned mathematics is an astonishing example of traveling to different places to learn firsthand from the giants of the twentieth century – from Hardy and Russell in Cambridge, and from Hilbert and Landau in Göttingen (Wiener 1953, 1956). It should be noted that Wiener also took a public stand against the militarization of science and the need for ethical considerations in Science. Such (auto) biographical accounts have great value for the community at large. They reveal the formative experiences and the openness of the mathematical community in the past. In a similar vein, Lifyland provides a personal account of influences in a mathematicians' (his) professional journey through mathematics. It reveals the interplay between practices and the development of a working philosophy of mathematics.

Zalamea surveys Grothendieck's "known" work (1949–1991), before his seclusion in the Pyrenees. This chapter offers an insight into the massive contributions of Grothendieck in addition to the dialectics between abstract categorical constructions and structured, concrete models. Zalamea writes that "the abstract and the concrete, the universal and the particular, categorical reason and mathematical heart, become all necessary to *nurture mathematical imagination*." His chapter ends with the

insight into Grothendieck's work as a *back-and-forth between types and archetypes*, elevated to a method.

Sinclair, on the other hand, examines mathematical practices from a postmodernist viewpoint that is in concordance with how human societies were actually shaped. It moves way from a linear, patriarchal depiction of mathematics to viewing how mathematical ideas can be used to generate new ways of imagining relations "that pertain to existence (who we are, as people, collectives, societies) and to experience." Numerous mathematical examples are used to "transform normative relations in order to produce new ones – in particular, new spatial imaginaries for disrupting systems of oppression."

Finally, the ubiquity of mathematics with the world of finance is explored in depth by Davis starting from its prehistoric origins to the use of Brownian motion and stochastic calculus to price stocks. Cutting-edge mathematical ideas coupled with advances in AI are continually applied in the world of finance, and the world at large. Mathematical practice is prevalent everywhere today both overtly and covertly – unimaginable in 1900.

Taken as a whole, this section of the Handbook provides an insight into a highly diverse set of current practices in mathematics shaped by our shared past culminating in the present.

Abstract

The reinterpretation of Plato's philosophy in terms of periodic anthyphairesis, in fact of palindromically periodic anthyphairesis in the *Politicus,* and the reading of Book X of *Euclid's Elements* under the new light, reveal deep mathematical contributions by Theaetetus, including a proof of the general Pell equation. Fascinating similarities of Theaeteus' reconstructed proofs with the Hindus' solution of the problem of Pell are noted.

Keywords

Plato · Theaetetus · Book X of Euclid's *Elements* · Palindromically periodic anthyphairesis · Pell equation · Cakravala

1 Introduction

Our study of Plato's work has shown that the basic entity in Plato's philosophical system, the intelligible Being, is a philosophical imitation of a dyad in periodic anthyphairesis. (The terms mentioned in the introduction will be defined in the main text below.) (The simple mathematics of anthyphairesis are reviewed in Sect. 2.) This becomes evident, among others, in the One of the second hypothesis of the *Parmenides* and in the Divisions of the Angler and the Sophist in the *Sophistes* (Sect. 3).

Thus, we should not be greatly surprised to find that Plato's philosophical theories are hiding and may reveal deep mathematical secrets. Especially so, as according to his own admission, Plato's later work was especially influenced by the mathematical discoveries of Theaetetus, as reported in the *Theaetetus* 147c-148d. We trace the imitation of which Plato is talking ("πειρῶ μιμούμενος," 148d4-5), in the *Philebus* 16c, 23a-25e, according to which an intelligible Being is the mixture of an anthyphairetic infinite/

incommensurable and an anthyphairetic finite/commensurable, and in the *Politicus* 283a-287b, according to which intelligible Beings are generated by the double measurements of an entity against its opposite, provided this is not a pleasure, and is thus finite, and against the geometric mean of the two, an infinite generation; and we recognize that both these are philosophical statements closely imitating Theaetetus' periodicity theorem, stated in semi-philosophical language in *Theaetetus* 147c-148d: "if a, b are lines commensurable in power only, in particular if $a^2 = Nb^2$ for some non-square number N, then the anthyphairesis of a to b is *periodic*" (Sect. 4).

More amazing, the elaborate definition of the Statesman, occupying the whole *Politicus*, is an imitation not only of periodic anthyphairesis, as was the case with the Divisions in the *Sophistes* (examined in Sect. 3), but of a *palindromically periodic* one, revealing with this imitation Theaetetus had established the Theorem: "if $a^2 = Nb^2$, N non-square, then the anthyphairesis of a to b is *palindromically periodic*," an important result that in modern era was gradually discovered by the work of Fermat, Wallis, and Brouncker (seventeenth century), and Lagrange and Euler (eighteenth century) (Sect. 6).

Armed with Plato's revelations we next attempt to reconstruct Theaetetus' proof. We find the complete set of tools in Book X of the *Elements*, a work known to be by Theaetetus. Already in 1572 Bombelli realized that Book X is devoted to the *conjugation* (established in Propositions X.112-114 of the *Elements*) between *apotome* (defined in X.73 and studied in Propositions X.73-107) and *binomial* lines (defined in X.36 and studied in Propositions X.36-72), a conjugation so striking that made him introduce the complex numbers with the name of *binomio*. It is thus the ideal tool for the proof of the palindromic periodicity of quadratic anthyphairesis. Once we know, thanks to Plato, that Theaetetus had indeed proved the palindromic periodicity theorem and the tools of Book X, then the reconstruction of the proof is one-way, essentially obligatory, simply consisting in the realization that the anthyphairetic remainders γ_n of the anthyphairesis of a to b, for $a^2 = Nb^2$, N non-square, are simple apotome lines of the form $\gamma_n = (-1)^n(q_n b - p_n a)$, and in the transformation of the anthyphairetic relations ($\gamma_{n-1} = I_n\gamma_n + \gamma_{n+1}$) into relations of conjugation $\varphi_n(I_n b + \varphi_{n+1}) = b^2$, necessarily with the help of the reduced remainders φ_n defined by $\gamma_n\, \varphi_{n+1} = \gamma_{n+1}\, b$.

The one basic argument yet needed for the proof and absent from Book X, the *pigeonhole principle*, is again gratefully supplied by Plato in precisely the point needed, namely when the first half of the period in the anthyphairetic division goes to its second palindromic half, in Plato's terms at the moment of transfer from the Kronos era to the Zeus era (*Politicus* 272d-e). We emphasize that the anthyphairetic interpretation of Plato's philosophy is what, despite his immersion in Greek philosophy and mathematics, Weil lacked, deciding, as he did, against an anthyphairetic use of the conjugation of Book X (Sects. 5 and 7).

Theaetetus had a strong motivation to deal with the Pell problem, since the case $N = 2$ was a venerated Pythagorean discovery not unnoticed by Plato (*Politeia* 546c), closely connected with their discovery of the periodicity of the anthyphairesis $a^2 = 2b^2$ (Sect. 8); and once Theaetetus obtained the palindromic periodicity theorem, the proof of the Pell property is within easy reach. But Theaetetus' preoccupation with the Pell problem can be traced in Book X: The classification of

apotome lines in six classes in X.84/85 makes sense only in relation to the Pell property. Thus, (i) the reconstructed Theaetetus' proof of periodicity in fact involves the Pell property, since the number λ_{n+1}, employed in the definition of m_{n+1} and φ_{n+1}, is the absolute value of the Pell number of the remainder γ_n; (ii) the first and the fourth apotome, in the classification X.84/85 of the apotome lines in the *Elements*, are apotomae with *positive Pell number* (corresponding to the *even remainders* of the anthyphairesis of a to b for $a^2 = Nb^2$, N non-square, and b the assumed "one foot" line), the second and fifth with *negative Pell number* (corresponding to the *odd remainders*); (iii) more impressive and relevant, the first and second apotome lines, in the classification X.84/85 of the apotome lines in the *Elements*, are those with *square Pell number*, the fourth and fifth with *non-square Pell number*; and (iv) Propositions X.97 produces an apotome with *square Pell number* from any apotome line. These are essentially the simple additional tools, available in Book X, needed to prove the Pell property (Sect. 9).

In conclusion, on the basis of our arguments that

(a) Plato's intelligible Beings are imitations of dyads in periodic anthyphairesis in his whole work
(b) Plato's intelligible Beings in the *Theaetetus*, *Politicus*, and *Philebus* are imitations of Theaetetus' theorem on the palindromically periodic anthyphairesis of lines incommensurable in length and commensurable in power
(c) The proof of Theaetetus' theorem employs the conjugacy of the quadratic lines apotome and binomial in the Theaetetean Book X of the *Elements*
(d) That there are strong indications that Book X is concerned with the proof of the general Pell property

we conclude that Theaetetus had a proof not only of the palindromic periodicity theorem, but also of the general property, a simple consequence of the palindromic periodicity theorem.

In the final Sect. 10 on the Hindus' contribution to the solution of the Pell problem we include the intriguing and fascinating evidence of the similarities between the reconstructed Theaetetus' proof of the palindromic periodicity of quadratic anthyphairesis and the Pell equality and the methods developed by the Hindus. We want to emphasize that we have no way of knowing if the origin of the methods developed by the Hindu mathematicians are in some way connected with Theaetetus' reconstructed proofs.

The Hindus' method of solving the problem of Pell has come in two stages.

First Brahmagupta in the seventh century AD, introduced the *bhavana* method, namely the composition rule of dyads, given a non-square natural number N:

$$(q,p)*(q',p') = (qq' + Npp',\ qp' + q'p),$$

used mostly for the square case ($q = q'$, $p = p'$); the *bhavana* * operation is multiplicative on the absolute value of the Pell number $q^2 - Np^2$ of the dyads (q, p).

The Brahmagupta rule of composition appears close to an arithmetized version of the geometric rule of "multiplying" simple apotomae or binomial lines, where $a^2 = Nb^2$:

$$(qb - pa)(q'b - p'a) = ((qq' + Npp')b - (qp' + q'p)a)b,$$

and which, for the square case, is closely connected with Proposition X.97 of the *Elements*.

The *bhavana* rule of squaring has been employed by Brahmagupta for the solution of the problem of Pell for those non-square N for which one can find a dyad (q, p) with Pell number equal to -4 or $+4$, or -2 or $+2$, or -1. These "global" reductions and shortcuts computationally are simple enough to verify, but their mathematics certainly rely on the palindromic nature of the periodicity of the quadratic anthyphairesis, since from a part of the period one can find the whole, and hence solve the Pell problem. The most interesting Brahmagupta reduction is the one when the Pell number is -4, because it appears to rely not only on the palindromicity but also on a "square root" argument related to the quite interesting Proposition X.91 of the *Elements*.

The second *cakravala*/circle method has been mostly advanced by Bhaskara II in the twelfth century AD, although it existed for at least a century before him. For a non-square number N, the basic step of *cakravala* is given by the Brahmagupta-type composition

$$(q, p)*(m/\lambda, 1/\lambda) = ((mq + Np)/\lambda, (q + mp)/\lambda),$$

where λ is the absolute value of the Pell number of the dyad (q, p), and m is a natural number to be determined by the *kuttaka* indeterminate method and an extremal condition.

Weil has presented the *cakravala* method, stripped of the mathematically unnecessary method of *kuttaka*, and unencumbered by ingenious shortcuts. In this "pure" form the *cakravala* method appears as the arithmetized form of the reconstructed Theaetetus conjugacy method presented in Sect. 5. Indeed, for a non-square number N, the *cakravala*

(a) Invariably starts with the dyad $(q_1 = m_1, p_1 = 1)$, or else, if N is nearer to $(m_1 + 1)^2$, with the dyad $(q_2 = m_1 + 1, p_2 = 1)$; these dyads appear as the arithmetized version(s) of the initial anthyphairetic remainder(s) $\gamma_1 = a - m_1 b$, or else $\gamma_2 = (m_1 + 1)b - a$, respectively, of the anthyphairesis of a to b, for $a^2 = Nb^2$.

(b) Proceeds inductively from the given dyad (q_n, p_n), whose Pell number ${q_n}^2 - N{p_n}^2$ has absolute value equal to λ_{n+1}, to the next dyad (q_{n+1}, p_{n+1}), with a Brahmagupta-type composition of the given dyad with the dyad $(m_{n+1}/\lambda_{n+1}, 1/\lambda_{n+1})$:

$$(q_n, p_n)*(m_{n+1}/\lambda_{n+1}, 1/\lambda_{n+1}) = \left(q_{n+1}, p_{n+1}\right),$$

where m_{n+1} is the greatest number satisfying the rule $m_n + m_{n+1} =$ multiple of λ_{n+1} and $m_{n+1} \leq m_1$; this procedure appears close to the arithmetized version of the geometric rule $\gamma_n \varphi_{n+1} = \gamma_{n+1} b$, namely

$$(-1)^n(q_n b - p_n a)\varphi_{n+1} = (-1)^{n+1}\left(q_{n+1}b - p_{n+1}a\right)b,$$

where φ_{n+1} has been determined by the conjugation relation $\varphi_n(I_n b + \varphi_{n+1}) = b^2$, into which the anthyphairetic relation $\gamma_{n-1} = I_n\gamma_n + \gamma_{n+1}$ has been transformed and thus shown by conjugacy to have the form $\varphi_{n+1} = (a - m_{n+1}b)/\lambda_{n+1}$, where m_{n+1} is determined by the rule $m_n + m_{n+1} = I_n\lambda_{n+1}$, according to the Theaetetus conjugacy method, as reconstructed in Sect. 5.

(c) Employs the term "*cakravala*," unmistakably indicating periodicity (and not just iteration).

This appears to refer to the periodicity of the geometric anthyphairesis of a to b, for the non-square number N, according to Theaetetus' periodicity theorem.

2 Geometric Anthyphairesis

2.1 Definitions

Let us recall the *geometrical concept of anthyphairesis* of a dyad of opposite magnitudes, the greater a and the smaller b, $a > b$:

$a = I_0 b + \gamma_1$,	with $\gamma_1 < b$,
$b = I_1\gamma_1 + \gamma_2$,	with $\gamma_2 < \gamma_1$,
...	
$\gamma_{n-1} = I_n\gamma_n + \gamma_{n+1}$,	with $\gamma_{n+1} < \gamma_n$,
$\gamma_n = I_{n+1}\gamma_{n+1} + \gamma_{n+2}$,	with $\gamma_{n+2} < \gamma_{n+1}$

...

Here

$$I_0, I_1, I_2, I_3, \ldots, I_n, I_{n+1}, \ldots,$$

denotes the sequence of successive quotients (natural numbers), and

$$a > b > \gamma_1 > \gamma_2 > \ldots > \gamma_n > \gamma_{n+1} > \ldots$$

the sequence of successive remainders (magnitudes) of the anthyphairesis of a to b.

If the anthyphairesis of a to b is *finite*, the last remainder necessarily divides the immediately previous remainder and is the greatest common divisor of a and b (Propositions VII.1, 2 of *Euclid's Elements* for natural numbers, Proposition X.3 for magnitudes).

In case a remainder never divides the immediately previous remainder, the anthyphairesis is said to be *infinite*. If the anthyphairesis of a to b is infinite, then a and b are *incommensurable* (Proposition X.2 of *Euclid's Elements*).

2.2 The Logos Criterion for Periodic Anthyphairesis

2.2.1 The Theaetetean Theory of Ratios of Magnitudes

Aristotle's *Topics* 158-9, a passage important for the history and reconstruction of Greek mathematics, informs us that before the theory of ratios of magnitudes that dominated Euclidean geometry, and which is Eudoxus' theory majestically presented in Book V of the *Elements*, there was a previous theory based on the

Definition If a, b are homogeneous magnitudes and c, d are homogeneous magnitudes then
$a/b = c/d$ if and only if $\mathrm{Anth}(a, b) = \mathrm{Anth}(c, d)$
(where $\mathrm{Anth}(a, b)$ denotes the sequence of successive *quotients* of the anthyphairesis of a to b).

A theory of ratios based on this pre-Eudoxian definition, If it were meant to be a theory as general as the Eudoxian theory, would need Eudoxus' condition (Def. 4 in Book V of the *Elements*), and so would be historically untenable. Knorr (1975) reconstructs such a theory which was quite adequate for the purposes of quadratic incommensurabilities, and for which, as can be shown, there is no need to an appeal to Eudoxus' condition. Parenthetically, it is worth mentioning that as carefully noted by Knorr, the crucial Theorem 6, p 338, the analogue of the fundamental Eudoxian Proposition V.8 of the *Elements*, makes essential use of the Eudoxus' condition (V, Def. 4). There is however evidence that this pre-Eudoxian theory applied only to a limited class of pairs of magnitudes, chiefly the lines that are rational with respect to an assumed line, in the sense of definition 3 of Book X of the *Elements*—hence the term "alogos" ("ἄλογος") for those ratios whose square is not commensurable. One anonymous comment in *Scholia in Euclidem* V.22 (eds: Heiberg and Stamatis 1977) alludes to a restricted, in fact quadratic, pre-Eudoxian theory of magnitudes, and another, *Scholia in Euclidem* X.2 (eds: Heiberg and Stamatis 1977), criticizes the general Eudoxian theory, clearly from a Platonic point of view and in favor of the earlier restricted quadratic theory of ratios of magnitudes.

It is generally accepted that the theory of ratios based on anthyphairesis is due to Theaetetus.

2.2.2 The Logos Criterion for Periodic Anthyphairesis

A natural consequence of Theaetetus' definition of equality of ratios for magnitudes is the following

Proposition (Logos Criterion for the Periodicity of an Anthyphairesis)

Let a, b be two line segments, with $a > b$, and anthyphairesis given as follows:

$a = I_0\, b + \gamma_1$, with $b > \gamma_1$,
$b = I_1\, \gamma_1 + \gamma_2$, with $\gamma_1 > \gamma_2$,
…
$\gamma_{n-1} = I_n\, \gamma_n + \gamma_{n+1}$, with $\gamma_n > \gamma_{n+1}$,
$\gamma_n = I_{n+1}\, \gamma_{n+1} + \gamma_{n+2}$, with $\gamma_{n+1} > \gamma_{n+2}$,
…
$\gamma_{m-1} = I_m\, \gamma_m + \gamma_{m+1}$, with $\gamma_m > \gamma_{m+1}$,
$\gamma_m = I_{m+1}\, \gamma_{m+1} + \gamma_{m+2}$, with $\gamma_{m+1} > \gamma_{m+2}$,
…
…….

and assume that there are indices n<m such that

$\gamma_n/\gamma_{n+1} = \gamma_m/\gamma_{m+1}$ ("Logos Criterion").

Then the anthyphairesis of a to b is eventually periodic, in fact

$$\mathrm{Anth}(a, b) = [I_0, I_1, \ldots, I_n, \text{period } (I_{n+1}, I_{n+2}, \ldots, I_m)].$$

Proof. By the Theaetetean definition of analogy, $\mathrm{Anth}(\gamma_n, \gamma_{n+1}) = \mathrm{Anth}(\gamma_m, \gamma_{m+1})$. But $\mathrm{Anth}(a, b) =$

$$\left[I_0, I_1, \ldots, I_n, \mathrm{Anth}\left(\gamma_n, \gamma_{n+1}\right)\right] =$$

$$\left[I_0, I_1, \ldots, I_n, I_{n+1}, I_{n+2}, \ldots, I_m, \mathrm{Anth}\left(\gamma_m, \gamma_{m+1}\right)\right] =$$

$$\left[I_0, I_1, \ldots, I_n, I_{n+1}, I_{n+2}, \ldots, I_m, \mathrm{Anth}\left(\gamma_n, \gamma_{n+1}\right)\right] =$$

$$\left[I_0, I_1, \ldots, I_n, I_{n+1}, I_{n+2}, \ldots, I_m, I_{n+1}, I_{n+2}, \ldots, I_m, \mathrm{Anth}\left(\gamma_m, \gamma_{m+1}\right)\right] =$$

…=
$\mathrm{Anth}(a, b) = [I_0, I_1, \ldots, I_n, \text{period } (I_{n+1}, I_{n+2}, \ldots, I_m)]$.

Proposition If a, b, c, d are lines, such that $ad = bc$, then $\mathrm{Anth}(a, b) = \mathrm{Anth}(c, d)$.

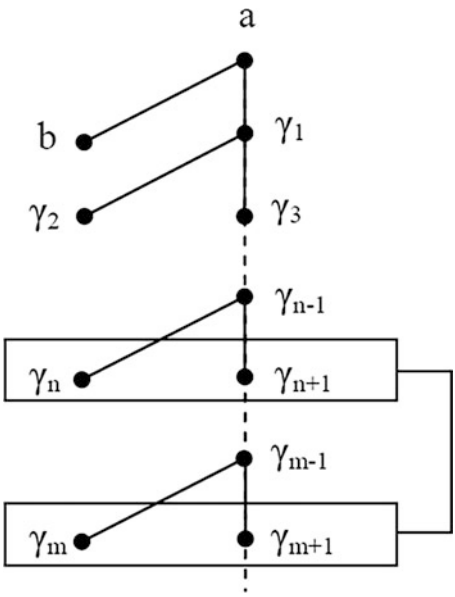
Proof Let
$a = I_0 b + \gamma_1$, $\gamma_1 < b$.
Hence $ad = I_0 bd + \gamma_1 d$. From hypothesis, $bc = I_0 bd + \gamma_1 d$.

By Proposition I.44-45 of the *Elements*, there is line δ_1, such that $\gamma_1 d = \delta_1 b$.
Hence $bc = I_0 bd + \delta_1 b$. Hence $c = I_0 d + \delta_1$. We note that $\delta_1 < d$, since $\gamma_1 < b$.
Hence the relation $c = I_0 d + \delta_1$, $\delta_1 < d$ is an anthyphairetic relation.
Thus $\mathrm{Anth}(c, d) = [I_0, \mathrm{Anth}(d, \delta_1)]$, $\mathrm{Anth}(a, b) = [I_0, \mathrm{Anth}(b, \gamma_1)]$,
and $\gamma_1 d = \delta_1 b$, as in the first step. The proof is now completed by induction.

Note. If we take as the definition of analogy the Theaetetean definition in terms of equality of anthyphairesis, then the proposition is a tautology.

2.2.3 An Abbreviated Representation of the Logos Criterion

We note that the criterion is stated solely in terms of the remainders, and no use is made in its statement of the quotients; thus, the criterion can be adequately represented in the following abbreviated, Zeno-like, form:



2.2.4 Example. The Anthyphairesis of *a* to *b* with $a^2 = 19b^2$

We exhibit the Logos Criterion with the first incommensurability that Theodorus did not prove in his lesson to Theaetetus and his companion in *Theaetetus* 147c-d.

(i) *The anthyphairesis of a to b*

$$a = 4b + \gamma_1, \gamma_1 < b \text{ (whence } \gamma_1 = a - 4b),$$
$$\text{(and } b = 2\gamma_1 + \gamma_2, \gamma_2 < \gamma_1 \text{(whence } \gamma_2 = 9b - 2a)),$$

$$\gamma_1 = \gamma_2 + \gamma_3, \gamma_3 < \gamma_2 \text{ (whence} \gamma_3 = 3a - 13b),$$
$$\text{(and } \gamma_2 = 3\gamma_3 + \gamma_4, \gamma_4 < \gamma_3 \text{(whence } \gamma_4 = 48b - 11a)),$$

$$\gamma_3 = \gamma_4 + \gamma_5, \gamma_5 < \gamma_4 \text{ (whence } \gamma_5 = 14a - 61b),$$
$$\text{(and } \gamma_4 = 2\gamma_5 + \gamma_6, \gamma_6 < \gamma_5 \text{(whence } \gamma_6 = 170b - 39a)),$$

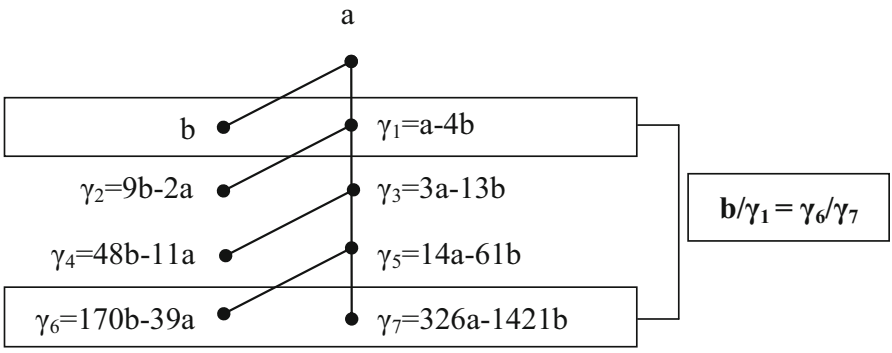
$$\gamma_5 = 8\gamma_6 + \gamma_7, \gamma_7 < \gamma_6 \text{ (whence } \gamma_7 = 326a - 1421b).$$

(ii) *Verification of the Logos Criterion* $b/\gamma_1 = \gamma_6/\gamma_7$.
In fact, $b \cdot \gamma_7 = b \cdot (326a - 1421b) = \gamma_1 \cdot \gamma_6 = (a - 4b) \cdot (170b - 39a)$.
The Logos Criterion results in the full knowledge of the ratio a/b:

$$\text{Anth}(a, b) = [4, \text{period } (2, 1, 3, 1, 2, 8)].$$

By Proposition X.2, of course it is concluded that a, b are incommensurable.

(iii) *Abbreviated, Zeno-like, representation of the Logos Criterion*



3 The Anthyphairetic Basis of Plato's Philosophy: An Intelligible True Being Is the Philosophical Analogue of a Dyad in Periodic Anthyphairesis (*Parmenides*, *Sophistes*)

According to our interpretation, an *intelligible (Platonic true) Being* consists of a dyad of parts satisfying the *philosophical analogue of a dyad in periodic anthyphairesis* (The first publications on this interpretation can be found in Negrepontis (1999) and AVGI (2000). Details on the anthyphairetic interpretation of the second hypothesis of the *Parmenides* have appeared in Negrepontis n.d.; of the Divisions in the *Sophistes* and *Politicus* in Negrepontis 2019, and of the *Philebus* in Negrepontis 2005. In the present work we have included, in upgraded form, those parts which are needed to make our arguments self-contained.). The paradigmatical true Being is the One of the second hypothesis in the *Parmenides*, consisting of the dyad <One, Being> (studied in Negrepontis n.d.), or of the dyad <Being, Not-Being>, such as <Just, Unjust>, in the *Sophistes* and *Politicus* (studied in Negrepontis 2012, 2018), in a philosophical analogue of geometric anthyphairesis, for which the exact analogue of the Logos Criterion for periodicity holds. The dialectic meaning of Logos is the Logos Criterion, the cause of periodic anthyphairesis.

3.1 The One of the Second Hypothesis of the *Parmenides* Consists of a Dyad <One and Being> in a Philosophical Analogue of Periodic Anthyphairesis

The paradigmatical true Being is the One of the second hypothesis in the *Parmenides* 142b1-155e3, consisting of the dyad

<One, Being>, or the dyad <Being, Not-Being> in the *Sophistes*, in the philosophical analogue of periodic anthyphairesis. The anthyphairetic interpretation of a platonic intelligible true Being has been obtained by our analysis of the dyad <One, Being> in the second hypothesis of the *Parmenides*, and of *Philebus* 15a-17a (Negrepontis n.d.).

3.1.1 The Infinite Anthyphairesis of the Dyad One and Being

In the first part, *Parmenides* 142d9-143a3, it is shown that the dyad < One, Being > is in infinite anthyphairetic division:

$$\begin{aligned}
&\text{One} = \text{Being} + \text{One}_1, \text{Being} > \text{One}_1,\\
&\text{Being} = \text{One}_1 + \text{Being}_1, \text{One}_1 > \text{Being}_1,\\
&\ldots\\
&\text{One}_n = \text{Being}_n + \text{One}_{n+1}, \text{Being}_n > \text{One}_{n+1},\\
&\text{Being}_n = \text{One}_{n+1} + \text{Being}_{n+1}, \text{One}_{n+1} > \text{Being}_{n+1},\\
&\ldots
\end{aligned}$$

Thus there is then an infinite multitude of remainders-parts of the anthyphairetic division:

$$\text{One} > \text{Being} > \text{One}_1 > \text{Being}_1 > \ldots > \text{One}_n > \text{Being}_n > \ldots$$

3.1.2 The Logos Criterion and the Anthyphairetic Periodicity of the *Parmenides* Dyad <One, Being>

We outline below the argument that shows that the dyad <One, Being> is not only in infinite anthyphairesis, but in fact in periodic one. In the sequel, the passage 144c2-d4 is concerned with the presence of the One in the Being, setting the dilemma whether the presence be of a part or of a whole of the One part in each part of the Being.

As noted by previous scholars, the passage has similarities to the passage 130e4-131e7 in the introduction of the *Parmenides*, posing the question (the "dilemma of participation") whether the presence of the One, be as part or as whole, in each of the sensibles that participate in the One.

However, the "whole" horn of the dilemma is rejected in both 144c-d and 130e-131e, but the "part" horn *only* in the 130e-131e, while fully accepted in 144c2-d4. Because of this crucial difference, we are led to conclude that the

"part" horn of the dilemma must have been found acceptable somewhere in the dialogue in between. And indeed, as it has not been noted by previous scholars, the place where the "part" horn is accepted is found to be the passage 138a3-7, where it is stated that the presence of the One in the parts of the Being is realized by a circle of "touchings" ("ἅψεις"). A "touching," as explained in the passage 148d5-149d7, occurs between parts of the dyad <One, Being>, successive in their order of generation, and the touchings generate numbers according to the formula

$$\text{Number of parts} - \text{units} = \text{touchings} + 1;$$

whose origin is clearly musical with terms-chords and musical intervals in place of parts-units and touchings, respectively. This correspondence suggests the interpretation that a "touching" in 138a3-7 is meant to be a ratio of consecutive parts of the anthyphairesis of One, Being.

In view of the earlier statement that the division of the One to Being is anthyphairetic, this interpretation is tantamount to the statement that the anthyphairesis of One to Being satisfies the "Logos" Criterion: there is an index k such that

$$\text{One}/\text{Being} = \text{One}_k/\text{Being}_k,$$

and thus finally the dyad <One, Being> satisfies a philosophical analogue of periodic anthyphairesis.

This interpretation is strengthened by the realization that the *Philebus* 15a1-c3 sets a whole-part dilemma, precisely as in the *Parmenides* 144c2-d4, and that this is followed by *Philebus* 15d4-5, a veritable replica of 138a3-7, with "logoi" ("λόγοι")-ratios running in circles in place of "touchings" in circles.

3.1.3 Equalization of Parts, in Consequence of Periodicity

The equalization of the One with the Being now proceeds smoothly, in the passage 144d4-e3 as follows:

$$\text{the } \textit{number} \text{ of parts of the One} =$$

$$\text{logoi between successive parts (from One on)} + 1,$$

a *finite* number, since the "logoi" will be different till a complete circle-period of ratios is achieved, and there will be no other ratios. The periodicity then implies that the number of parts of the One = the number of parts of the Being.

The equalization ("ἐξισοῦσθον") of One and Being rests on the above equality.

3.1.4 The Self-Similar Property of One and Many

The two basic features of the One of the second hypothesis are summarized by the statement that the One of the second hypothesis is both One and Many, in the sense that

The One is divided anthyphairetically into Many, in fact an infinite multitude of, parts.

Each part of the Many is equalized by the periodicity of the anthyphairesis, and thus the One of the second hypothesis is indeed a One in the sense of self-similarity, namely that each part is the same as the whole (144e8-145a2).

3.1.5 The One of the Second Hypothesis in the *Parmenides* is the Paradigmatical True Intelligible Being

The One of the second hypothesis is declared, in 155d3-6, to be a true intelligible Being, a Platonic Idea.

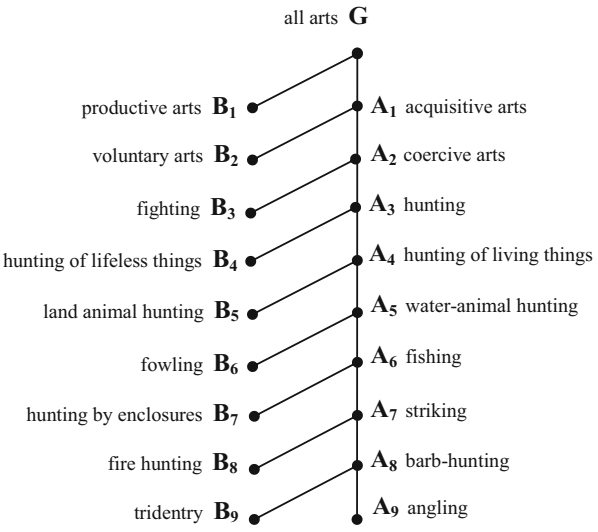
The One of the second hypothesis, although infinite in structure, nevertheless is fully knowable, possesses "ἐπιστήμη" 155d6, since full knowledge of the One is achieved, at a finite stage, when a full period of the Logoi is completed.

3.2 The Division and Collection of the Platonic Idea "the Angler" in the *Sophistes* 218b-221c

3.2.1 The Division of the Angler

The method of Division and Collection, also called "Name and Logos" (cf. *Theaetetus* 201e2-202b5, *Sophistes* 218c1-5, 221a7-b2, 268c5-d5) is exemplified at the start of the *Sophistes* 218b-221c by the definition of the Being Angler. In the scheme below, the binary division process which leads to the Angler is reproduced.

The Division of the Angler (*Sophistes* 218b-221c)



3.2.2 Logos Criterion of the Angler

The description of the Logos Criterion of the Angler is contained in the *Sophistes* 220e2-221c3 passage (which are presented below divided into two parts [A] and [B] for the sake of convenience) (The emphasis and italics in the present quote and in all future quotes are due to the authors.):

> [A] "Stranger: Then of striking which belongs to barb-hunting [A_8],
> that part which proceeds *downward from above ("ἄνωθεν εἰς τὸ κάτω"),*
> is called, because tridents are chiefly used in it, tridentry [B_9],
> I suppose. . ..
> Stranger: The kind that is characterized by the opposite sort of blow,
> which is practised with a hook and strikes,...
> and proceeds *from below upwards ("κάτωθεν εἰς τοὐναντίον ἄνω")*,
> being pulled up by twigs and rods.
> By what name, Theaetetus, shall we say this ought to be called?
> Theaetetus: I think our search is now ended and we have found the very thing we set before us a while ago as necessary to find.
> Stranger: Now, then, you and I are only agreed about the name of angling, [A_9]"
> (220e2-221b1)
> [B] "but *we have acquired also a satisfactory "Logos"* of the thing itself.
> *For* **(γὰρ)**
> of art as a whole, half was acquisitive,
> and of the acquisitive, half was coercive,
> and of the coercive, half was hunting,
> and of hunting, half was animal hunting,
> and of animal hunting, half was water hunting,
> and of water hunting [A_5]
> *the whole part from below ("τὸ κάτωθεν τμῆμα ὅλον")* was fishing, [A_6]
> and of fishing, half was striking,
> and of striking, half was barb-hunting, [A_8]
> and of this [A_8]
> the part in which the blow is pulled
> *from below upwards ("τὸ περὶ τὴν κάτωθεν ἄνω")* was angling. [A_9]" (221b1-c3).

(Plato, *Theaetetus* and *Sophistes*, trans: Fowler 1921), with modifications by the authors).

In [A], the opposing relation of tridentry to angling is carefully explained: all fishing with a hook is divided into

> Tridentry (=fishing with a trident), which is described as
> fishing with a hook with an art that proceeds **from above downwards**, and
> Angling (=fishing with a rod), which is described as
> fishing with a hook with an art that proceeds **from below upwards**.
> We have pushed Division all the way to the angling; thus, we have certainly found "the name" of angling.

But now, in [B], it is claimed that "the Logos" of the angling has been found, too.

The justification—the proof—that we have indeed found the Logos, too, is contained in the remainder of [B], since this remaining part of [B] starts with a "for" ("gar"), and this justification can be seen to consist of:

(i) An accurate recounting of all the division-steps, abbreviated in the sense that of the two species into which each genus is divided, only the one that contains the Angler is mentioned, while the species opposite to it is omitted
(ii) A reminder that the last species, the angling, is characterized as the part of its genus that proceeds "from below upwards"
(iii) The ONLY new information (since (i) and (ii) are repetitions of things already contained in the Division and in [A]), concerns the species of fishing, three steps before angling, and which informs us for the first time that this species is "the whole part from below" of its genus.

Since this is an abbreviated account, there is no explicit information on the species opposite to "fishing"—namely "fowling," but since "fishing" was described not simply as "the part from below" of its genus, but emphatically as "the whole part from below," it follows that the opposite species—"fowling"—must be characterized as "the (whole) part from above" of the same genus. In fact, there can be no other justification for the presence of the term "whole" in the description of "fishing" with a view to arguing that we have obtained "Logos," except to indicate and imply this description for its opposite species, "fowling."

We recall that the part of [B] from the word "for" ("γὰρ") on is explicitly a justification of the claim that we have succeeded in finding the "Logos" of the angling. We may then ask: What is the "Logos" of the Angler that reasonably results from such a justification? There can really be only one answer: The "Logos" we are looking for is the equality of the "philosophic ratio" of tridentry to angling, namely the equality of the ratio "of from above downwards to from below upwards," to the ratio "of fowling to fishing."

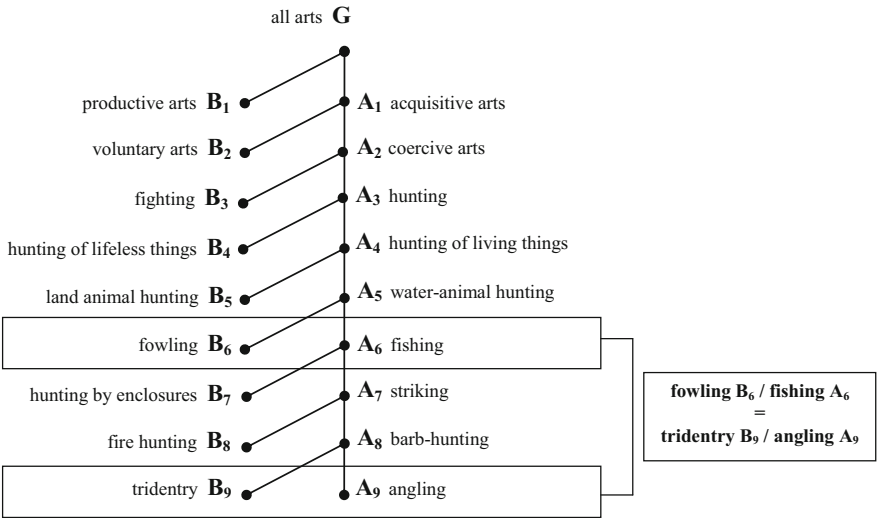
Thus

fowling B_6/fishing A_6 = tridentry B_9/angling A_9 =
from above downwards/from below upwards.

Since the species tridentry and angling form a pair of opposite species, and the species fowling and fishing form another pair of opposite species in the division scheme for the Angler, the resulting "Logos" bears a most uncanny similarity to the Logos Criterion for the periodicity of the anthyphairesis of geometric magnitudes, and of geometric powers in particular.

3.2.3 The Division and Collection of the Angler

The Division and Collection of the Angler thus takes the following form:



Thus the Division and Collection of the Angler consists of the Division, and of the Logos, described in b, analogous to the Logos Criterion for periodicity for geometric anthyphairesis established in Sect. 2.

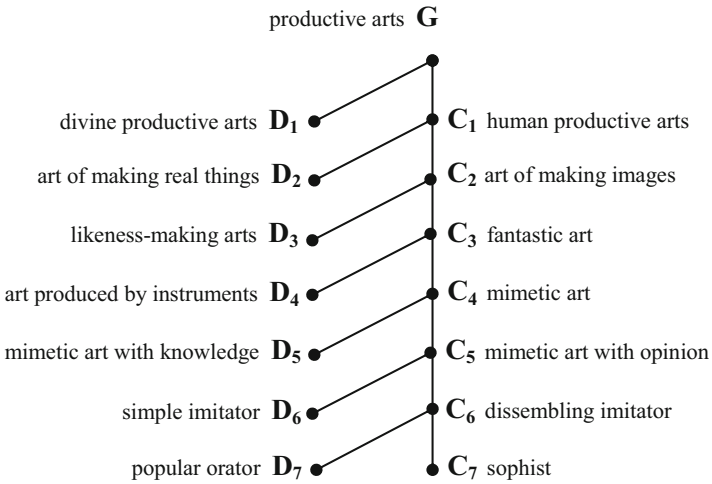
3.3 The Division and Collection of the Platonic Idea "the Sophist" in the *Sophistes* 234e-236d and 264b-268d

It now appears that the Division and Collection of a Platonic Idea—and the Angler is certainly a lowly paradigm of a Platonic Idea—is very much like the anthyphairetic division and the Logos Criterion of a geometric "power." When Socrates expressed, in the *Theaetetus* 145c7-148e5, his exhortation to imitate the geometric situation, it seems that he meant a much closer imitation that anybody has thus far suspected! But before proceeding on to wide-ranging conclusions, it would be prudent to examine whether the Division and Collection of the Sophist, in the *Sophistes* 264b-268d, has the same kind of structure and, in particular, whether there is a similar type of "Logos." So we shall take a look at the Division and Collection of the Sophist.

3.3.1 The Division of the Sophist

The Division for the Sophist follows the same pattern as the Division of the Angler, starting with a Genus, in this case "all the productive arts," proceeding by binary division of each Genus to two species, where the next Genus is that species of the previous step in the division that contains the entity to be defined, in this case the Sophist, and ending with the division-step that produces the Sophist as a species. The whole division scheme is as follows:

Division of the Sophist (*Sophistes* 264b-268d)



3.3.2 The Fundamental Analogy in the Divided Line of the *Politeia* 509d-510b and the Logos Criterion-Collection of the Sophist

We will make essential use of the fundamental analogy in the Divided Line of the *Politeia* 509d-510b (Plato 1969):

the opinable/the knowable = the likeness/that of which it is a likeness.

The Logos Criterion for the Sophist is now immediately recognized:

The art of making real things D_2/the art of making images C_2 = mimetic art with knowledge D_5/mimetic art with opinion C_5.

3.3.3 The Next Two Logoi of the Division and Collection of the Sophist Analogous to the Geometrical Ratios of Periodic Anthyphairesis

The definition of the Sophist presents an additional feature that ties it even closer to the mathematical model: There are two Logoi after the Logos Criterion, and if the mathematical anthyphairetic model is indeed followed, we would expect to have two further equalities of Logoi, namely the logos of the third step should be equal to the ratio of the sixth division-step, and the logos of the fourth division-step should be equal to the ratio of the seventh and final division-step.

(c1) *The equality of the third and sixth ratios of the Division of the Sophist*. In the third division-step, the Genus "humanly produced images" is divided into two species,

"Stranger: I see the likeness-making art ("εἰκαστικὴν") as one part of [the image-making art]. This is met with, as a rule, whenever anyone produces the imitation by following the proportions of the

original in length, breadth, and depth, and giving, besides, the appropriate colors to each part." (235d6-e2);
"Stranger: Now then, what shall we call that which appears, because it is seen from an unfavorable position, to be like the beautiful, but which would not even be likely to resemble that which it claims to be like, if a person were able to see such large works adequately? Shall we not call it, since it appears, but is not like, an appearance?
Theaetetus: Certainly." (236b);
"Stranger: And to the art which produces appearance, but not likeness ("φάντασμα ἀλλ' οὐκ εἰκόνα"), the most correct name we could give would be "fantastic art" ("φανταστικὴν"), would it not?
Theaetetus: By all means.
Stranger: These, then, are the two forms of the image-making art ("εἰδωλοποικῆς") that I meant, the likeness-making ("εἰκαστικὴν") and the fantastic ("φανταστικήν")." (236c3-7);
"Stranger: We must remember that there were to be two parts of the image-making class ("εἰδωλουργικῆς"), the likeness-making ("εἰκαστικόν") and the fantastic ("φανταστικὸν")" (266d8-9).

In the sixth division-step, described in 267e7-268a8, the Genus opinionated-imitator is divided into the two species, "the simple" ("ἁπλοῦν") and "the dissembling" ("εἰρωνικὸν") opinionated-imitator, the simple imitators being those who

> "think they know that about which they have only opinion,"

while the "dissembling" are those who

> "because of their experience in the rough and tumble of arguments, strongly suspect and fear that they are ignorant of the things which they pretend before the public to know."

Thus the simple imitators do not distort their opinion, but rather express a likeness of their opinion, while the dissemblers distort and disguise their opinion behind a false appearance. Therefore we have

> *Proposition*. The ratio of the third step in the Division of the Sophist,
> namely **the ratio of the likeness-making arts to the phantastic arts**,
> is equal to
> the ratio of the sixth step in the Division of the Sophist,
> namely **the ratio of the simple imitator to the dissembling imitator**.

(c2) *The equality of the fourth and seventh ratios*. In the fourth division-step, described in 267a1-b3, the Genus "fantastic arts" is divided into two species, as follows:

"Stranger: Let us, then, again bisect the fantastic art.
Theaetetus: How?
Stranger: One kind is that produced by instruments, the other that in which the producer of the appearance offers himself as the instrument.
Theaetetus: What do you mean?
Stranger: When anyone, by employing his own person as his instrument, makes his own figure or voice seem similar to yours, that kind of fantastic art is called mimetic."

Thus, in mimetic art the instrument of imitation is the imitator himself, while in the nameless opposite art the instrument of imitation is other than the imitator.

In the seventh division-step, described in 268a9-c4, the dissembler is divided into the demagogue and the sophist, the demagogue being

> "one who can dissemble in long speeches in public before a multitude,"

while the sophist is someone

> "who does it in private in short speeches and forces the person who converses with him to contradict himself."

Thus, he who listens to a dissembler is deceived, if that dissembler is a demagogue, and contradicted not by himself but by another instrument of deceit (namely the demagogue himself), while if the dissembler is a sophist, the listener is forced by the sophist to himself become the instrument of deceit.

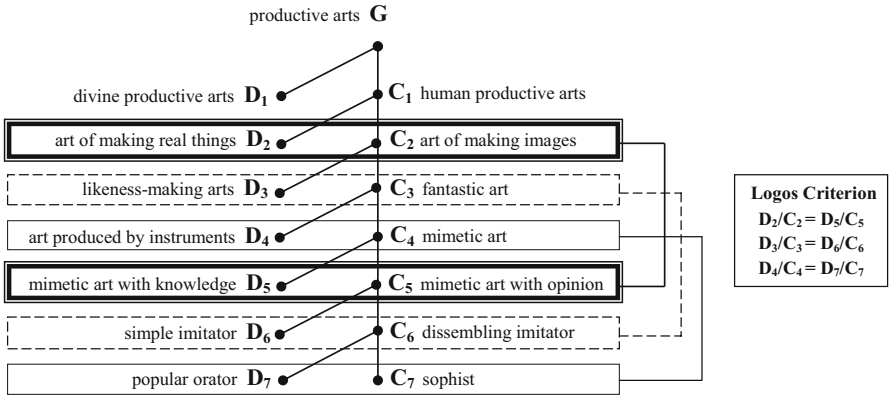
Thus we have:

> *Proposition.* The ratio of the fourth step in the Division of the Sophist,
> namely the ratio of the imitator who uses other instruments of imitation to the imitator who is himself the instrument of imitation
> is equal to
> the ratio of the seventh step in the Division of the Sophist,
> namely the ratio of the demagogue,
> whose listener is contradicted and deceived not by himself but by another, to the sophist,
> whose listener is forced to be contradicted and deceived by himself.

Propositions (c1) and (c2) provide powerful additional evidence in favor of the anthyphairetic interpretation of Division and Collection.

3.3.4 The Division and Collection of the Sophist

The complete Division and Collection of the Sophist (*Sophistes* 264b-268d) can thus be summarized in the following scheme:



Thus, we have full confirmation for the anthyphairetic meaning of Logos that we proposed in the Division and Collection of the Angler. This time, the Logos is not of the simple-minded, obvious type that appeared in the definition of the Angler (from above downwards/from below upwards), but of a more sophisticated and philosophical kind, playing a central role in the dialectics of the *Politeia* (The correlation of the *Politeia* ratio in the divided line with the Division and Collection of the Sophist in the *Sophistes* is hinted at by Proclus in *eis Politeian* 1,290,7–10).

3.4 The Cyclical-Periodic Nature of "Collecting/Comprehending in One"

There are several descriptions of the method of Division and Collection in Platonic dialogues, specifically in the *Sophistes*, *Politicus*, *Phaedrus*, and *Philebus*; in every one of these descriptions, Collection is described by an expression that denotes that it has a *cyclical-periodic nature*. Here is a list of such descriptions, indicating, in each of them, the term showing cyclical nature-periodicity.

[1]
Eleatic Stranger. Look sharp, then; it is now our business not to let the beast get away again
(ΞΕ. Ἄγε δή, νῦν ἡμέτερον ἔργον ἤδη τὸν θῆρα μηκέτ' ἀνεῖναι),
for we have almost *comprehended* (*περιειλήφαμεν*) him
into a kind of *encircling net of the devices* (*ἐν ἀμφιβληστρικῷ τινι*)
we employ *"logoi"* about such subjects (τῶν *ἐν τοῖς λόγοις* περὶ τὰ τοιαῦτα ὀργάνων). *Sophistes* 235a10-b2

The Sophist (the beast) must be defined by catching, comprehending, and encircling him in a net of "logoi." *Circularity* most clearly indicated by the terms *"περιειλήφαμεν" and "ἐν ἀμφιβληστρικῷ τινι."* The term *"περιειλήφαμεν"* is the same as the term used in Book XIII of *Euclid's Elements* to describe the *comprehension* of each of the five canonical solids in a sphere (e.g., Proposition XIII.15: Κύβον συστήσασθαι καὶ *σφαίρᾳ περιλαβεῖν*).

[2]
[*Eleatic Stranger*] The *division of species in genera* (*Τὸ κατὰ γένη διαιρεῖσθαι*) . . .
and of *many kinds* differing from one another (καὶ πολλὰς ἑτέρας ἀλλήλων)
but *circularly contained in one greater form* (*ὑπὸ μιᾶς ἔξωθεν περιεχομένας*)
and again of one idea (καὶ μίαν αὖ) through many wholes (δι' ὅλων πολλῶν) into one (ἐν ἑνὶ).
Sophistes 253d1- e3

The nature of Division and Collection is first Division and then cyclical Collection into One, cyclicity indicated somewhat ambiguously by the term "*περιεχομένας*."

[3]
Eleatic Stranger.Then let us try again (Πάλιν τοίνυν ἐπιχειρῶμεν);
let us *divide in two* (*σχίζοντες διχῇ*) the class we have taken up for discussion
and proceed always by way of the right-hand part of the thing divided (πορεύεσθαι κατὰ τοὐπὶ δεξιὰ ἀεὶ μέρος τοῦ τμηθέντος),

clinging close to the company to which the sophist belongs (ἐχόμενοι τῆς τοῦ σοφιστοῦ κοινωνίας),
until, having *circularly stripped* (*περιελόντες*) him of all common properties,
and left him only his own peculiar nature (τὴν οἰκείαν λιπόντες φύσιν ἐπιδείξωμεν μάλιστα μὲν ἡμῖν αὐτοῖς). *Sophistes* 264d10-265a1

This passage precisely describes the Division, as it is presented in the case of the Angler and the Sophist (cf. Sects. 3.2, 3.3 above), and indicates the circularity by the term "*περιελόντες*."

[4]
Eleatic Stranger. Why did *we go around in circle* (*περιήλθομεν ἐν κύκλῳ*)
making a great many *divisions* in vain? (πάμπολλα *διοριζόμενοι* μάτην)
Younger Socrates. For my part, I thought nothing that was said was in vain (μάτην οὐδὲν τῶν ῥηθέντων ἔδοξε ῥηθῆναι). *Politicus* 283b1-c2

Explicit statement that Division is circular and periodic: *"περιήλθομεν ἐν κύκλῳ,"* seemingly in vain, but in fact not so.

[5]
[*Eleatic Stranger*.] the *dissimilarities* of all sorts (τὰς δὲ αὖ παντοδαπὰς *ἀνομοιότητας*), when seen in multitudes (ὅταν ἐν πλήθεσιν ὀφθῶσιν),
he must find it impossible to be discouraged or to stop
(μὴ δυνατὸν εἶναι δυσωπούμενον παύεσθαι) until (πρὶν ἂν)
one *circularly confines* (*περιβάληται*) all the things which are related to each
(σύμπαντα τὰ οἰκεῖα) *into one circle of similarity* (*ἐντὸς μιᾶς ὁμοιότητος*),
circularly enclosing (*ἕρξας*) them, on the basis of their essential nature (οὐσίᾳ) of some genus. *Politicus* 285a4-b6

The circularity of Division and Collection here is strongly indicated by the terms *"περιβάληται," "ἐντὸς μιᾶς ὁμοιότητος," and "ἕρξας."*

[6]
[*Eleatic Stranger*.] By far our first and most important object should be to exalt
the method itself of ability to *divide in kinds* (*κατ' εἴδη. . . διαιρεῖν*),
and therefore, if a *"logos"* (*λόγον*), even though it be very long, makes the hearer better able to discover the truth, we should accept it eagerly and should not be offended by its length, or if it is short, we should judge it in the same way.
And, moreover, anyone who finds fault with *the length of "logoi"* (*λόγων μήκη*)
in our divisions and *of the circular periods* (*καὶ τὰς ἐν κύκλῳ περιόδους*)
must not merely find fault with the speeches for their length and then pass them quickly and hastily by. . . *Politicus* 286d6-287a6

The periodicity is described by the terms *"λόγων μήκη," "τὰς ἐν κύκλῳ περιόδους."*

[7]
Socrates. We say that *One and Many* (*ἓν καὶ πολλὰ*) are identified always, both now and in the past, by *"logoi"* (*ὑπὸ λόγων*) *running circularly around* (*περιτρέχειν*)
everywhere *in every intelligible being* (*καθ' ἕκαστον τῶν λεγομένων ἀεί*).
Philebus 15d4-8

In every intelligible Being, the Many, generated by anthyphairetic division, become One by the circularity, periodicity (*περιτρέχειν*) of the "logoi" resulting in the equalization and Collection of the Many into One.

[8]
and one way,
dividing the left-hand part (ὁ μὲν τὸ ἐπ' ἀριστερὰ *τεμνόμενος* μέρος),
continued to divide (*πάλιν τοῦτο τέμνων*),
did *not return to the previous parts* (*οὐκ ἐπανῆκεν πρὶν ἐν αὐτοῖς*)
discovered a sort of left-handed love ἐφευρὼν (ὀνομαζόμενον σκαιόν τινα ἔρωτα),
which it very justly reviled (ἐλοιδόρησεν μάλ' ἐν δίκῃ),
but the other way,
leading us to the right-hand part of madness,
discovered a love having the same name as the first, but divine, which it held up to view and praised as the author of our greatest blessings. *Phaedrus* 266a3-b1

Phaedrus 264e-266c. The Division and Collection of the right Love is periodic by its opposition to the explicit nonperiodicity of the left-sinister Love. The right, good eros, is the one who is not bad, like the left, its badness consisting in not having periodic division. Nonperiodicity is indicated by the terms: "*οὐκ ἐπανῆκεν πρὶν ἐν αὐτοῖς*."

[9]
is able to divide beings in kinds (κατ' εἴδη τε διαιρεῖσθαι τὰ ὄντα) and
to *circularly comprehend* (*περιλαμβάνειν*) each of them under one idea (μιᾷ ἰδέᾳ δυνατὸς).
Phaedrus 273d8-e4

Circularity indicated, as in [1], by the term *"περιειλήφαμεν."*

4 Deciphering the Mathematical Statement of the Weak Theaetetus' Periodicity Theorem from the Philosophical Statement of the Theorem in the *Theaetetus* 147d-148b and Its Imitations by Plato in the *Politicus* 283a-287b and the *Philebus* 16c, 23a-25e

Our aim is to understand Theaetetus' contribution and to show that it is stated in mathematical terms as follows:

> *weak Theaetetus' Periodicity theorem*: if a, b are lines, such that $a^2 = Nb^2$ for a non-square number (or more generally, such that a, b are commensurable in square only), then the anthyphairesis of a to b is periodic.

We will not be content only for a direct examination of the passage *Theaetetus* 147d-148b, but will also look at (some of) the imitations announced in 148d5.

In the beginning paragraphs of the dialogue *Theaetetus* (145d6, e9), written in memory of the deceased in battle Theaetetus, the question "what constitutes knowledge of an intelligible Being?" is set by Socrates; soon after (147d3-148b2) Plato

describes a mathematical discovery by Theaetetus (and his friend) and he makes clear that this discovery by Theaetetus is of paramount importance for Plato's philosophy, in particular for the question set above, and that therefore Theaetetus' mathematical discovery is worthy of imitation in his philosophy, hence Socrates' urge to Theaetetus "try to imitate" (πειρῶ μιμούμενος, 148d5).

Our main concern in the present section, and the subsequent Sect. 6, is to decide what is the exact nature of Theaetetus' mathematical discovery. Plato's statements on Theaetetus' mathematical discovery and contribution are couched in philosophical language, not providing an unambiguous mathematical statement, and unfortunately we have no other ancient sources on that matter. It is clear that we will have a chance of success only if we reach a deep understanding of Plato's philosophy and of how Plato has proceeded with the imitation, in the hope that understanding the philosophical imitation will throw light in and decipher the mathematical original. This is no mean task, because the "imitation" turns out to extend throughout the whole trilogy *Theaetetus-Sophistes-Politicus*, dedicated to the knowledge of the intelligibles, and even beyond, to the work of Plato in his last years including notably the *Philebus*.

In the present Sect. 4 we will examine three crucial passages.

The *first* (in Sects. 4.1–4.4) is the description by Plato of the mathematical discovery of Theaetetus, following a lesson on some quadratic incommensurabilities by Theodorus, described in the *Theatetus* 147d3-148b2 in semi-philosophical language, according to which

> every power is infinite/incommensurable and is collected into One.

The *second* (in Sect. 4.5) is the principal philosophical statement in the *Philebus* 16c, 23a-25e, according to which

> every intelligible Being is the mixture of
> the two Philebean principles of Infinite and Finite, interpreted as
> Anthyphairetic Infinite/Incommensurability and
> Anthyphairetic Finite/Commensurability, respectively.

The *third* (in Sect. 4.6) is the difficult but illuminating passage in the *Politicus* 283a-287b, according to which

> every intelligible Being is the product of two measurements,
> the one against its opposite, from which pleasure is to be excluded, and
> the other against their mean.

A comparison of these key passages confirms that the late period of Plato's philosophy has been heavily influenced from the mathematical work of Theaetetus, and we are led to the following *weak form* of Theaetetus' Theorem on Quadratic Incommensurabilities.

Weak periodicity form of Theaetetus' Theorem. If N is a non-square natural number and a, b are lines such that $a^2 = Nb^2$, then the anthyphairesis of a to b is periodic.

In the next Sect. 5 we will reconstruct the proof of the periodicity theorem, employing tools solely in the Theaetetean Book X of the *Elements*, in Sect. 6 we will study in detail Plato's imitation of the strong form of Theaetetus' theorem on palindromic periodicity in the *Politicus*, and in Sect. 7, we will reconstruct the strong palindromic periodicity theorem, using essentially the same tools from Book X.

4.1 *Theaetetus* 147d3-148b2

The "distributive" interpretation of the plural "hai dunameis" ("αἱ δυνάμεις") in 147d7-8 opens the way for a meaningful understanding of this crucial passage. But why was Plato interested for Theaetetus' mathematical discovery? It is not simply to eulogize Theaetetus; he has something more significant in mind.

4.1.1 Socrates Asks Theaetetus What Is the Nature of Knowledge of an Intelligible Being 145d6, e9

Socrates, with a characteristic ironic understatement (μικρὸν δέ τι ἀπορῶ, 145d6), sets the basic question for the trilogy *Theaetetus, Sophistes, and Politicus*,

What constitutes knowledge (ἐπιστήμη) of an intelligible Being (ἐπιστήμη ὅτι ποτὲ τυγχάνει ὄν, 145e9).

4.1.2 Theaetetus Realizes that Socrates' Question Is Similar to a Mathematical Discovery He Had Made Recently 147c7-d1

After some abortive attempts, Theaetetus realizes that Socrates' question on the acquisition of knowledge of intelligible Beings (ἐπιστήμη) is similar, relevant to his (and his companion's) treatment of the mathematical problem, conceived during Theodorus' lesson on quadratic incommensurabilities.

Theaetetus. It seems easy just now, Socrates, as you put it;
but you are probably asking the kind of thing that came up among us recently
(οἷον καὶ αὐτοῖς ἡμῖν ἔναγχος εἰσῆλθε)
when your namesake, Socrates here, and I were talking together. 147c7-d1

4.1.3 Theaetetus' Definition of "dunamis" 148a6-b1

Theaetetus. Those lines γραμμαὶ which square (τετραγωνίζουσι) the square (ἰσόπλευρον) number
we called length (μῆκος), and
those which square the non-square (ἑτερομήκη) number
we called powers/"dunameis" (δυνάμεις). 148a6-b1

4.1.4 Theodorus' Lesson 147d3-6

Theodorus here was drawing some figures (ἔγραφε) for us
about powers/"dunameis", about the three square feet and five square feet

showing [ἀποφαίνων] these "dunameis" are not commensurable in length (μήκει οὐ σύμμετροι) with the one foot line, and so, selecting (προαιρούμενος) each one in its turn up to the seventeen square feet "dunamis"
and at that he somehow stopped (πως ἐνέσχετο). 147d3-6

4.1.5 Theaetetus Mathematical Discovery 147d7-e1

Now we had the idea (ἡμῖν οὖν εἰσῆλθέ τι τοιοῦτον),
since the "dunameis" were shown (ἐφαίνοντο) to be
infinite in multitude (ἄπειροι τὸ πλῆθος),
to try (πειραθῆναι) *to collect them into one (συλλαβεῖν εἰς ἕν),*
by which we could henceforth call all the "dunameis". 147d7-e1

4.1.6 Explaining Further Theaetetus' Mathematical Discovery 148b1-2, d5-6

because (ὡς)
[the dunameis] are not commensurable in length (μήκει μὲν οὐ συμμέτρους) with
the others [namely, the lengths],
but [are commensurable] only in the areas of the planes which they have the power (δύνανται) to form. 148b1-2
Socrates. you *comprehended (περιέλαβες)* them [the "dunameis"],
though they were many (πολλὰς οὔσας), *in one kind (ἑνὶ εἴδει).* 148d5-6
(Plato, *Theaetetus*, trans: Fowler 1921, with modifications by the authors)

4.2 The Mathematical Interpretation of the *Theaetetus* 147d3-148b2 Passage, Describing the Weak Theaetetus' Periodicity Theorem in Semi-Philosophical Terms

4.2.1 The Distributive Plural Reading of "dunameis" in 147d7-8: *Every* "dunamis" Separately, *Not All* "dunameis" Collectively, Possesses Division Ad Infinitum and Collection into One

Our starting point is our attempt to make some sense of how Theodorus' lesson resulted in that

"the "dunameis" were shown (ἐφαίνοντο) to be infinite in multitude (ἄπειροι τὸ πλῆθος)" (147d7-8, in Sect. 4.1.5 above).

4.2.2 The Traditional Reading of 147d7-8 and Its Rejection

We look at Burnyeat's (Burnyeat 1978) treatment:

"The key sentence is 147d 7-e 1, which I render as follows:
*Since the dunameis were turning out to be unlimited in number, it occurred to us to attempt to collect them up into a single way of speaking [*i.e*., a formula or definition] of all these dunameis together.*
Theaetetus is recounting the thoughts suggested to himself and his companion *by and during Theodorus' lesson*, and the idea that there is an endless series of whole number squares (or sides of such squares) *would hardly need to be prompted by a process as protracted as Theodorus' lesson*.

> That there are an indefinite, perhaps infinite, number of squares with incommensurable sides, on the other hand, is precisely the hypothesis that would suggest itself as Theodorus proceeded from case to case proving more and yet more examples of incommensurability, perhaps by a method which could be endlessly reapplied.
> Therefore, it is likely that, in context, "all these dunameis" refers to squares with incommensurable sides rather than to squares generally."

Thus Burnyeat correctly rejects the interpretation that

> the expression "infinitely many powers" in 147d7-8 should mean "infinitely many non-square numbers,"

as this infinity would be already known, trivial anyway, and not prompted by Theodorus' lesson.

But the suggestion of Burnyeat that

> the expression "infinitely many powers" in 147d7-8 should mean "infinitely many incommensurable sides,"

is open to the same objection, namely that it "*would hardly need to be prompted by a process as protracted as Theodorus' lesson,"* since the incommensurability of the power for $N = 2$, known to the Pythagoreans a long time ago and for this reason expressly omitted from Theodorus' lesson, is seen to imply the *incommensurability of the infinitely many powers,* namely for each N of the form $N = 2 \cdot n^2$, with $n = 1$, 2,. . . Thus Burnyeat's interpretation should be equally rejected.

4.2.3 The Distributive Plural Interpretation of "dunameis" in 147d7-8

Once these two interpretations are rejected, it is hard to think of any other interpretation of an infinite set of "dunameis" distinguished by Theodorus' lesson.

We have already argued in (Negrepontis 2018) that the only interpretation of the sentence in question that makes sense is by switching to a *distributive plural,* and render the passage *Theaetetus* 147d7-e1 as follows:

> Because, as a result of Theodorus' lesson, it was shown that *every power* was divided into an infinite multitude of parts ("ἄπειροι τὸ πλῆθος") (147d7-8), Theaetetus and his companion had the idea and in fact succeeded in *collecting* [the infinitely many parts of] *every power* into One ("συλλαβεῖν εἰς ἕν").

Distributive Plural of Dunameis Before and After 147d7-8 Throughout Passage 147d3-148b2

We find initial support for this distributive interpretation in the observation that in fact the plural about powers is distributive *throughout passage 147d3-148b2*:

in the occurrence of "dunameis" in 147d4-5 (in item 3.1.4 above),
just before 147d7-8

> [Theodorus] showing [ἀποφαίνων] these "dunameis" are not commensurable in length (μήκει οὐ σύμμετροι) with the one foot line

since it means of course that every "dunamis" separately is not commensurable in length with the one foot line and not all the "dunameis" together; and,

in the occurrence of "dunameis" in 148b1-2 (in item 3.1.6 above),

just after 147d7-8

> [the dunameis] are not commensurable in length (μήκει μὲν οὐ συμμέτρους) with the others [namely, the lengths],
> but [are commensurable]only in the areas of the planes which they have the power (δύνανται) to form,

since it means of course that every "dunamis" separately is incommensurable or commensurable to the one foot, and not all the "dunameis" together.

It is natural then to conclude that the plural about "dunameis" in the crucial in-between occurrence 147d7-8 (in Sect. 4.1.5 above) is distributive as well.

Schematically

[Theodorus] showing [ἀποφαίνων] these *"dunameis"* are not commensurable in length (μήκει οὐ σύμμετροι) with the one foot line 147d4-5	Distributive plural of "dunameis" before 147d7-8
"the *"dunameis"* were shown (ἐφαίνοντο) to be infinite in multitude (ἄπειροι τὸ πλῆθος)" 147d7-8	What plural of "dunameis" at 147d7-8?
[the *"dunameis"*] are not commensurable in length (μήκει μὲν οὐ συμμέτρους) with the others [namely, the lengths], but [the *"dunameis"*are commensurable] only in the areas of the planes which they have the power (δύνανται) to form 148b1-2	Distributive plural of "dunameis" after 147d7-8

Support for Distributive Reading of "dunameis" in 147d7-8 from *Scholia in Platonem*

A commentary to the *Theaetetus* passage 162e6-7 on Theodorus, found in the anonymous work *Scholia in Platonem* (abbreviated SIP), runs as follows:

> If we accept the judgement of the many as the dominant one in geometry,
> we would be ridiculous to claim
> (καὶ γὰρ εἰ τὴν τῶν πολλῶν κρίσιν λάβοιμεν ἐπὶ γεωμετρίας κυρίαν, γελοῖοι ἂν ὦμεν),
> that maginitudes are *incommensurable* to each other
> (ἀσύμμετρα λέγοντες ἀλλήλοις μεγέθη),
> and that *the finite line is divisible* ad infinitum
> (καὶ τὴν πεπερασμένην εὐθεῖαν διαιρετὴν εἶναι εἰς ἄπειρον,
> and *the like* (καὶ τὰ τοιαῦτα).

The following reading of the commentary is suggested:

Theodorus, when proving that each of the "dunameis" (of 3,5,. . .,17 feet) and the one foot line (the magnitudes) are *incommensurable* to each other, as in statement 147d3-6, employed,

not any considerations of probability

(which would be worthless and make him ridiculous),

but logically impeccable proofs ("ἀπόδειξιν δὲ καὶ ἀνάγκην," 162e4-5) involving the *division* ad infinitum of each of these finite lines,

so that every one of these lines, each power, is *infinite in multitude*, as in statement 147d7-8.

This reading leads to a distributive interpretation of "hai dunameis" in 147d7-8.

Support for Distributive Reading of "dunameis" in 147d7-8 from the *Anonymi Commentarius in Platonis Theaetetum*

The *Anonymi Commentarius in Platonis Theaetetum* (*ACIPT*), possibly Eudorus, first century BC (cf. Tarrant (Tarrant 1985)), lends strong support to the distributive interpretation. Indeed, commenting on the infinity arising from the "powers infinite in multitude," and their collection achieved by Theaetetus and his companion, in the *Theaetetus* 147d-148b passage, he makes the following statements:

[1]. an infinity (τὸ ἄπειρον) in general must be collected (περιλαμβάνειν καὶ ὁ[ρίζ]ειν), if possible (καθ' ὅσον ἐνδ[έ]χεται) *ACIPT* 37, 3-12;

[2]. a line admits of the infinite either by (infinite) increase or (infinite) division (αἱ γραμμαὶ ἐπιδέχονται τὸ ἀόριστον, εἴ τις αὐτὰς ἢ αὔξοι ἢ διαιροῖ) *ACIPT* 36,45-48;

[3]. the collection of an infinity in a line can be achieved by passing over to numbers (ὁρίζονται δ' ὑπὸ τῶν ἀριθμῶν) *ACIPT* 36,48-37,3; (μετέβησαν οὖν καὶ ἐπὶ τούτων ἐπὶ τοὺς ἀριθμούς, ἵνα περιορίσωσι καθολικῶι τινι) *ACIPT* 42, 30-33.

Note: Collection renders 'perilambanein' (as in the *Theaetetus* 148d6) (26,11; 37,5; 37,10; 37,29; 37,43; 37,46; 45,48; 46,39), periorizein (42,32) and horizein (37,1; 37,11).

[4]. a line infinite by increase cannot be collected by numbers (Ὁ ἀριθμὸς ἄπειρός ἐστιν κατὰ τὸ αὔξεσθαι· οὐ δύναται οὖν τις τὸ ἐπ' ἄπειρον προϊὸν περιλαβεῖν) *ACIPT* 37, 39-44;

Thus collection can be achieved only for a line divided into infinite parts

[5]. the collection of an infinity in a line can be achieved by passing over to numbers, because numbers are commensurable to each other (ἦλ]θ[ον] οὖν ἐπὶ τὸ[ν ἀριθμ]ὸν διὰ τὸ [.]κ[.....]ρν τῶι πάντα[ς] τοὺς ἀρι[θμ]ο[ὺ]ς συμμ[έτ]ρους [εἶ]να[ι] πρ[ὸς] ἀλλή[λους]) *ACIPT* 26,13-18;

[6]. the collection of an infinity in a line is achieved by passing from the less clear magnitudes to the more clear numbers (ὥσπερ δὲ οἱ περὶ Θεαίτητον μετέβησαν ἐπὶ τοὺς ἀριθμοὺς ὡς σαφεστέρους) *ACIPT* 32,1-4; (πρῶτον μὲν οὖν ἀπὸ τῶν ἀσαφεστέρων ἐπὶ τὰ σαφέστερα δεῖ μεταβαίνειν ὡς ἀπὸ τῶν μεγεθῶν μετέβησαν ἐπὶ τοὺς ἀριθμούς) *ACIPT* 44,50-45,3; namely from incommensurables to commensurables, that is to "as number to number" (ἔχει γὰρ λόγον, ὃν ἀριθμὸς πρὸς ἀριθμόν) *ACIPT* 41,40-42,18.

Note. Exactly the same point is made in the *Scholion* X.39 to the *Elements*.

> In analogy to the description for cubes: "they came to the cubes," as "the solid itself is commensurable to the solid; for it has ratio, as number to number, while the sides are incommensurable."

The interpretation of these statements is the following:
By statement [2] we conclude that

> the plural in the expression "the "dunameis" infinite in multitude", as already suspected, is distributive and "every "dunamis" infinite in multitude" is meant;

by statement [4] and the fact that Theaetetus and his companion succeeded in collecting the infinite in multitude "dunameis," we conclude that

> every "dunamis" is infinite in power by division ad infinitum;

by statements [3], [5], and [6] we conclude that

> the infinity of every "dunamis" is due to incommensurability; and,

by statements [3], [5], [6], we conclude that

> 'collection into One' concerns the infinite multitude of parts of a "dunamis" brought about by Theodorus' incommensurability proofs, and is made possible because a "dunamis" is not just any line incommensurable in length, but a line whose square is commensurable, namely a Theaetetean mixture of commensurability and incommensurability.

Support for Distributive Reading of "dunameis" in 147d7-8 from the Definition of a Platonic Idea as "dunamis" in the *Sophistes* 247d-248d

In the *Sophistes* 247d-248d Plato defines the Platonic Idea as a "dunamis." The meaning of this definition will be explained briefly. According to this definition the fundamental property of a Platonic Idea is that, in interaction, active or passive, with an opposite element, forming an indefinite dyad, it has the "power," in fact the "power to communicate" with each other (252d3, 253a8, 253e1, 254b8, 254c5), in fact the "power for equalization with each other" (257b).

Irrespective of the precise meaning of the definition, Plato imitates here the term used in the *Theaetetus* 147d-148d for the mathematical "dunamis." In the *Sophistes* the Division and Collection is a method for the acquisition of knowledge of a Platonic Idea, thus of a "dunamis"; it is certainly the case that every "dunamis" separately is Collected into One. This suggests again that in the *Theaetetus* the Collection of the "dunameis" (who were collected into One because they appeared to be infinitely many) is to be understood distributively, for each power separately.

4.3 The Mathematical Statement of Theaetetus' Theorem Reported by Plato in the *Theaetetus* 147e2-148b3 in Semi-Philosophical Terms

We are now able to interpret the passage 147e2-148b3 that describes in semi-philosophical terms Theaetetus' mathematical contribution. There are two main problems in producing a mathematical statement that makes us understand Theaetetus' mathematical discovery and contribution and reaching an understanding of Theaetetus' mathematical theorem:

(i) The kind of infinity in Sect. 4.1.5
(ii) The mathematical meaning of "collection," "comprehension" of the power(s) in One in Sect. 4.1.5 and Sect. 4.1.6.

Since, according to the clarification, Sect. 4.2.2 above, Theodorus' proofs were showing that every *power*, namely every line a such that $a^2 = Nb^2$ for some non-square number N, was *infinite* in multitude, namely was divided into an infinite multitude of parts, Theaetetus (and young Socrates) tried to collect ("συλλαβεῖν εἰς ἕν" [147d8], in Sect. 4.1.5), or to comprehend ("ἐνὶ εἴδει περιέλαβες" [148d6] in Sect. 4.1.6), the infinite multitude of these parts into One, namely according to our interpretation of Collection in Sect. 3, to equate all parts, something achieved by anthyphairetic periodicity.

Thus the mathematical statement of Theaetetus' theorem must be as follows:

Weak Theaetetus' periodicity theorem. If N is a non-square number, b is the one foot line, and $a^2 = Nb^2$, then the anthyphairesis of a to be is periodic.

4.4 "peiro mimoumenos" (πειρῶ μιμούμενος) in *Theaetetus* 148d4-5: The Plan to Imitate Theaetetus' Periodicity Theorem in Platonic Philosophy

In view of the importance for our work to determine with certainty the theorem that Plato tells us that Theaetetus proved, we will not be content with the arguments interpreting the passage itself that describes the theorem, but we will look carefully into the philosophical imitations of this theorem that Plato, as he tells us, employed (cf. *Theaetetus* 148d4-5); specifically we will look at two impressive imitations, in the *Philebus* 16c, 23b-25e (Sect. 4.5) and in the *Politicus* 283a-287b (Sect. 4.6).

4.5 Philosophical Imitation of the Weak Theaetetus' Periodicity Theorem in the *Philebus* 16c, 23b-25e: Every Intelligible Being Is the Mixture of the Anthyphairetic Infinite and the Anthyphairetic Finite

The most striking philosophical imitation of the weak Theaetetus' periodicity theorem is the central theme in the *Philebus* 16c, 23b-25e:

Every intelligible Being is the mixture of the the two Philebean principles, Infinite and Finite.

A dyad of lines that are incommensurable but have commensurable squares is a dyad of lines with infinite anthyphairesis with squares with finite anthyphairesis, thus a mixture of anthyphairetic infinite and anthyphairetic finite; and,

such a dyad has, according to the weak Theaetetus' periodicity theorem, periodic anthyphairesis, and is thus a geometric entity whose philosophic analogue is an intelligible Being, as we have seen in Sect. 2.

Thus to establish that the central *Philebus* thesis is indeed a philosophic imitation of the weak Theaetetus' periodicity theorem, we simply have to prove that the Philebean Infinite is the anthyphairetic Infinite and the Philebean Finite is the anthyphairetic Finite. This will be done in Sect. 4.5.1 below.

4.5.1 The Philebean Infinite Is the Philosophical Analogue of Infinite Anthyphairesis and of Incommensurability, and the Philebean Finite Is the Philosophical Analogue of Finite Anthyphairesis and of Commensurability (*Philebus* 23b-25e)

We first examine Plato's description of the *Philebus principle of the Finite*:

> And the things which do not admit of more and less and the like, but do admit of all that is opposed to them (τούτων δὲ τὰ ἐναντία πάντα δεχόμενα) —first *equality* and the equal (τὸ ἴσον καὶ ἰσότητα), then the *double* (τὸ διπλάσιον), and *anything which is a ratio of number to number* (πᾶν ὅτιπερ ἂν πρὸς ἀριθμὸν ἀριθμὸς) or measure to measure, all these might properly be assigned to the class of *the finite* (τὸ πέρας). 25a6-b2
> The class of the *equal* (ἴσου) and *double* (διπλασίου), and everything which puts an end (παύει) to the differences between opposites and makes (ἀπεργάζεται) them *commensurable* (σύμμετρα) and harmonious (σύμφωνα) by the introduction (ἐνθεῖσα) of number (ἀριθμὸν). 25d11-e2

(Plato, *Philebus*, trans: Fowler 1925, with modifications by the authors)

A comparison of these passages with Propositions 1-8 of Book X of the *Elements* immediately implies that the *Philebean principle of the Finite* is the philosophic analogue of *finite anthyphairesis* and thus, by means of Proposition X.2 of the Elements, of *commensurability.*

Proclus, in *Scholia in Euclidem* 7,1-5 (Morrow 1970) fully confirms the identification of Philebean Finite with commensurability:

> And if the Finite were absent (*τοῦ δὲ πέρατος ἀναιρεθέντος*),
> there would be no (*οὐκ ἄν ποτε*) commensurability (*συμμετρία*) or equality of ratios (κοινωνία λόγων), no identity of kinds (ταυτότης εἰδῶν) and equality (ἰσότης) in mathematics (*ἐν τοῖς μαθήμασιν ἐφαίνετο)*, nor anything else that belongs in the column of the better (ὅσα τῆς ἀμείνονός ἐστι συστοιχίας), nor any knowledge of such matters (οὐδ' ἂν ἐπιστῆμαι τῶν τοιούτων ἦσαν), nor any fixed and precise concepts (οὐδὲ καταλήψεις μόνιμοι καὶ ἀκριβεῖς). 7,1-5

We next examine Plato's description of the *Philebus principle of the Infinite*:

> For wherever they are present, they do not allow *each (of the dyad) to be a quantity* (ποσὸν ἕκαστον) to exist; they always (ἀεὶ) introduce in every instance an opposition—*(the dyad) more emphatic than that which is quieter, or* vice versa (σφοδρότερον ἡσυχαιτέρου καὶ τοὐναντίον) —and thus they create *the (dyad) more and less* (τὸ πλέον καὶ τὸ ἔλαττον), thereby doing away with *fixed quantity* (ποσὸν). 24c2-6
> For, as I said just now, if they did not abolish *quantity* (ποσὸν), but allowed it and *measure* (τὸ μέτριον) to make their appearance in the abode *of the (dyad) more and less* (μᾶλλον καὶ ἧττον), *the (dyad) emphatically and gently* (σφόδρα καὶ ἠρέμα), those latter would be banished from their own proper place. When once they had accepted *quantity* (τὸ ποσόν), they would no longer be *(the dyad) hotter or colder*; for *(the dyad) hotter and colder* (θερμότερον. . .ψυχρότερον) are always (ἀεὶ) progressing and never stationary; but *quantity* (ποσὸν) is at rest and does not progress. By this reasoning *(the dyad) hotter and its opposite* are shown to be *infinite* (ἄπειρον). 24c6-d7
> we ought to collect all things that are *scattered* (διέσπασται) and *split up* (διέσχισται) to be put in the class of *the infinite* (τὸ τοῦ ἀπείρου γένος). 25a1-3

An Infinite is a dyad of the general form "the (dyad) More and Less" (μᾶλλόν τε καὶ ἧττον) (25c5-d2), as for example the (dyad) Hotter and Colder (θερμοτέρου καὶ ψυχροτέρου, 24a7-8), or the (dyad) Emphatic and Gentle (τὸ σφόδρα καὶ ἠρέμα, 24c1-2). The first observation is that *the Philebean infinite is a dyad of opposites*.

The dyad More and Less is Infinite if it renews itself at every stage, ad infinitum (ἀεὶ), so that it becomes divided into an infinite multitude of parts. But if, on the other hand, the process stops then each part of the dyad turns into quantity/number, and becomes an element of the class Finite (Here are some passages, by Pythagoreans and neo-Pythagoreans, that employ "ποσὸν" (quantity) and "ἀριθμὸς" (number) as equivalent: Xenocrates, *Fragment* 87; Theon Smurneus 19,15-18; Nicomachus, *Introductio Arithmetica* (1,2;1,7,1,1-2; 2,22; 2,23,1,1-6), *Harmonicum enchiridion* (4,1,37-38; 6,1,1-6), and *Theologoumena arithmeticae* (20,1-21,2); lamblichus, *Commentaria in Nicomachi Geraseni Pythagorei introductionem arithmeticam* 1,49,1-3; Iamblichus, *De communi mathematica scientia* 7,33-61; Proclus, *Comments to Euclid* 35,21-36,3 (Procli Diadochi 1873); *Anonyma Scholia to Euclid's Elements* V.9, V.10, X.39.). But we have already seen that an element of

the Finite is a commensurable pair of finite anthyphairesis. It is now clear that *the Philebean Infinite* is a dyad in *infinite anthyphairesis*, and thus, by Proposition X.2 of the *Elements*, *incommensurable*.

Proclus, in *Scholia In Euclidem* 6,19-22 (Morrow 1970), fully confirms the identification of Philebean Infinite with incommensurability:

> If there were no Infinite (*τῆς μὲν ἀπειρίας οὐκ οὔσης*),
> all magnitudes would be commensurable (*τά τε μεγέθη πάντα σύμμετρα ἂν ἦν*) and
> there would be nothing irrational or ratioless (*οὐδὲν ἄρρητον οὐδὲ ἄλογον*),
> features that are thought to distinguish geometry from arithmetic (οἷς δὴ δοκεῖ διαφέρειν τὰ ἐν γεωμετρίᾳ τῶν ἐν ἀριθμητικῇ). 6,19-22

4.5.2 Every Intelligible Being Is the Mixture of the Infinite and the Finite (*Philebus* 16c, 23c-d, 25b)

According to the *Philebus*, each of the Platonic Ideas is a *mixture* of the Philebean *Infinite* and the Philebean *Finite* (Some scholars, e.g., Cherniss (Cherniss 1945), Ryle (Ryle 1966), do not think that "ta aei legomena einai" refer to the intelligible Beings; this position is to be understood within a general view that, Plato's repeated dithyrambic descriptions of Division and Collection not withstanding, downgrades the method.)

Socrates. One which is easy to point out, but very difficult to follow for through it *all the inventions of art* have been brought to light. See this is the road I mean.
Protarchus. Go on what is it?
Socrates. A gift of gods to men, as I believe, was tossed down from some divine source through the agency of a Prometheus together with a gleaming fire; and the ancients, who were better than we and lived nearer the gods, handed down the tradition that
all the things which are ever said to exist ("τῶν ἀεὶ λεγομένων εἶναι") *consist of one and many and have inherent in them the finite and the infinite* ("πέρας δὲ καὶ ἀπειρίαν ἐν αὐτοῖς σύμφυτον ἐχόντων"). *Philebus* 16c
Note. "a Prometheus" is most likely a reference to Pythagoras, whose philosophy is based on the principles of the Infinite and the Finite (Philolaus, *Fragments* 1, 2, 6 and Aristotle, *Metaphysics* 987a13-28). But see also Sect. 4.7 below.

Socrates. We said that God revealed in the universe two elements, *the infinite and the finite*, did we not?
Protarchus. Certainly.
Socrates. Let us, then, assume these as two of our classes, and a third, made *One by combining ("ἕν τι συμμισγόμενον") these two*. *Philebus* 23c-d

Socrates. Well, what shall we say is the nature of *the third class, made by combining ("τὸ μεικτὸν") these two? Philebus* 25b

Thus, we will be able to discover the nature of Platonic Ideas and Beings, if we understand the meaning of the terms "Philebean Finite," "Philebean Infinite," and "Philebean mixture" of Infinite and Finite.

4.6 Philosophical Imitation of the Weak Theaetetus' Periodicity Theorem in the *Politicus* 283a-287b: Every Intelligible Being Is the Product of a Double Measurement, First Against the Opposite (Excluding a Pleasure, Which Is a Philebean Infinite, Hence a Finite), Secondly Against the Geometric Mean of These Opposites (a Generation, Hence an Infinite)

4.6.1 The "double measurement" in the *Politicus* 284e2-8

According to the *Politicus* 284e2-8, numbers, magnitudes, and qualities are subject to the *double measurement*, as follows:

> *Eleatic Stranger.* We should evidently divide the art of measurement (*μετρητικήν*) into two parts in accordance with what has been said.
> *One part* is all the arts which measure (*μετροῦσιν*) number, length, depth, breadth, and thickness against their opposites (*πρὸς τοὐναντίον*);

(Plato, *Statesman*, trans: Fowler 1921, with modifications by the authors)

Thus a number, a magnitude, or a quality, say x, is measured firstly against its opposite, say y; measurement against the opposite is about dyads, such as length and shortness, excess and deficiency, greatness and smallness, the greater and the less, or the great and the small (283c-e), of a magnitude or number or quality against its opposite (284e).

> *the other* is those which measure them in relation to the moderate (τὸ μέτριον), the fitting (τὸ πρέπον), the opportune (τὸν καιρὸν), the needful (τὸ δέον), and all the other standards that are situated *in the mean* (*τὸ μέσον*) between the extremes (τῶν ἐσχάτων). *Politicus* 284e2-8

Secondly, x is measured against the *mean* of x and y.

4.6.2 The First Measurement Must Not Be Pleasure (286c8-d6)

Not all opposite dyads x, y are worthy of a double measurement. In fact if the dyad of opposites (*x*, *y*) is a *pleasure* (ἡδονὴ) (and pain), then such a pair is unworthy of a second measurement.

> **Eleatic Stranger.** What I have to say, then, is that you and I, remembering what has just been said, must praise or blame the brevity or length of our several discussions,
> not [only] by comparing their various lengths with one another (μὴ πρὸς ἄλληλα τὰ μήκη κρίνοντες),
> but with reference to that part of the art of measurement (κατὰ τὸ τῆς μετρητικῆς μέρος), which we said before must be borne in mind; I mean the standard of fitness (πρὸς τὸ πρέπον).
> **Younger Socrates**. Quite right.
> **Eleatic Stranger.** But we must not measure all lengths by fitness (πρὸς τὸ πρέπον), either.
> For we shall *not in the least want to measure by fitness* (*οὐδὲν προσδεησόμεθα*) a length (μήκους) whose first measurement has produced (ἁρμόττοντος) *pleasure* (*πρὸς τὴν ἡδονὴν*,
> except, perhaps, as a secondary consideration (πάρεργόν τι). 286c8-d6

4.6.3 Every Pleasure (ἡδονὴ) Is a Philebean Infinite (*Philebus* 27e,31a,41d); Thus the First Measurement Is a Philebean Finite

We might be mystified why Plato rejects a dyad of opposites that represents a pleasure. It will begin to make sense if we realize that pleasure is a philosophical term for the Philebean anthyphairetic Infinite: Every pleasure (ἡδονὴ), or more precisely every dyad (pleasure and pain) (ἡδονὴ καί λύπη), is an Infinite.

Socrates. Is *pleasure and pain* a *finite*, or are they among the things which *admit of more and less*?
Philebus. Yes, they are among those which *admit of the more*, Socrates; for *pleasure* would not be absolute good if it were not *infinite in multitude and in the more*.
Philebus 27e

Socrates. Let us, then, remember . . . that *pleasure* was itself *infinite* and belonged to the class which, in and by itself, has not and never will have either beginning or middle or end. *Philebus* 31a

Socrates. And have we not also said and agreed and settled something further?
Protarchus. What?
Socrates. That both *pleasure and pain* admit of *the more and less* and are of the class of *the infinite*.
Protarchus. Yes, we have said that, certainly. *Philebus* 41d

That "the dyad x, y produces *pleasure*" is equivalent, as explicitly stated in the Platonic dialogue on pleasures *Philebus* 27e, 31a, 41d, with "the dyad x, y is an *Infinite*." Thus the condition on the first measurement is that the dyad x, y *is not a Philebean Infinite*, hence necessarily it is a *Philebean Finite*.

4.6.4 The Second Measurement Is x Against the Geometric Mean of the Dyad x and y

We interpret "the mean (x, y)," in the description of the second measurement in Sect. 4.6.1, to mean the philosophical analogue of the *geometric mean* of x and y.

This choice is strongly supported in the *Elements*, and specifically in the Theaetetean Book X of the *Elements*. It is remarkable that in the *Elements* there are 738 occurrences of the term "*μέσου*" (and its variants), and these exclusively and without exception refer to the "geometric mean" (of two numbers or of two magnitudes), while NONE of them refers to the arithmetic or any other mean, or any other sense; of them, the great majority 624 occur in the Theaetetean Book X (This remark is credited to A. Bassiakou (Bassiakou 2004)). The alternative term used "μέτριον" (283e, 284a, c, d, e) has normally a meaning equivalent to "*μέσον*."

4.6.5 The Second Measurement Is an Intelligible Generation, a Philebean Infinite

In the *Parmenides* 142c-143a, the infinite anthyphairetic intelligible division of the dyad One, Being, outlined in Sect. 3, is described, with an insisted repeated use of words referring to generation, such as "*γίγνεσθαι*" (142d5), "*γί[γ]νεται*" (142e4), "*γίνηται*" (142e6), and "*γιγνόμενον*" (143a1). Proclus in *Platonic Theology* 3,91, 9-24, comments on this frequent occurrence, as referring to "the progress/division of the intelligible multitude" (*περὶ τῆς προόδου τοῦ νοητοῦ πλήθους*).

A similar description of the Infinite intelligible anthyphairetic division as generation can be seen is the *Philebus*: "generation in substance" (*γένεσιν εἰς οὐσίαν*, *Philebus* 26d-8), "generated substance" (*γεγενημένην οὐσίαν*, 27b7-9).

The same insistent use of words related to generation, such as "*ὄντως γιγνόμενον*" (283e3-7), "*κατὰ τὴν τῆς γενέσεως ἀναγκαίαν οὐσίαν*" (283d7-9), *"πρὸς τὴν τοῦ μετρίου γένεσιν"* (284b9-c1, d5-6), refers to the intelligible infinite anthyphairetic division of the second measurements against the mean in the *Politicus*.

Thus the condition on the second measurement is that the dyad x, mean (x, y) is a *Philebean Infinite*.

4.6.6 Deciphering the Meaning of the Double Measurement: The Philosophical Double Measurement of the *Politicus* 283a-287b Is the Philosophical Imitation of the Theaetetus' Condition of a Dyad of Lines Incommensurable in Length Only

In order to understand the meaning of these two measurements, let us assume that x and y are lines, and $m = \text{mean}(x, y)$ is the geometric mean of x and y, given by Propositions VI.13 and II.14, namely m is a line such that $x/m = m/y$.

Let r be any "assumed line" ("προτεθείσα εὐθεῖα"), as in Definition X.3.

By Proposition II.14, there are lines a, b, such that $xr = a^2$, $yr = b^2$.

By Proposition VI.1, $\boldsymbol{x/y = a^2/b^2}$.

On the other hand, mr is the geometric mean of the squares a^2, b^2, since, by Proposition VI.1, $a^2/mr = xr/mr = x/m = m/y = mr/yr = mr/b^2$.

But the geometric mean of a^2, b^2 is obviously ab.

Hence $ab = mr$.

Therefore, $\boldsymbol{x/m = a/b}$,

since, again by Proposition VI.1, $x/m = xr/mr = a^2/ab = a/b$.

Thus the philosophical double measurement of the *Politicus* x against y a Finite, and x agaist m an Infinite is revealed to be the exact imitation, philosophical analogue of the condition of the weak Theaetetean theorem a against b incommensurable and a^2 against b^2 commensurable.

4.6.7 The Double Measurement Is the Cause of all Division and Collection in an Intelligible Being (*Politicus* 283a-287b)

Each of the Angler, the Sophist, the Statesman, the Weaving is an intelligible Being. An intelligible Being is knowable to humans as an Art, an entity with ontological status inferior to that of an intelligible Being, in that divisions are more spread out and Unity and Collection is less pronounced than in the intelligible Being itself. All Arts, and therefore all intelligible Beings become known to the human soul by the method of *Division and Collection* (284e-285c), equivalently "Division according to Kinds" (286d-287a), equivalently "Name and Logos" (285c-286b). The method of Division and Collection is the philosophical analogue of periodic anthyphairesis.

The cause of Division and Collection, and eventually of all intelligible Beings, is the fundamental condition of the double measurement (284a5-7, 284b7-c1, 286b9-10).

4.7 The Equivalence of the Three Passages Reveals the Statement of the Weak Theaetetus' Periodicity Theorem

Schematically:

Theaetetus 147d-148b	*Philebus* 16c, 23b-25e	*Politicus* 283a-287b
If a, b are lines, such that $a^2 = Nb^2$ for a non-square number, or more generally such that a, b commensurable in square only	The mixture of the Philebean Infinite, the Incommensurable, and the Philebean Finite, the Commensurable	The double measurement, against the opposite, excluding pleasure, hence a Finite, and against the mean, a generation in substance, hence an Infinite
then the infinitely many parts are collected into One	produces every intelligible Being, namely every philosophical analogue of a dyad in periodic anthyphairesis, and Collection of the Many into One	produces every intelligible Being, or every Division and Collection

In view of the fact, described in Sect. 3, that an intelligible Being is the philosophical analogue of a dyad in periodic anthyphairesis, whose parts are equalized and collected into One precisely because of anthyphairetic periodicity, we recognize that

> each of the *Philebus* 16c, 23b-25e and the *Politicus* 283a-287b
> is a philosophical analogue, philosophical imitation,

of the following

> *weak Theaetetus' Periodicity theorem*: if a, b are lines, such that $a^2 = Nb^2$ for a non-square number N (or more generally, such that a, b are commensurable in square only), then the anthyphairesis of a to b is periodic.

We have insisted on the details showing the philosophical imitation and analogy, so that the statement of the mathematical original, the weak Theaetetus' periodicity theorem, would be established with certainty and exactness.

4.8 The Philebean Finite Compared to the Pythagorean Finite

It should be pointed out that according to the Pythagoreans, too, the two principles of Beings is the Infinite and the Finite (cf. Philolaus, *Fragments* 1, 2, 6, and Aristotle, *Metaphysics* 987a13-28). But, while the Infinite, in both Plato and the Pythagoreans, is anthyphairetic in content, the Finite for the Pythagoreans is the Gnomon. The evolved corresponding Platonic concept is Logos, as may also be seen from a comparison of (the possibly nongenuine) *Fragment* 11 by Philolaus (knowledge is achieved by Gnomon) with the passage 546b-c of the *Politeia* on geometric number

(where Gnomon is in effect replaced by Logos). But Plato in the *Philebus*, not content with such replacement, insists that the principle of Finite has anthyphairetic content as well. Plato is able to modify the original Pythagorean scheme *only because* he has now in his possession the Theaetetus' periodicity theorem.

5 The Reconstruction of the Proof of the Weak Theaetetus' Periodicity Theorem, Employing Solely Tools from Book X of Euclid's *Elements* (the Apotome Lines (Propositions X.73-107), the Binomial Lines (Propositions X.36-72), and Their Conjugacy (Propositions X.112-114), and a Pigeon Hole Argument

Once the statement of (the weak form of) Theaetetus' theorem has been determined (in Sect. 4), the next step, to be attempted in the present Sect. 5, is to find out how Theaetetus was able to prove this theorem. We know that Book X of the *Elements* is generally attributed to Theaetetus, and it is natural to try to find in that Book the possible tools for a reconstruction of the proof of Theaetetus' theorem.

The reconstruction of the proof of the weak Theaetetus' periodicity theorem rests on the apotome lines (examined in Sect. 5.1), on the conjugacy of the apotome lines with the binomial lines (examined in Sect. 5.2), on the inductive transformation of the anthyphairetic relations of the quadratic equation $a^2 = Nb^2$ for non-square N into conjugacy relations (in Sect. 5.5), and on a pigeonhole argument.

5.1 Apotome Lines

The first concept in Book X that will turn out to be relevant in our quest for tools needed for the proof of the Theaetetus' periodicity theorem is the concept of an *apotome* line.

5.1.1 The Definition of the Apotome Line

Definition

Apotome Line (Proposition X.73 of the *Elements*)

An *apotome* line $\gamma = \zeta - \eta$ *with assumed line* r is equal to the difference of a *whole* line ζ, an *annex* line η, with $\zeta > \eta$, such that ζ, η are incommensurable, ζ^2, η^2 commensurable to the square r^2 of the *assumed line r.*

The study of the apotome lines occupies a part of Book X of considerable significance, Propositions X.73-107, 35 in total, consisting of (almost) six hexads, as follows:

X.73-78, defining six classes of subtractional irrational lines, one of which (X.73) is the *apotome* line, and showing the "alogia," incommensurability in square, of

each of these lines (these "alogoi" lines will be related to apotome lines in the hexad X.91-96 below);
X.79-84, showing the uniqueness of representation of each of these lines;
X.84/85, defining the six classes of apotome lines and,
X.85-90, constructing each of these lines;
X.91-96, constructing the "square-root" of each of these apotome lines defined in X.84/85 and corelating it to a line defined in X.73-78;
X.97-102, constructing the "square" of each of the lines defined in X.73-78, and corelating it to an apotome line defined in X.84/85; and,
X.103-107, a curtailed hexad, showing invariance under commensurability of each of the lines defined in X.73-78.

5.1.2 Simple Apotome Lines

The only place in Book X where apotome lines are expressly *constructed* is in the hexad of Propositions X.85-90. We notice that the apotome lines constructed there are somewhat less general than what one might expect from the definition of an apotome line. In order to explain this difference we introduce the following definition.

Definition

A line γ is a *simple apotome* if there are a non-square number N, lines a and b such that $a^2 = Nb^2$, and natural numbers p, q, λ, such that either $\lambda\gamma = pa - qb$ or $\lambda\gamma = qb - pa$.

A simple apotome is *integral* if $\lambda = 1$, *fractional* if $\lambda > 1$.

The canonical choice for the assumed line of a simple apotome is the line b, corresponding to the one foot line of *Theaetetus* 147d5, or the line a, or any other line r commensurable in power to a, namely such that a^2, r^2 commensurable areas.

Note. In the *Elements* the definition of a simple apotome is *not* explicitly given, but it is clear that Book X is preoccupied with simple apotomes, since all six kinds of apotome lines constructed in Propositions X.85-90, the only construction of apotome lines in Book X, are simple apotome lines.

Indeed, for the construction of the line in Propositions X.85-87, we let N be a non-square number, such that $N = q^2 - p^2$ (a method for finding such numbers is described in Lemma 1 in X.28/29), lines a, b such that $a^2 = Nb^2$, and construct the apotome line $qb - a$ (with respect to assumed line b in X.85, a in X.86, and r incommensurable to both a and b in X.87).

For the construction of the line in Propositions X.88-90, we let N be a non-square number, such that $N = q^2 + p^2$ (a method for finding such numbers is described in Lemma 2 in X.28/29), lines a, b such that $a^2 = Nb^2$, and construct the apotome line $a - qb$ (with respect to assumed line a in X.88, b in X.89, and r incommensurable to both a and b in X.90).

We will return in Sect. 9 to some more detailed remarks on the apotome lines in X.85-90.

It must be emphasized that the general definition of an apotome line (in X.73) allows for lines of the form $\zeta - \eta$, where $\zeta^2 = Nb^2$, $\eta^2 = Mb^2$, for some two (different)

non-square numbers N, M. Such an apotome line indeed appears in Proposition XIII.17 of the *Elements*: The side s of the face of the canonical 12hedron is the line $1/3(a - a')$, where $a^2 = 15d^2$, $a'^2 = 3d^2$, and d the diameter of the sphere in which the 12hedron is comprehended.

Thus Theaetetus in Book X is interested in the general apotome lines, so that a line such as the one arising in the study of the 12hedron will be included in the definition of apotome lines, and this appears to be the sole reason for adopting the general definition, but his central interest, as attested by all his explicit constructions in Book X, appears to be the *simple* apotome lines arising from the lines a, b, where $a^2 = Nb^2$, for some non-square number N.

5.1.3 All the Anthyphairetic Remainders of the Anthyphairesis of $a^2 = Nb^2$, for Some Non-square Number N, Are Simple Apotome Lines

The following proposition connects the concept of an apotome line with the study of the anthyphairesis of a to b wnen $a^2 = Nb^2$, and is the first serious indication that the concept is introduced in Book X precisely for the purpose of studying the quadratic antyphairesis.

Proposition If N is a non-square number, a, b lines such that $a^2 = Nb^2$, then every anthyphairetic remainder of the anthyphairesis of a to b is a simple apotome.

Notation. For two *incommensurable* (homogeneous) magnitudes a, b, with $a > b$, we denote the infinite *anthyphairesis* of a to b by

$$
\begin{aligned}
&a = I_0 b + \gamma_1, && \text{with } b > \gamma_1,\\
&b = I_1\gamma_1 + \gamma_2, && \text{with } \gamma_1 > \gamma_2,\\
&\gamma_1 = I_2\gamma_2 + \gamma_3, && \text{with } \gamma_2 > \gamma_3,\\
&\dots\\
&\gamma_n = I_{n+1}\gamma_{n+1} + \gamma_{n+2}, && \text{with } \gamma_{n+1} > \gamma_{n+2},\\
&\dots,
\end{aligned}
$$

the infinite sequence of successive *quotients* of the anthyphairesis of a to b by

$$I_0, I_1, I_2, I_3, \dots, I_{2n}, I_{2n+1}, \dots, \text{and}$$

the infinite sequence of successive *remainders* of the anthyphairesis of a to b by

$$a > b > \gamma_1 > \gamma_2 > \dots > \gamma_{2n} > \gamma_{2n+1} > \dots.$$

Definition *The generalized side-diameter numbers p_n, q_n*

$$
\begin{aligned}
&p_1 = 1, && q_1 = I_0,\\
&p_2 = I_1, && q_2 = I_1 I_0 + 1,\\
&\dots && \dots\\
&p_{2n-1} = I_{2n-2}\, p_{2n-2} + p_{2n-3}, && q_{2n-1} = I_{2n-2}\, q_{2n-2} + q_{2n-3},\\
&p_{2n} = I_{2n-1}\, p_{2n-1} + p_{2n-2}, && q_{2n} = I_{2n-1}\, q_{2n-1} + q_{2n-2},\\
&\dots && \dots
\end{aligned}
$$

Note. The (classical) side and diameter numbers are identified to the generalized side and diameter numbers of the anthyphairesis of the diagonal (diameter) to side of a square.

Indeed the anthyphairesis of diameter to side of a square is $I_0 = 1, I_1 = I_2 = I_3 = \ldots = 2$.

Then $p_1 = 1$, $q_1 = 1$, and,

by the recurrence relation of the generalized side-diameter numbers,

$$p_{n+2} = 2p_{n+1} + p_n, q_{n+2} = 2q_{n+1} + q_n.$$

We assume by induction, for the term n, that

$$p_{n+1} = p_n + q_n, q_{n+1} = 2p_n + q_n.$$

Then by the recurrence relations of the side-diameter numbers

$$\begin{aligned} p_{n+2} &= 2p_{n+1} + p_n = p_{n+1} + p_{n+1} + p_n = p_{n+1} + (p_n + q_n) + p_n \\ &= p_{n+1} + (p_n + q_n + p_n) = p_{n+1} + (2p_n + q_n) = p_{n+1} + q_{n+1}, \text{ and} \end{aligned}$$

$$\begin{aligned} q_{n+2} &= 2q_{n+1} + q_n = q_{n+1} + q_{n+1} + q_n = q_{n+1} + 2p_n + q_n + q_n \\ &= q_{n+1} + 2(p_n + q_n) = q_{n+1} + 2p_{n+1}, \end{aligned}$$

hence, for the next term $n + 1$, we have

$$p_{n+2} = p_{n+1} + q_{n+1},$$

$$q_{n+2} = 2p_{n+1} + q_{n+1}.$$

Note. A major difference at this stage between the classical side and diameter numbers and the generalized ones is that the recursive rule defining the generalized side and diameter numbers is far inferior to the classical rule, in that at the stage n they are defined in terms of the *previous two stages*, $n-1$ and $n-2$, and not just in terms of the immediately previous one $n-1$. The recursive relations analogous to the side and diameter numbers in terms of the previous stage only will be obtained in Sect. 5.6 below.

The generalized side and diameter numbers are useful in expressing the anthyphairetic remainders in terms of the initial magnitudes a and b.

Lemma ***(anthyphairetic remainders in terms of the generalized side and diameter numbers).*** For all $n = 1, 2, \ldots$

$$\gamma_{2n-1} = p_{2n-1}\, a - q_{2n-1}\, b$$

$$\gamma_{2n} = -p_{2n}\, a + q_{2n}\, b,$$

$$\ldots$$

Proof The proof is by induction.

$$\text{For } n = 1$$

By the anthyphairetic relation $a = I_0 b + \gamma_{1,}$ it follows

$$\gamma_1 = p_1 a - q_1 b, \text{hence}$$

$$p_1 = 1, q_1 = I_0.$$

By the anthyphairetic relation $b = I_1 \gamma_{\ 1} + \gamma_{2,}$ it follows

$$\gamma_2 = b - I_1 \gamma_1$$

$$= b - I_1 (a - I_0 b)$$

$$= -I_1 a + (1 + I_0 I_1) b, \text{hence}$$

$$\gamma_2 = -p_2 a + q_2\, b, \text{with } p_2 = I_1, q_2 = 1 + I_0 I_1.$$

Inductive step
If $n > 1$, assume that

$$\gamma_{2n-3} = p_{2n-3}\, a - q_{2n-3}\, b,\ \gamma_{2n-2} = -p_{2n-2}\, a + q_{2n-2}\, b,$$

then we need to see the same relations holding true for γ_{2n-1} and $\gamma_{2n.}$
By the anthyphairetic relation $\gamma_{2n-3} = I_{2n-2}\, \gamma_{2n-2} + \gamma_{2n-1}$ it follows

$$\gamma_{2n-1} = \gamma_{2n-3} - I_{2n-2}\, \gamma_{2n-2}$$

$$= (p_{2n-3}\, a - q_{2n-3}\, b) - I_{2n-2}\, (-p_{2n-2}\, a + q_{2n-2}\, b)$$

$$= (I_{2n-2}\, p_{2n-2} + p_{2n-3})\, a - (I_{2n-2}\, q_{2n-2} + q_{2n-3})\, b,$$

thus, by setting

$$p_{2n-1} = I_{2n-2}\, p_{2n-2} + p_{2n-3}, q_{2n-1} = I_{2n-2}\, q_{2n-2} + q_{2n-3},$$

we have that

$$\gamma_{2n-1} = p_{2n-1}\, a - q_{2n-1} b.$$

By the anthyphairetic relation $\gamma_{2n-2} = I_{2n-1}\, \gamma_{2n-1} + \gamma_{2n,}$ it follows

$$\gamma_{2n} = \gamma_{2n-2} - I_{2n-1}\, \gamma_{2n-1}$$

$$= (-p_{2n-2}\, a + q_{2n-2} b) - I_{2n-1}\, (p_{2n-1} a - \mathrm{q}_{2n-1} b)$$

$$= -(I_{2n-1}\, p_{2n-1} + p_{2n-2})\, a + (I_{2n-1}\, q_{2n-1} + q_{2n-2})\, b,$$

thus, by setting

$$p_{2n} = I_{2n-1}\, p_{2n-1} + p_{2n-2}, q_{2n} = I_{2n-1}\, q_{2n-1} + q_{2n-2},$$

we have that

$$\gamma_{2n} = -p_{2n}\, a + q_{2n}\, b.$$

Finally, the *uniqueness* of the generalized side and diameter numbers is a direct consequence of the incommensurability of a, b.

e.g., if $\gamma_{2n-1} = p_{2n-1}\, a - q_{2n-1}\, b = pa - qb$,
then $(p_{2n-1} - p)\, a = (q_{2n-1} - q)\, b$,
and if $p_{2n-1} - \mathrm{p} > 0$
then ($q_{2n-1} - q > 0$, thus) $a/b = (q_{2n-1} - q)/(p_{2n-1} - p)$,
in that case a, b would be commensurable magnitudes.

5.2 Binomial Lines and Their Conjugacy with the Apotome Lines

5.2.1 The Definition of Binomial Lines

Definition
Let r be an assumed line, ζ, η lines with $\zeta > \eta$, incommensurable, and such that ζ^2, η^2 are commensurable to r^2. Then (given in Proposition X.36 of the *Elements*) the line $\zeta + \eta$ is called *line of two names* ("ἐκ δύο ὀνομάτων"), or *binomial*.

The *greater part* of the apotome is the line ζ and the *smaller part* is the line η.

Propositions X.36–72 are exclusively about binomial lines, forming about one-third of Book X of the *Elements*.

X.36–41 is the hexad for binomial lines corresponding	to the hexad X.73–78,
X.42–47	to X.79–84,
X.47/48	to X.84/85,
X.48–53	to X.85–90,
X.54–59	to X.91–96,
X.60–65	to X.97–102 and
X.66–72	to the pentad X.103–107.

5.2.2 Simple Binomial Lines

The definition of a simple binomial line is entirely analogous to the definition of a simple apotome line, and will not be given explicitly. The constructions of binomial lines in Book X, X.48–53 are completely analogous to the ones for apotomes in X.85–90, and they produce simple binomial lines.

5.2.3 Question

Thus the binomial lines are exactly as important for Book X as the apotomes. We have found a connection of the apotomes with the remainders of the quadratic anthyphairesis a to b, for $a^2 = Nb^2$, N non-square number. The question then is: What is the role of the binomials in Book X?

5.2.4 The Role of the Binomial Lines in Book X as Conjugate to the Apotome Lines

The question on the role of the binomial lines is answered by the appearance, toward the end of Book X, of the three fundamental and truly miraculous Propositions X.112–114 on the *conjugacy* between the lines of two names and the apotomae lines.

Proposition X.112.
If r is a rational line, ζ is a line of two names, with names $\zeta_1 > \zeta_2$, and η is a line such that $\zeta \cdot \eta = r^2$, then η is an apotome with names $\eta_1 > \eta_2$, and $\zeta_1/\eta_1 = \zeta_2/\eta_2$ is a commensurable ratio.

Proposition X.113.
If r is a rational line, ζ is an apotome, with names $\zeta_1 > \zeta_2$, and η is a line such that $\zeta \cdot \eta = r^2$, then η is a line of two names with names $\eta_1 > \eta_2$, and $\zeta_1/\eta_1 = \zeta_2/\eta_2$ is a commensurable ratio.

Proposition X.113 *(Construction of conjugate to an apotome).*
Let BD $[\zeta]$ = BC − CD $[\zeta_1 - \zeta_2]$ be an *apotome* with assumed line A $[r]$, and
KH $[\eta]$ be a line with rectangle BD·KH $[(\zeta_1 - \zeta_2)\cdot\eta = r^2]$ equal to A^2.
Then KH is a *binomial* line KH = KF + FH $[\eta = \eta_1 + \eta_2]$, such that
the terms of KH are commensurable with the terms of BD and
in the same ratio (namely BC/KF=CD/FH $[\zeta_1/\eta_1 = \zeta_2/\eta_2 = \mu/\nu]$ commensurable), and
KH has the same order as BD.

(namely, if BD is an apotome line (of class 1,2,3, 4,5,6 wrt A,
then KH is a binomial line of class 1,2,3, 4,5,6, respectively, wrt A; and,
the side of a square equal to $BC^2 - CD^2$ is commensurable to BC
iff the side of a square equal to $KF^2 - FH^2$ is commensurable to KF.
The line KH is the *conjugate* to the apotome line BD.).

Proposition X.114.
If ζ is a line of two names, with names $\zeta_1 > \zeta_2$, η is an apotome with names $\eta_1 > \eta_2$, $\zeta_1/\eta_1 = \zeta_2/\eta_2$ is a commensurable ratio, and $\eta\cdot\zeta = r^2$,
then r is a rational line.

Note that

if $\gamma = qb - pa$ is a simple apotome wrt b, where N is a non-square number and $a^2 = Nb^2$, we set $\delta = qb + pa$, and note that $\gamma \cdot \delta = q^2b^2 - p^2a^2 = (q^2 - Np^2)b^2 = \lambda b^2$.

Set $\lambda\gamma^{-1} = qb + pa$.

Then $\gamma \cdot \gamma^{-1} = b^2$, namely the line γ^{-1} is the "inverse" to the apotome line γ. Informally we might think that $\gamma/b \cdot \gamma^{-1}/b = 1/1$, namely the ratio (essentially, the modern real number) γ^{-1}/b is the inverse of γ/b.

5.3 The Realization of the Importance of the Conjugacy Propositions of Book X in the Modern Era

5.3.1 The Insightful Connection of Bombelli of the Binomial Line with the Complex Number

Even before any careful examination of Book X, we are immediately stricken by the basic contents of the Book, no less than Bombelli was impressed in 1572. A. Weil (Weil 1984, p. 202) describes beautifully the connection:

> "The first concept, motivated by the work of the Italian algebraists of the sixteenth century on equations of degree 3 and 4, had been introduced by *Bombelli* in Book I of his Algebra of 1572, in close imitation of Euclid's theory of irrationals of the form $a + \sqrt{b}$ in his Book X ('*binomial*' in the terminology of Campanus' Latin translation of Euclid; accordingly, *binomio* is Bombelli's word for a complex number $a + \sqrt{-b}$). Further developments belong to the history of algebra and analysis rather than to number theory; suffice it to say that Euler played a decisive role in extending to complex numbers the main operations of analysis."

What impressed Bombelli in 1572 (Bombelli 1572) were the principal concepts of Book X, the apotome (introduced in X.73) and the binomial line (introduced in X.36), and their conjugacy in Propositions X.112–114, a conjugacy very similar to the relation between a complex number and its conjugate.

5.3.2 Euler Employed, for his Theory of Quadratic Continued Fractions, Conjugation of Quadratic Expressions Very Similar to the Theaetetus Conjugacy of Book X

The conjugation of quadratic expressions, very similar to the conjugacy of the apotome and binomial lines, has been used effectively for the examination of the continued fraction expansion of the square roots of non-square natural numbers by Euler (in the middle of the eighteenth century). Euler, in computing the continued fraction of, say, $\sqrt{54}$ formed the remainder/"apotome" $\sqrt{54}–7$, where $7 = m_1 =$ the integral part of $\sqrt{54}$. In order to proceed to the next step, he formed the conjugate "binomial" $\sqrt{54} + 7$, and applied the equivalent of X.113, to find $(\sqrt{54}–7) \cdot (\sqrt{54} + 7) = 5$. Thus the inverse of $\sqrt{54} + 7$ is $(\sqrt{54} + 7)/5$. The great advantage of conjugacy is that it allows for the trivial computation of both the next quotient I_1, the integral part of $(\sqrt{54} + 7)/5$, $I_1 = 2$, and the next remainder/"apotome" $(\sqrt{54} + 7)/5–2 = (\sqrt{54}–3)/5$.

But there is no evidence that Euler was in any way aware of Theaetetus conjugacy.

5.3.3 Heiberg's Failure to Realize the Importance of the Conjugacy Propositions

It is perhaps not surprising that the importance of the conjugacy Propositions of Book X has been lost by the erudite philologist and historian but nonmathematician Heiberg:

> Heiberg considers that this proposition and the succeeding ones are interpolated, though the interpolation must have taken place before Theon's time. His argument is that X.112-115 are nowhere used. (Heath 1908, 1926, p 246)

5.3.4 Weil's Disappointing Oversight to Realize Theaetetus' Motivation in Introducing the Conjugacy Propositions of Book X

Weil (Weil 1984, p 15) realizes the importance of the presence of conjugacy in Book X, but at the end dismisses the possibility that these conjugacies were used in the manner that they inspired Bombelli:

> "Not only is Euclid himself well aware of
> the relation $(\sqrt{r} + \sqrt{s})\,(\sqrt{r} - \sqrt{s}) = r - s$
> but even
> the identity $1/(\sqrt{s} + \sqrt{r}) = \sqrt{r}/(r - s) - \sqrt{s}/(r - s)$
> may be regarded as the essential content of prop. 112 of that book.
> *Unfortunately*, Euclid's motivation in Book X seems to have been
> the wish to construct a general framework for the theory of regular polygons and polyhedra, and *not*, as modern mathematicians would have it, an algebraic theory of quadratic fields.
> So we are left to speculate idly whether, in antiquity or later, identities involving square roots may not have been used, at least heuristically, in arithmetical work."

Knorr (Knorr 1983, p 60) provides further information on Weil's view. Knorr, after himself dismissing the role of Propositions X.112–114,

> "Certain potentials of the subject matter are entirely missed, for instance, insight into how products of the form $(a \pm b\sqrt{N})\,(c \pm d\sqrt{N})$ bear on the finding of solutions to integral relations of the form $x^2 - Ny^2 = \pm m$";

he then confirms Weil's view at footnote (Knorr 1983, p 66, fn. 53):

> "At the time of his course of lectures on the history of the Pell equation (Institute for Advanced Study, 1978–79), Professor A. Weil expressed to me his disappointment over Euclid's *utter failure* to perceive this potentially fruitful development of the theory of Book X."

The intimate connection of Plato's philosophy with periodic anthyphairesis, including the theorems proved by Theaetetus, has been partially presented in Sects. 3 and 4 above, but, as we shall see in the next Sect. 6, Plato was so deeply impressed by *the palindromic periodicity of quadratic anthyphairesis* established by Theaetetus that he made palindromic periodicity the dominant theme in the *Politicus*.

It seems to us clear that Weil's disappointing oversight to realize the true role of the conjugation of the lines of apotome and binomial lines in the Theaetetean Book X of the *Elements* was the result of a lack of a deeper understanding on his part of the intimate connection of Plato's philosophy with periodic anthyphairesis, and of the deep influence that Theaetetus exercised on Plato's later philosophy (especially on the trilogy *Theaetetus-Sophistes-Politicus* and the *Philebus*). This oversight is

especially disappointing since Weil was in fact steeped in Greek Mathematics and Plato's philosophy.

5.4 The Role of the Assumed Line ("προτεθείσα," "ἐκκειμένη") of Apotome and the Binomial Lines

Before proceeding with the reconstruction of the proof of Theaetetus' weak periodicity theorem we make a simple remark on the role of the *assumed line*.

For the same apotome line γ, say $\gamma = pa - qb$ or $\gamma = qb - pa$, the external classification of apotome lines (X.84/85) distinguishes three cases: The assumed line is either (commensurable to) a, or (commensurable to) b, or some other line c incommensurable to a and to b but commensurable to them in square and thus rational.

It is clear that the *internal* structure of an apotome line is not affected at all by the choice of the assumed line. Why then is there a need for the assumed line? Its role can only be *external*, i.e., in the compatibility of the apotome line with other apotome or binomial lines, for the purpose of performing simple algebraic or geometric operations. Thus we compose a line with its conjugate, or square a line, or take the square root of a line, or take a commensurable "perturbation" of the line, only if we have lines with the same assumed line. In fact, these operations are all applications of Proposition I.44–45 and the assumed line takes the role of the "fourth" proportional.

We consider further the role of the assumed line in Sect. 9 as well.

5.5 The Transformation of the Anthyphairetic Relations of a to b for $a^2 = Nb^2$ for Some Non-Square Number to Conjugation Relations

Once we have established

(a) That Plato states unequivocally that Theaetetus has proved the quadratic periodicity theorem (and imitates in the *Politicus* the stronger palindromic one, as we shall see in Sect. 6)
(b) That the theory of the apotome and binomial lines and their conjugacy, the ideal tools for proving the quadratic (palindromic) periodicity theorem, is fully developed in Book X,

then the reconstruction of the proof of quadratic periodicity theorem is *one way*, essentially obligatory, consisting of the natural transformation of the anthyphairetic relations into conjugate relations. This is precisely the content of the next.

Theorem (Theaetetus) (The transformation of the anthyphairetic relations of a to b for $a^2 = Nb^2$ for some non-square number to conjugation relations).

Let N be a non-square number, a, b lines with $a^2 = Nb^2$, and let the anthyphairesis of a to b be denoted as follows.

$a = I_0 b + \gamma_1$, with $b > \gamma_1$,
$b = I_1\gamma_1 + \gamma_2$, with $\gamma_1 > \gamma_2$,
$\gamma_1 = I_2\gamma_2 + \gamma_3$, with $\gamma_2 > \gamma_3$,
...
$\gamma_n = I_{n+1}\gamma_{n+1} + \gamma_{n+2}$, with $\gamma_{n+1} > \gamma_{n+2}$,
...

Then there are natural numbers
m_n, with $m_1 =$ the unique number such that ${m_1}^2 < N < (m_1 + 1)^2$, namely I_0 and λ_n, with $\lambda_1 = 1$, such that setting

$$\varphi_n = (a - m_n b)/\lambda_n, N - {m_n}^2 = \lambda_n\lambda_{n+1}, m_{n+1} = \lambda_{n+1}I_n - m_n,$$

we have

$$b^2 = \varphi_n\left(I_n b + \varphi_{n+1}\right), \text{ the conjugacy relations, and}$$

$$\gamma_1 = \varphi_1, \text{and } \gamma_n\varphi_{n+1} = \gamma_{n+1}b, \text{for } n = 1, 2, \ldots.$$

Proof *Step 1* (*The transformation of the second anthyphairetic relation into a conjugation relation*).

The *first anthyphairetic relation* is then

$$a = m_1 b + \gamma_1, \text{with } \gamma_1 < b.$$

$\gamma_1 = a - m_1 b$, an apotome; set $\varphi_1 = \gamma_1$. Set $\lambda_2 = N - {m_1}^2$.

(a) Setting φ_2 by $\gamma_2 b = \gamma_1\varphi_2$, we find that $b^2 = \varphi_1(I_1 b + \varphi_2)$, and $\lambda_2 I_1 > m_1$
(b) Setting $m_2 = \lambda_2 I_1 - m_1$, we find that $\varphi_2 = (a - m_2 b)/\lambda_2$
(c) Setting $\lambda_3 = 1 + I_1(m_1 - m_2)$, we find that $N - {m_2}^2 = \lambda_2\lambda_3$

Proof of Step 1:

(a) The second anthyphairetic relation is $b = I_1\gamma_1 + \gamma_2$.
We want to transform this anthyphairetic relation into a conjugation relation.
From it we obtain $b^2 = \gamma_1 I_1 b + \gamma_2 b$.
In order to factor $\gamma_1 = \varphi_1$ we employ Propositions I.44–45 to construct a line φ_2, such that

$$\gamma_2 b = \gamma_1\varphi_2;$$

indeed we then have

$$b^2 = \gamma_1 I_1 b + \gamma_1 \varphi_2 = \varphi_1 (I_1 b + \varphi_2).$$

This transformed anthyphairetic relation is now a conjugation relation, allowing for the use of X.113.

Since $\varphi_1 = a - m_1 b$, the line $a + mb$ is a binomial line, an N-binomial, and

$$\varphi_1 \cdot (a + m_1 b) = a^2 - {m_1}^2 b^2 = Nb^2 - {m_1}^2 b^2.$$

Set $N - {m_1}^2 = \lambda_2$.
Hence $I_1 b + \varphi_2 = (a + m_1 b)/\lambda_2$, hence $\lambda_2 \varphi_2 + \lambda_2 I_1 b = a + m_1 b = S_2$.
Note that $a > m_1 b$ and $\lambda_2 I_1 b > \lambda_2 \varphi_2$;
since $\gamma_2 b = \gamma_1 \varphi_2$ and $\gamma_1 > \gamma_2$, hence $b > \varphi_2$;
thus $\lambda_2 I_1 b > S_2/2 > m_1 b$, hence $\lambda_2 I_1 > m_1$.

(b) We set

$$m_2 = \lambda_2 I_1 - m_1.$$

We find immediately that

$$\varphi_2 = (a - m_2 b)/\lambda_2,$$

a fractional N-apotome.

(c) We note that $N - {m_2}^2 = (N - {m_1}^2) + ({m_1}^2 - {m_2}^2) = \lambda_2 + (m_1 - m_2) \cdot (m_1 + m_2) =$
$= \lambda_2 + (m_1 - m_2) \cdot \lambda_2 I_1 = \lambda_2 (1 + I_1 (m_1 - m_2)) = \lambda_2 \lambda_3$.

Step 2 (*The transformation of the third anthyphairetic relation into a conjugation relation*).

(a) Setting φ_3 by $\gamma_3 b = \gamma_2 \varphi_3$, we find that $b > \varphi_3$, $b^2 = \varphi_2 (I_2 b + \varphi_3)$, and $\lambda_3 I_2 > m_2$
(b) Setting $m_3 = \lambda_3 I_2 - m_2$, we find that $\varphi_3 = (a - m_3 b)/\lambda_3$
(c) Setting $\lambda_4 = \lambda_2 + I_2 (m_2 - m_3)$, we find that $N - {m_3}^2 = \lambda_3 \lambda_4$

Proof of Step 2:

(a) We transform the third anthyphairetic relation $\gamma_1 = I_2 \gamma_2 + \gamma_3$ into a conjugation relation.
From it we obtain $\gamma_1 b = I_2 \gamma_2 b + \gamma_3 b$.
In order to factor γ_2 we employ Propositions I.44–45 to construct a line φ_3, such that

$$\gamma_3 b = \gamma_2 \varphi_3;$$

we then have

$$b > \varphi_3 \text{ and}$$

$$\gamma_1 b = I_2\gamma_2 b + \gamma_2\varphi_3 = \gamma_2(I_2 b + \varphi_3).$$

From it we obtain $\gamma_1 b^2 = \gamma_2 b(I_2 b + \varphi_3)$.
Recalling that $\gamma_2 b = \gamma_1\varphi_2$, we have $\gamma_1 b^2 = \gamma_2 b(I_2 b + \varphi_3) = \gamma_1\varphi_2(I_2 b + \varphi_3)$, hence

$$b^2 = \varphi_2(I_2 b + \varphi_3).$$

This transformed anthyphairetic relation is now a conjugation relation, allowing for the use of X.113.
Since $\varphi_2 = (a - m_2 b)/\lambda_2$, then

$$\varphi_2\cdot(a + m_2 b) = \left(a^2 - {m_2}^2 b^2\right)/\lambda_2 = \left(Nb^2 - {m_2}^2 b^2\right)/\lambda_2 = \left(N - {m_2}^2\right)b^2/\lambda_2$$
$$= \lambda_2\lambda_3 b^2/\lambda_2 = \lambda_3 b^2.$$

Hence $I_2 b + \varphi_3 = (a + m_2 b)/\lambda_3$, hence $\lambda_3\varphi_3 + \lambda_3 I_2 b = a + m_2 b = S_3$.
Note that $a > m_2 b$ and $\lambda_3 I_2 b > \lambda_3\varphi_3$, since $\gamma_3 b = \gamma_2\varphi_3$ and $\gamma_2 > \gamma_3$, hence $b > \varphi_3$; thus $\lambda_3 I_2 b > S_3/2 > m_2 b$, hence $\lambda_3 I_2 > m_2$.

(b) We set

$$m_3 = \lambda_3 I_2 - m_2.$$

We find immediately that

$$\varphi_3 = (a - m_3 b)/\lambda_3,$$

a fractional *N*-apotome.

(c) We note that $N - {m_3}^2 = (N - {m_2}^2) + ({m_2}^2 - {m_3}^2) = \lambda_2\lambda_3 + (m_2 - m_3)\cdot(m_2 + m_3) =$
$=\lambda_2\lambda_3 + (m_2 - m_3)\cdot\lambda_3 I_2 = \lambda_3(\lambda_2 + I_2(m_2 - m_3)) = \lambda_3\lambda_4.$

General step (*the transformation of the general anthyphairetic relation into a conjugation relation*).
We assume that for some natural number n, line φ_n, and natural numbers m_n, λ_n, λ_{n+1} have been defined, such that

$$\varphi_n = (a - m_n b)/\lambda_n, N - {m_n}^2 = \lambda_n\lambda_{n+1}.\text{Then}$$

(a) setting φ_{n+1} by $\gamma_{n+1}\, b = \gamma_n\varphi_{n+1}$,
we find that $b > \varphi_{n+1}$, $b^2 = \varphi_n(I_n b + \varphi_{n+1})$, and $\lambda_{n+1} I_n > m_n$

(b) setting $m_{n+1} = \lambda_{n+1} I_n - m_n$,
we find that $\varphi_{n+1} = (a - m_{n+1} b)/\lambda_{n+1}$; and,
(c) setting $\lambda_{n+2} = \lambda_n + I_n(m_n - m_{n+1})$,
we find that $N - {m_{n+1}}^2 = \lambda_{n+1}\lambda_{n+2}$.

The *Proof* is entirely analogous to the proof of Step 2, shown just above. The details are omitted.

Note. The transformation of the anthyphairetic relations into conjugacy relations is realized with the introduction of the "reduced apotomes" φ_n.

As mentioned already, the introduction of these reduced apotomes provide a one-way, essentially obligatory, transition from the anthyphairetic relations to the conjugacy relations, so that Theaetetus' conjugacy theory can be applied.

It should be pointed out that the definition of φ_{n+1}, via the equality $\gamma_{n+1} b = \gamma_n \varphi_{n+1}$, an elementary application of Proposition I.44 of the *Elements*, does not appear explicitly in Book X; and that the reduced apotomes play a basic role in the proof of the palindromic periodicity theorem in Sect. 7 and in the proof of the general Pell property in Sect. 9 below. It is, however, quite remarkable that, as we shall see in Sect. 10, the reduced apotomes make their unmistakable reappearance in the *cakravala* method of dealing with the Pell problem by the Hindu mathematician Bhaskara II.

5.6 The Recursive Definition of Generalized Side and Diameter Numbers

Proposition $(-1)^n (q_n b - p_n a)((a - m_{n+1} b)/\lambda_{n+1}) = (-1)^{n+1}(q_{n+1} b - p_{n+1} a) b$,
$\lambda_{n+1} q_{n+1} = m_{n+1} q_n + N p_n$,
$\lambda_{n+1} p_{n+1} = q_n + m_{n+1} p_n$.

These are the general recursive formulas really analogous to the recursive formulae for the side and diameter numbers for $N = 2$, in the sense that the recursion is not from the previous two steps, but only from the previous one.

5.7 The Proof of the Weak Theaetetus' Periodicity Theorem: The Anthyphairesis of *a* to *b* for $a^2 = Nb^2$ for Non-Square Number *N* is Periodic

From Theorem 4.5 just proved, and from the fact that the set of pairs (λ, m) of natural numbers, with λ bounded above by N and m by m_1, is finite, it follows, by an application of *the pigeonhole principle*, that there are indices k and s, with $k < s$, such that $\varphi_k = \varphi_s$. The equality $\varphi_k = \varphi_s$ clearly implies the equality $\gamma_k/\gamma_{k+1} = \gamma_s/\gamma_{s+1}$, and this is exactly the Logos Criterion for eventual periodicity of the anthyphairesis.

Note. It would be highly desirable, but there is no trace of the combinatorial pigeonhole argument to be found in Book X; however, a more careful application of the pigeonhole argument for the proof of a stronger Theaetetus theorem on

palindromic periodicity can be clearly associated with a passage in Plato's *Politicus*, as we shall see in Sects. 6 and 7 below.

6 The Definition of the Intelligible Being "the Statesman" in the *Politicus* Is a Philosophical Imitation of the Strong Theaetetus' Palindromic Periodicity Theorem

The third dialogue in the trilogy on Plato's theory of knowledge is the *Politicus*. The express purpose of the dialogue is the definition of the art of statesmanship by the method "Name and Logos," equivalently "Division and Collection," involving steps with binary division and the Logos Criterion, in agreement with the method employed in the *Sophistes*. We have seen in Sect. 3 that in the *Sophistes* an intelligible Being, like the Angler or the Sophist, becomes fully known by the definition of an Art, the Art of angling or the Art of sophistry, respectively, employing the method of Division and Collection, equivalently of "Name and Logos," which we interpreted as a philosophical analogue of periodic anthyphairesis.

6.1 The First Ten Steps of the Division and Collection (258b-267c)

The aim of the *Politicus* is to obtain the knowledge ("ἐπιστήμη") of the intelligible Being the Statesman, by the method of Division and Collection, the method employed in the *Sophistes*. In the first part of the dialogue, 258b-267c, the first ten steps of the Division are obtained. The initial genus G of all arts is successively divided in the binary manner familiar from the *Sophistes*. It is clear that the same interpretation of the Division as philosophical analogue of periodic anthyphairesis holds here as well.

Thus,

G divided into [practical B_1, scientific ("γνωστική") A_1], (258b-259d)

A_1 divided into [appraise, determine ("κρίνειν") B_2, command A_2], (259d-260c)

A_2 divided into [someone else's commands B_3, one's own commands A_3], (260c-261b)

A_3 divided into [lifeless herd B_4, herd of living beings (=animals) A_4], (261b-d)

A_4 divided into [herd of a single animal ("μονοτροφίαν") B_5, herd of many animals A_5], (261d-e)

A_5 divided into [herd of aquatic animals B_6, herd of land animals A_6], (264b-d)

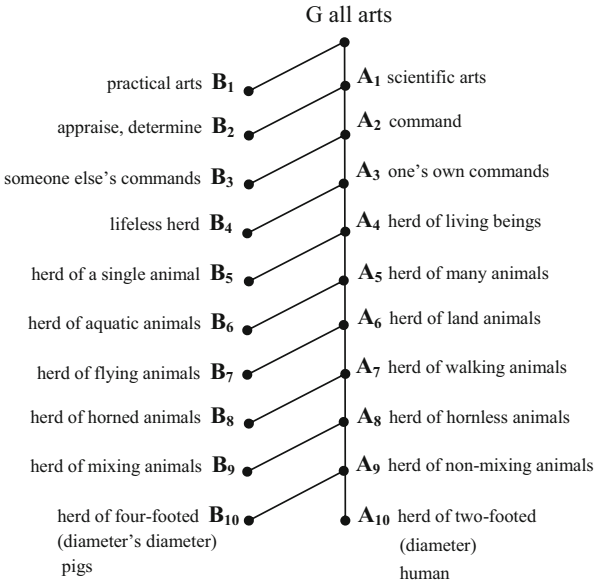
A_6 divided into [herd of flying animals B_7, herd of walking animals A_7], (264e-265b)

A_7 divided into [herd of horned animals B_8, herd of hornless animals A_8], (265b-d)

A_8 divided into [herd of mixing animals B_9, herd of nonmixing animals A_9], (265d-e)

A_9 divided into [herd of four-footed (diameter's diameter) pigs B_{10}, herd of two-footed (diameter) (human) A_{10}], (265e-266d).

Here is the figure summarizing these ten initial steps of the Division.



Note that after A_4 we are dealing with

the arts of feeding an animal herd ("ἀγελαιοτροφικὴ," 261b-d);

what is really being divided is the nature of the herd, narrowing it down, by successive binary division and exclusion, till we get to

the arts of commanding a human herd (A_{10}, 265e-266d).

6.2 The Need to Continue the Division (267c-268d and 274e-277c)

The division steps described in Sect. 6.1 is by no means the end of our quest for the definition of the Statesman, as one might think. This is so because A_{10} consists of the arts of commanding a human herd but we are interested to define the statesmanship, namely the optimal art of commanding a human herd.

This means that there is still ahead of us a second process of successive binary divisions, in all of which the herd is now fixed as the human herd, and what is being successively narrowed down, by binary division and exclusion, is the nature of commanding this human herd ("ἀγελαιοκομικὴ," 275e), till we get to the optimal commanding.

6.3 The Myth of Palindromic Periodicity with Kronos Era and Zeus Era (268d-274e)

According to this myth 268d-274e, there are two eras in the world, the Kronos era and the Zeus era.

The world, to be thought of as a spherical entity, rotates in a certain direction during the Kronos era. After a long time, when all the possible stages of the Kronos era are exhausted ("τὸ γήινον ἤδη πᾶν ἀνήλωτο γένος" "πάσας τὰς γενέσεις ἀποδεδωκυίας"), it is necessary to reverse the direction ("πάλιν ἀνέστρεφεν") and to go from the Kronos era to the Zeus era (272d6-e6).

When the Zeus era is in danger of losing its direction and God perceives that it is in trouble, and that "it might founder in the tempest of confusion and sink in the infinite sea of dissimilarity ("κηδόμενος ἵνα μὴ χειμασθεὶς ὑπὸ ταραχῆς διαλυθεὶς εἰς τὸν τῆς ἀνομοιότητος ἄπειρον ὄντα πόντον"), he … reversed ("στρέψας") whatever had become unsound and unsettled in the previous period when the world was left to itself, set the world in order, restored it and made it immortal ("ἀθάνατον") and ageless ("ἀγήρων")," thus returning (273c4-e4). In this way, we are back again to the Kronos period and completing a full period. The change from the Zeus era to the Kronos era is in order to avoid the bad, nonperiodic infinite, something achieved by the Logos Criterion.

The world moves forever repeating this period, alternating the Kronos era with the Zeus era.

The relation of the two eras is especially interesting. It is schematically described as follows: In the Zeus era (in which era we are presently) men come from nonexistence (a) into existence (b), then they grow (c), then they get a beard (d), then their beard becomes white (e), then they grow old and are about to die (f). If at this time the world happens to switch to the Kronos era, then the human will go from stage (f) to (e) then to (d) then to (c) then to (b) and then they pass into nonexistence (a) (270d-271a).

Summarizing, according to the myth, the world is periodic, and the period consists of two half periods, the Kronos era followed by the Zeus era, in other words it is palindromically periodic.

6.4 The Division for the Statesman Must Be Continued According to the Myth of Palindromic Periodicity (276a1-7)

The first ten division steps of the definition of the Statesman, corresponding to the Kronos era, must be completed with the last ten division steps of the Zeus era, in **palindromic** to the Kronos era manner, with **Logos circularly** comprehending both of them (276a). Thus every Division and Collection has palindromically periodic (and thus infinite) form.

The passage 276a1-7 below is crucial for our interpretation of the *Politicus*, because in this passage Plato makes perfectly clear that *the palindromic periodicity of the myth must be applied for the Division and Collection of the Statesman*. The passage 276a1-7 is the following:

		Younger Socrates:. . .but *how (τίνα τρόπου)* would *the next division (ἡ μετὰ τοῦτο διαίρεσις)* be made? Stranger: *In the same kinds (κατὰ ταὐτὰ)*
as (καθ' ἅπερ) we divided (διηρούμεθα) before (ἔμπροσθεν) the art of *feeding herds* in		
	those that go on foot [A_7]	
and the winged, [B_7]		
	and the unmixed breeds [A_9]	
	and the hornless, [A_8]	
		we must *divide* *the art of tending herds* *in arts similar to (τοῖς αὐτοῖς)*
those (τούτοις),		
comprehending (περιειληφότες) in the logos (ἐν τῷ λόγῳ) both (ὁμοίως)		
		the present [Zeus] era (τὴν ἀγελαιοκομικὴν τήν τε νῦν)
and *the Kronos era.* *(καὶ τὴν ἐπὶ Κρόνου βασιλείαν)*		

We may describe the application of the myth of the two eras as describing in symbolic and philosophical manner the palindromic periodicity of the definition of the Statesman, an imitation by Plato of the Theaetetus' palindromically periodic quadratic anthyphairesis:

	The second half of the division (*ἀγελαιοκομική*, where the commanded herd is the human herd, held fixed, and the nature of the commanding herdsman is the variable) corresponds to the **Zeus** era,
while the first half (*ἀγελαιοτροφική*, where the nature of the commanded herd is the variable) corresponds to the **Kronos** era,	
in the myth of the two eras (Sect. 6.3). Thus (276a) is precisely the point in the *Politicus*, where the method of Division and Collection, namely the method of philosophical periodic anthyphairesis, is explicitly connected to *palindromicity*, since	
the Kronos era	
	and the Zeus era

(continued)

<table>
<tr><td colspan="2">are in palindromic relation in the myth of world ‘aneilixis’.</td></tr>
<tr><td>In this passage
the first half of the process,

A'_{10} divided into B'_9, A'_9,
. . .,
A'_2 divided into B'_1, A'_1,
corresponding to
the Zeus era,
palindromic to</td></tr>
<tr><td>the Kronos era</td><td></td></tr>
<tr><td colspan="2">the whole comprising a full period, cycle,
achieved by the Logos Criterion $B''_1/A''_1 = B_1/A_1$.</td></tr>
</table>

(There are also the many steps A_{11}, A_{12},. . ., . . ., A'_{12}, A'_{11} which are not examined in detail, but are given collectively in groups, in the form of **“contingent causes”** (287b-289a). We will not be concerned with this part of the definition of the Statesman, as it is of no importance for our reconstruction.

This is the place to be reminded of that *all descriptions* of the method of (Division and) Collection in the Platonic dialogues exhibit *the cyclical, periodic nature* of the method (as noted in Sect. 3 above). In particular, the Platonic Division and Collection is not like the Aristotelian division into a genus and differentia, clearly a strictly finite division, but, having a periodic form, is an infinite division. In accordance with the Divisions and Collections of the *Sophistes*, this cycle must be realized by the *Logos Criterion*. This takes the following form:

The last genus of the Zeus era, denoted A'_1, will be divided into

the art of the strategy B''_1 and of the statesmanship A''_1,
for which the *Logos Criterion* indeed holds $B''_1/A''_1 = B_1/A_1$.

The new element in the *Politicus* Division and Collection, introduced in Sects. 6.3 and 6.4, in relation to the *Sophistes*, is not only periodicity, as in the *Sophistes*, but in addition the presence of *palindromicity within the period*; in other words we expect that the anthyphairesis will have a period, but one presenting a symmetry with respect to the middle of the period. In the language suggested by the myth of Sect. 6.3, the division

steps within the period will be divided into two parts, the first half to be the Kronos era, and the second half the Zeus era. We then expect that the definition of the Statesman must exhibit the palindromicity of these two eras. We show in Sects. 6.5 and 6.6 below that this is precisely the plan suggested and realized by Plato for defining the Statesman.

6.5 The Last Ten Division Steps and the Logos Criterion for the Statesman (267c-268d and 274e-277c, 289e-305e)

The last ten steps $A'_{10},\ldots,A'_1$ in the Zeus era and the Logos Criterion in the definition of the Statesman are described in 289e-305e.

6.5.1 The Game (277e)

Plato has no intention to give the Zeus steps explicitly and in succession, so these steps are not given in their correct order, in which they appear in the definition of the Statesman, but in the form of a *game*, reminding of a grammatical children's game, as explicitly stated in 277e. To find the right order and the Logos Criterion and thus complete the definition of the Statesman is going to be our task.

6.5.2 The Rules of the Game

However, Plato sets precise rules which enable us to complete this definition.

Rule 1. There is a *one to one correspondence between the already defined genera* B_j *and the palindromically analogous to them genera* B'_j *to be defined for* $j = 1, 2,\ldots,10$ *(276a, 277e-279a)*

To every division step (B_j, A_j) of the Kronos era, namely of "agelaiotrophike," where some type of herd B_j, governed and led, is *rejected,*

there is a unique division step (B'_j, A'_j) of the Zeus era, namely of "agelaiokomike," where some "similar" type of governing and leadership B'_j of the human herd is rejected, for $j = 1,..,10$.

The "positive" genera A'_j are *not given*, but the method of Division and Collection implies that in principle each A'_j is uniquely defined, as relative complement of B'_j in A'_{j+1}.

Rule 2. Ordering of government systems (291c-303b)

There are six types of conventional government, namely
government (I) by one, or by few, or by many, and
government (II) with laws, or without laws,
in every possible combination in each of the two criteria (I) and (II).
Thus
Tyranny is government by one, without laws,
Oligarchy by few without laws,
Anarchy by many without laws,
Democracy by many with laws,
Aristocracy by few with laws, and
Monarchy by one with laws.

(Plato does not use the term Anarchy for the government by many without laws in the *Politicus*, but he does use the term elsewhere, e.g., in the *Laws* 942a-d).

There is a quite long discussion on these types of government in the *Politicus* 291c-303b with the following conclusions:

(2a) There is an ordering of these six types of government as follows:
All six known types of government, all governments without true knowledge, will be eventually rejected; of them the worst is Tyranny (government by one, without laws), then Oligarchy (government by few, without laws), then Anarchy/ Democracy without laws, and then, in reverse /palindromic order, government with laws: first Democracy, then Aristocracy, then Monarchy.

This ordering is so, because

(i) in the absence of government by knowledge, it is better to have laws, than to be governed without laws, and

(ii) (without laws the many govern better than the few and the few better than the one, while in the presence of laws the situation is precisely the reverse.

(2b) All these conventional types of government are to be rejected, because they are not based on true knowledge. Hence each of them (possibly more than one at a time) will be rejected at some A′j.

(2c) All types of government with laws are to be rejected because laws, and in fact everything written, is *lifeless*, as opposed to true knowledge, which has life and soul. This is strongly supported by Plato's similar rejection, in the final part of the *Phaedrus* 274c5-277a5, of the written word, in general, as an image and as not truly alive.

Rule 3. Ordering of the genera B'_j to be rejected (303d-e)

In the Zeus era, a relatively better type of government will *be rejected later,* namely will appear as B'_j, with smaller index j, while a relatively worse type of government will appear as B'_k with greater index k.

Rule 4. The three arts to be rejected last (303e-305e)

The arts of judgeship, rhetoric, and strategy are the relatively highest arts of government, and are thus the last three to be rejected; they will then be the genera B'_2, B'_1, B''_1, respectively.

6.5.3 The Search for the Ten Palindromic Correspondences

We now apply the Rules set by Plato in order to find out the palindromic nature of the Division for the Statesman.

[*Division step rejecting* $\mathbf{B'_4}$ *palindromic to* $\mathbf{B_4}$]

This is definitely the most interesting palindromic correspondence. In a famous passage in the *Phaidrus* 274c-277a Plato argues against the written word, as lifeless. Evidently it is for this reason that Plato introduces the highly artificial division step into herds of living entities and lifeless herds B_4. We realize that this is done precisely in order to reject as its palindromical analogue all governments that are based not on true intelligible knowledge, but on written laws.

	at $\mathbf{B'_4}$ every government with written laws (including Democracy D, Aristocracy Ar, Monarchy M) must be rejected as being, according to *Phaidrus* 274c5-277a5, *lifeless* government, in *palindromic* fashion to
the rejection at $\mathbf{B_4}$ of the *lifeless herds*	

[*Division step rejecting* $\mathbf{B'_3}$, $\mathbf{B'_6}$, $\mathbf{B'_7}$ *palindromic to* $\mathbf{B_3}$, $\mathbf{B_6}$, $\mathbf{B_7}$, respectively]
It is fairly clear by Rule 1 that

	at $\mathbf{B'7}$ the heralds, whose patron god Hermes, the herald of the Gods, is flying, are to be rejected as governors (290a-c) in *palindromic* fashion to
the rejection at $\mathbf{B_7}$, of the herds of flying animals;	

	at $\mathbf{B'_6}$ *the merchants and shipmasters* are rejected as governors (289e-290a), in *palindromic* fashion to
the rejection at $\mathbf{B_6}$, of *the herds of aquatic animals*; and	

	at $\mathbf{B'_3}$ *the priests and diviners* are to be rejected as governors (290c-291a) in *palindromic* fashion to
the rejection at $\mathbf{B_3}$	

[*Division step rejecting* $\mathbf{B'_{10}}$ *palindromic to* $\mathbf{B_{10}}$]

Some argument is needed to convince us that the rejection of the sophists as governors in 291b-c, and again in 303b-c (of the sophists' sophists, this second time to be exact), is palindromically related to the rejection of the pigs as herd at B_{10} (265e-266c). Here Plato is multiply playful: In the first place the distinction of the pig from human is that it is four-footed; this is playfully described, in geometric language, as "diameter's diameter." We observe that the queer expression *"diameter's diameter"* has some similarity of form with the equally queer expression *"sophists' sophists."*

But we would be rather at a loss to find any more significant association; unless we note that while a true dialectician is preoccupied with "the diameter itself" (*Politeia* 510d5-511a1), a partless Being, it is the *sophists* who, according to *Meno* 85b4, call *"diameter"* the straight line that joins one edge of a square with its opposite edge, a divisible magnitude. The meaning of this distinction is possibly the following: Sophists occupy themselves with magnitudes and in general with

sensibles, while the dialectician occupies himself with the idea of the diameter, something that is rather the logos of the diameter to the side of a square. In any case the *Meno* suggests that there is a connection between the diameter and the sophists; hence there is also indeed a connection between "*diameter's diameter"* the four-footed pig and "*sophists' sophists,"* hinting of course that the worst sophists are like pigs. We are clearly ready, granted a certain playfulness, to accept that, by Rule 1,

	the sophists' sophists, rejected as governors at $\mathbf{B'_{10}}$, is palindromically related with
the herd of pigs, described playfully as "diameter's diameter," rejected at $\mathbf{B_{10}}$	

[*Division step rejecting* $\mathbf{B'_8}$, $\mathbf{B'_9}$ *palindromic to* $\mathbf{B_8}$, $\mathbf{B_9}$, respectively]

It follows necessarily, by the rules 2 and 3, that the two types of conventional government without laws, namely the lowest Tyranny and next lowest Oligarchy must be associated with the two lowest remaining free positions in the Zeus era, namely B'_9, B'_8, respectively. It becomes immediately clear why Plato likens twice (in 291a-b, 303c-d) the worse classes of conventional politicians with Centaurs, creatures of mixed breed, and Satyrs, horned creatures! Thus

	at $\mathbf{B'_9}$ the *Tyrants,* likened to *Centaurs*, creatures of mixed breed, must be rejected, as palindromically related to
herds of *animals with mixed breed* already rejected at $\mathbf{B_9}$, and	
	at $\mathbf{B'_8}$ the Oligarchs, likened to Satyrs, horned creatures, must be rejected, as palindromically related to
herds of horned animals already rejected at **B8**	

[*Division step rejecting* $\mathbf{B'_5}$ *palindromic to* $\mathbf{B_5}$]

It is not immediately obvious from the *Politicus* why Democracy without laws, Anarchy, should be palindromic to the rejected herd at B_5, and thus be placed in the position of the rejected part in B'_5. However, this is well explained in the *Nomoi* (Laws) (Plato 1967 & 1968):

	Democracy without laws at B'_5 identical with the Anarchy described in the *Nomoi* 942a5-d2, as "κατὰ μόνας δρᾶν," i.e., as a government where each person acts singly, is palindromically related to

(continued)

the rejected herd at B_5, described as "μονοτροφία," i.e., as herd consisting of a single animal	

[*Division step rejecting* $\mathbf{B'_2}$, $\mathbf{B'_1}$ *palindromic to* $\mathbf{B_2}$, $\mathbf{B_1}$, respectively]

We are left with the arts of judging, rhetoric, and strategy, for which Plato sets Rule 4, that they will be rejected last (303e-305e). Of them

	at $\mathbf{B'_2}$ *the Judges* are rejected as governors (305b-c) in *palindromic* fashion to
the rejection at $\mathbf{B_2}$, of *the art of* "κρίνειν"(260a-c)	

	at $\mathbf{B'_1}$ *the Rhetoricians* are rejected as governors (304c-e) in *palindromic* fashion to
the rejection at $\mathbf{B_1}$, of *the* practical *arts*	

This completes the quest for the palindromic correspondences between the first ten steps of the Kronos era with the last ten steps of the Zeus era. The art of strategy is still not rejected. It is left to be rejected at the last step when the Logos Criterion must be formed.

6.6 Logos in the Division and Collection of the Statesman

The very last division is the division of A'_1 into the practical art of the strategy B''_1 and the gnostical art of the statesman A''_1 (304e-305a).

The Logos Criterion consists in equating

the initial logos:

practical arts B_1/ scientific arts A_1

with

the final logos:

the practical art of strategy B''_1/the scientific art of statesmanship A''_1.

Thus $B_1/A_1 = B''_1/A''_1$, and periodicity is insured.

6.7 The Definition of the Statesman as a Philosophical Palindromically Periodic Anthyphairesis (*Politicus* 258c-267c, 289e-305e)

We are now ready to collect all the pieces of the Division and Collection of the Statesman. The following figure incorporates the information needed for the definition of the Statesman as a philosophic palindromically periodic anthyphairesis in the *Politicus*.

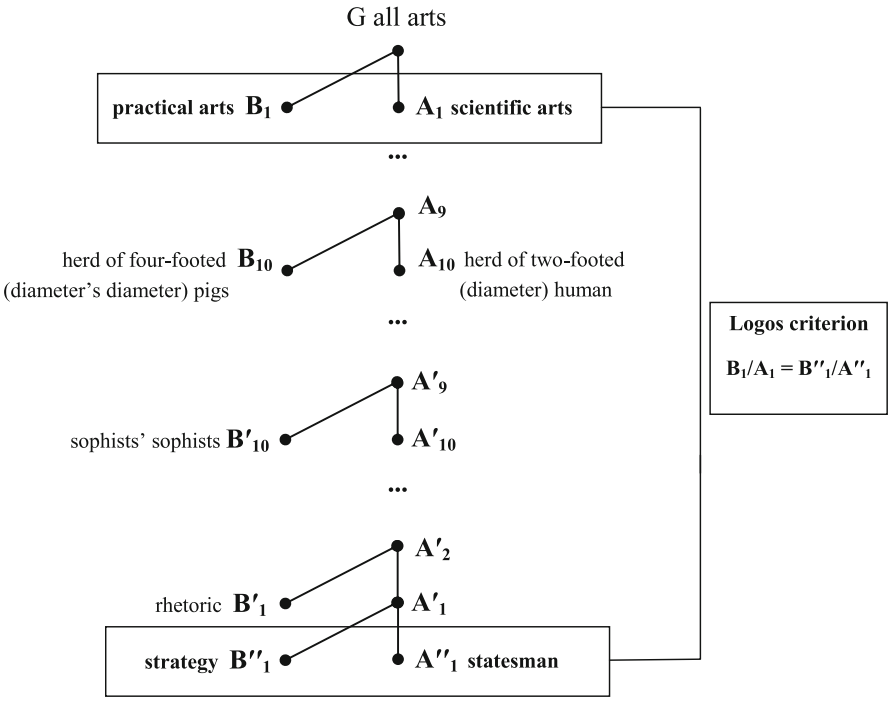
The figure of the Division of the Statesman is to be read as follows:

start the division with the left column,
read from up G downwards to A_{10},
consisting of the ten first binary division steps of the *Kronos era*
the initial genus G is divided into B_1 and A_1,
A_1 is divided into B_2 and A_2,
...,
A_9 is divided into B_{10} and A_{10};
continue with the contingent causes
A_{10} to A_{11} to . . .to A'_{11},
the summary steps in the division steps, and
complete the division with the right column,
read from below A'_{11} upward to A'_1,
consisting of the ten last binary division steps of the *Zeus era*
A'_{11} is divided into B'_{10} and A'_{10},
A'_{10} is divided into B'_9 and A'_9,
...,
A'_2 is divided into B'_1 and A'_1, and
A'_1 is divided into B''_1 and A''_1.

Finally the *Logos Criterion* $B_1/A_1 = B''_1/A''_1$, shown in the figure below,

results in the definition of Statesman as the philosophical analogue not simply of periodic, but of *palindromically periodic* anthyphairesis.



It is clear that the purpose of the *Politicus* is to exhibit that the perfect definition of an intelligible Being is by means of a philosophical analogue of a palindromically periodic anthyphairesis. There can be no doubt that the whole of *Politicus* is a philosophical imitation of the strong Theaetetus' theorem on the palindromic periodicity of the anthyphairesis of quadratic incommensurability $a^2 = Nb^2$ for non-square number N. This will be examined in the next Sect. 7.

7 The Reconstruction of the Proof of the Strong Theaetetus' Palindromic Periodicity Theorem, Employing Methods Solely from the Theaetetean Book X of Euclid's *Elements* and the Pigeonhole Argument at the *Politicus* 272d-e

7.1 The Strong Theaetetus' Palindromic Periodicity Theorem

The Division and Colletion for the Statesman in the *Politicus* is clearly a continuation of the examples of Division and Collection that were given in the *Sophistes*, principally for the Angler and for the Sophist, which were shown (in Sect. 3) to be philosophical imitations of a dyad in periodic anthyphairesis.

Furthermore, it has been shown in Sect. 4 that the theorem Plato has (a) reported in the *Theaetetus* 147c-148d that Theaetetus has proved and (b) imitated philosophically in the *Politicus* 283a-287b and the *Philebus* 16c, 23a-25e, is the Theorem: "if $a^2 = Nb^2$ for non-square number N, or more generally if a, b are commensurable in power only lines (namely commensurable in power a^2 to b^2 and incommensurable in length a to b), then the anthyphairesis of a to b is periodic," and in Sect. 6, that a reconstruction of the proof can be obtained with tools exclusively from the Theaetetean Book X of the *Elements* PLUS a pigeonhole argument.

But now prompted by the extremely elaborate philosophical imitation of the periodic palindromicity theorem in the *Politicus*, described in Sect. 6, we have no choice but to admit that in fact Plato is forcefully declaring that in fact Theaetetus has proved the following:

> *Strong Theaetetus' Palindromic Periodicity Theorem.* If a and b are two lines, such that $a^2 = Nb^2$ for a non-square number N, or more generally, incommensurable in length only, then the anthyphairesis of a to b is *palindromically periodic*.

This of course is essentially the important

> *Theorem* Fermat (de Fermat 1679), Brouncker, Wallis, Euler (Euler 1767), Lagrange (Lagrange 1769a, 1769b, 1770).
> If N is a non-square natural number, then the continued fraction of $\sqrt{N}$ is periodic, and in fact palindromically periodic. In fact,there are numbers n and m, $k_1, k_2, \ldots, k_{n-1}, (k_n)$, such that the sequence of successive quotients of the continued fraction of $\sqrt{N}$ has the form
> $[m, \text{period } (k_1, k_2, \ldots, k_{n-2}, k_{n-1}, (k_n), k_{n-1}, k_{n-2}, \ldots, k_2, k_1, 2m)]$,

which was established gradually during the seventeenth and eighteenth century, with contributions by Fermat, Brouncker, Wallis, Euler (who gathered important experimental evidence on the periodicity of the continued fractions of particular quadratic irrationals), and Lagrange (who proved the periodicity). Modern proofs of this result can be found in Hardy and Wright 1938; Weil 1984; Kahane 1985; Fowler 1987.

We have no great difficulty to provide a reconstruction of the proof of the strong Theaetetus' palindromic periodicity theorem with the same tools that we have found in Book X. of the *Elements* and which have been used to prove the weak Theaetetus' periodicity theorem, in Sect. 5. This is done in Sect. 7.2 below.

We emphasize that our reconstruction is based solely on tools from Book X of the *Elements*, but assumes a historical relevance only because of the compelling imitation by Plato with which he constructs the whole of *Politicus*. It is inconceivable that Plato based his later philosophy on something mathematical that was not resting in absolutely solid ground (Recall Plato's passage on the importance of necessity and mathematical proof in geometry (examined in Sect. 4.2.2):

ἀπόδειξιν δὲ καὶ ἀνάγκην οὐδ' ἡντινοῦν λέγετε ἀλλὰ τῷ εἰκότι χρῆσθε,
ᾧ εἰ ἐθέλοι Θεόδωρος ἢ ἄλλος τις τῶν γεωμετρῶν χρώμενος γεωμετρεῖν,
ἄξιος οὐδ' ἑνὸς μόνου ἂν εἴη. *Theaetetus* 162e4–7).

The unmistakable and necessary consequence of our analysis is that, despite the lack of any explicit ancient mathematical evidence, Theaetetus' palindromic periodicity theorem was in possession of the Academy.

Of course the reconstruction of the strong palindromic periodicity theorem makes heavy use of the pigeonhole principle. But, as we have noted in Sect. 5, there is no trace of such principle in Book X of the *Elements*, in fact in any ancient mathematical source. Thus a basic argument, the pigeonhole principle, needed for the proof is missing from Book X.

However, it is remarkable that Plato makes a clear reference to the pigeonhole principle, and in fact precisely at the point needed: In the *Politicus* 272d6-e6, namely when he wants to explain why a soul makes the transition fom the Kronos era to the Zeus era, namely from the first half of the period in the anthyphairetic division to its second palindromic half, Plato explains this transition by means of an argument that seems pure pigeonhole: The soul is forced to go to the Zeus era, to the second palindromic semi-period, because "the time of the generations was accomplished," "the Kronos type generations have all been used up," "the soul had fulfilled all its generations," and "there were as many seeds fallen on the earth as prescribed"—essentially many ways of saying that "all pigeonholes were filled" (Sect. 7.3).

7.2 The Reconstruction of Theaetetus' Palindromic Periodicity Theorem

We next proceed with the proof of the full theorem on palindromic periodicity, described in philosophical imitation by Plato in the *Politicus* (The original proof is contained in the unpublished manuscript Negrepontis 2003).

Definition (Inverse of the conjugate φ_n*) Define the line ω_n by the equality

$$\varphi_n{}^* \cdot \omega_n = b^2$$

(where we have set $\varphi_n{}^* = (a + m_n\ b)/\lambda_n$, which implicitly has been used in Sect. 5 anyway).

Since $\varphi_n{}^*$ is a line of two names, it follows from Book X conjugacy (*Proposition X.112*) that ω_n is an apotome. In fact we can obtain more detailed information.

Proposition (Properties of ω_n).

(i) The line ω_n is an apotome, and in fact

$$\lambda_{n+1}\ \omega_n = a - m_n\ b;$$

(ii) $\omega_n < b$
(iii) $\omega_1(\varphi_1 + 2\ m_1 b) = b^2$
(iv) $\omega_{n+1}(I_n b + \omega_n) = b^2$

Proof All statements follow easily by the definition of ω_n and the periodicity theorem, proved in Sect. 5; the details are left for the reader.

We order the elements of the two sequences (φ_n) and (ω_n) in one sequence as follows:

$$\varphi_1, \omega_1, \varphi_2, \omega_2, \ \ldots, \varphi_n, \omega_n, \ \ldots.$$

From *the pigeonhole principle*, using the periodicity theorem and the above Proposition, there exists *a first element* in the sequence so ordered, such that all the previous elements of the sequence are pairwise distinct, and the element in question coincides with a previous element.

There are two cases to examine:

Case I: The elements φ_1, ω_1, φ_2, ω_2,. . ., φ_{k-1}, ω_{k-1} are pairwise distinct and the element φ_k coincides with a previous element. Then we claim that $\omega_{k-1} = \varphi_k$.
Case II: The elements φ_1, ω_1, φ_2, ω_2,. . ., φ_{k-1}, ω_{k-1}, φ_k are pairwise distinct and the element ω_k coincides with a previous one. Then we claim that $\varphi_k = \omega_k$.

Proof for Case I. There are three subcases:

(a) If the apotome line φ_k coincides with the apotome line φ_1, then we have a contradiction [Proof similar to (b) below]
(b) If the apotome line φ_k coincides with the apotome line φ_j for some j with $1 < j < k$, then we have a contradiction.

[we are to obtain a contradiction from (b).

From the supposition it follows that the two conjugate lines of two names are equal, i.e., that $\varphi_k^* = \varphi_j^*$, and since $\varphi_k^* \cdot \omega_k = \varphi_j^* \cdot \omega_j = b^2$ (by the definition of φ_k^*), we obtain that $\omega_k = \omega_j$. But we have $\omega_j(I_{j-1}b + \omega_{j-1}) = b^2$ and $\omega_k(I_{k-1}b + \omega_{k-1}) = b^2$ (both by Proposition (iv)). Hence $I_{k-1}b + \omega_{k-1} = I_{j-1}b + \omega_{j-1}$; since (on account of Proposition (ii)) both sides of the equation represent the anthyphairetic division of the same whole line with respect to the same line b it follows that the remainders are equal, i.e., $\omega_{k-1} = \omega_{j-1}$, a contradiction, since the elements $\varphi_1, \omega_1, \varphi_2, \omega_2, \ldots, \varphi_{k-1}, \omega_{k-1}$ have been assumed to be pairwise different. Hence φ_k is not equal to φ_j for some j with $1 < j < k$.]

(c) If the apotome line φ_k coincides with the apotome line ω_j, for some j with $j < k-1$, then we have a contradiction. [Proof similar to (b) above.]

Therefore, since φ_k is equal to one of the elements $\varphi_1, \omega_1, \varphi_2, \omega_2, \ldots, \varphi_{k-1}, \omega_{k-1}$, the only possibility left, by (a), (b), and (c), is to have $\omega_{k-1} = \varphi_k$.

Case II is dealt with similarly and we obtain $\varphi_k = \omega_k$.

We now complete the proof by showing the palindromicity in Case I.

From the fact, already proved, that $\omega_{k-1} = \varphi_k$, and the relations $\varphi_k(I_k b + \varphi_{k+1}) = b^2$ (Theorem of Sect. 5.5) and $\omega_{k-1}(I_{k-2}b + \omega_{k-2}) = b^2$ (Proposition of Sect. 7.2. (iv)), we deduce that

$$I_k b + \varphi_{k+1} = I_{k-2}b + \omega_{k-2};$$

since (on account of Theorem of Sect. 5.5 and Proposition of Sect. 7.2) both sides of this equation represent the anthyphairetic division of the same whole line with respect to the same line b, it follows that the two remainders and the two quotients are equal, i.e.,

$$I_k = I_{k-2} \text{ and } \varphi_{k+1} = \omega_{k-2}.$$

Continuing in the same way we obtain that

$$I_{k+1} = I_{k-3} \text{ and } \varphi_{k+2} = \omega_{k-3}.$$

Still continuing in the same way we obtain that

$$I_1 = I_{2k-3} \text{ and } \varphi_{2k-2} = \omega_1.$$

But we have that
$\varphi_{2k-2}(I_{2k-2}b + \varphi_{2k-1}) = b^2$ (Sect. 5) and
$\omega_1(2m_1 b + \varphi_1) = b^2$ (Proposition of Sect. 7.2. (iv));
hence

$$I_{2k-2}b + \varphi_{2k-1} = 2\, m_1 b + \varphi_1.$$

Since (on account of Theorem of Sect. 5.5) both sides of this equation represent the anthyphairetic division of the same whole line with respect to the same line b, it follows that the two remainders and the two quotients are equal, i.e.,

$$I_{2k-2} = 2\, m_1 \text{ and } \varphi_{2k-1} = \varphi_1.$$

From the equality $\varphi_{2k-1} = \varphi_1$ (Logos Criterion (Theorem of Sect. 5.5)),
we deduce
the *periodicity of the anthyphairesis*, and
from the equalities $I_{2k-2} = 2\, m_1$, and $I_1 = I_{2k-3}$, $I_2 = I_{2k-4}$,. . ., $I_k = I_{k-2}$, and $I_{k+1} = I_{k-3}$,
we deduce
the *palindromicity in the period of the anthyphairesis*, as required.
Case II is dealt with similarly.

The general commensurability in power only requires only minor modifications left to the reader. The proof of the theorem is complete.

7.3 Plato's Argument for Going from the Kronos Era to the Zeus Era (*Politicus* 272d6-e6) Appears to be a Philosophical Version of the Pigeonhole Argument Employed in the Proof

For when the time of all these [Kronos era] generations was accomplished (ἐτελεώθη)	
	and the change to[Zeus era] was to take place (μεταβολὴν ἔδει γίγνεσθαι)
and all the earth-born [Kronos era] genus had already been used up (ἀνήλωτο), since every soul (ἑκάστης τῆς ψυχῆς) had fulfilled (ἀποδεδωκυίας) all its generations (πάσας τὰς γενέσεις), by falling into the earth (εἰς γῆν πεσούσης) as many seeds (τοσαῦτα σπέρματα) as prescribed to it (ὅσα ἦν ἑκάστῃ προσταχθὲν), then	
	the heldsman (κυβερνήτης) of the universedropped the tiller and *withdrew* *(ἀπέστη)* to his place of outlook, and fate (εἱμαρμένη) and innate desire (σύμφυτος ἐπιθυμία) made the universe (κόσμον) turn backwards (πάλιν ἀνέστρεφεν). 272d6-e6

Thus for a soul a change from the Kronos era to the Zeus era becomes necessary when the (definitely finite) number of generations of the soul in the Kronos era and

the seeds prescribed to the soul in this era have all been used up; this is precisely the pigeonhole argument.

Not only is Plato in the *Politicus* 272d6-e6 describing, in philosophical-mythological terms a *pigeonhole principle*, but he does so at the point of passing from the Kronos era to the Zeus era, in other words at the point of passing from the first semiperiod to the second and palindromically symmetric to the first. It is remarkable that this is precisely the point, in our reconstructed proof of the strong Theaetetus' palindromically periodic theorem, where the mathematical pigeonhole principle is employed.

Sections 8, 9, 10 The Ancient History of the Pell Problem
We now have all the information we need from Plato and from Book X of the *Elements* to deal with the Pythagorean proof of the Pell property for $N = 2$ (Sect. 8), the reconstructed poof of the Pell property for any non-square number N by Theaetetus (Sect. 9), and the solution of the problem of Pell by the Hindu mathematicians (Sect. 10).

8 The Pell Equation for $N = 2$ by the Pythagoreans

The Pythagoreans discovered the incommensurability of the diameter to the side of a square, by proving that the anthyphairesis of the diameter to the side is infinite, in fact with sequence of quotients the infinite sequence [1, 2, 2, 2,...], and applying Proposition X.2 of the *Elements*. They next introduced the double sequence of the *side p_n and diameter q_n numbers* defined *recursively* by

$$p_1 = q_1 = 1,$$

$$p_{n+1} = p_n + q_n, q_{n+1} = 2p_n + q_n \text{ for } n = 1, 2, \ldots,$$

whose anthyphairesis has as sequence of quotients a finite initial segment of the infinite anthyphairesis of the diameter to the side of a square. According to the ancient authors recounting the side and diameter numbers, Theon Smyrneus (Theon Smyrnaeus, ed.: Hiller 1878) 44,18-45,8, Iamblichus, *Comments to Nikomachus* (Iamblichus, ed.: Pistelli 1894) 92,23-93,6, and mainly Proclus, *Commentary to Politeia* (Procli Diadochi, ed.: Kroll 1899–1901) 2, 24,16–25,13 and 2, 27, 1–29,4, the Pythagoreans verified and then showed that these numbers satisfy the Pell Diophantine equation

$$q_n{}^2 = 2p_n{}^2 + (-1)^n.$$

Some scholars (such as Freudenthal 1953) support, but more recently others are either ambivalent (such as Fowler 1994) or have challenged (such as Unguru 1991; Acerbi 2000) the thesis that the Pythagoreans had obtained a real proof by induction, or in fact any kind of proof of the Pell property. In our work (Negrepontis and

Farmaki 2019, Chap. 8), reading the sources meticulously, we have some novel arguments showing that the Pythagoreans had indeed an inductive proof, but without the principle of mathematical induction.

The Pythagoreans noted that each rational diameter by itself is not a true diameter, because its square is not equal to double the square of its side (something impossible for numbers, by the incommensurability of the diameter to the side of a square, as noted by Proclus 2,27,1-4), but equal to double the square minus 1 or plus 1; however, they found encouragement into the fact that the square of the diameter is double the square minus 1 or plus 1 in an alternating (ἐναλλάξ, Theon 44,14, Iamblichus 92,23) manner. In consequence, in order to ensure exact diameter type equality to side (ἀπίσωσις,92,27; ἰσότης, 93,1; ἀπισώσει, 93,3 in Iamblichus; ἰσότητα, 45,5 in Theon) they were led to form the sum of the square of a rational diameter together with (*μετὰ*) the square of the next diameter, which sum is then exactly equal to the double (in Proclus 2, 25,11) of the square of the side and (*καὶ*, a connective different from *μετὰ*) the square of the next side. Proclus describes this basic *heuristic* idea of the Pythagoreans, as follows:

> ἐὰν δὲ λάβωμεν ἁπάσας τὰς ἀπὸ τῶν τοιούτων διαμέτρων, ἔσονται διπλάσιαι ὄντως, ***ὧν***
> ἑκάστη μονάδι μείζων ἢ ἐλάσσων διπλασίου·
> οἷον ἡ ἐννέα ***μετὰ*** τοῦ μθ′ τῆς τοῦ κε′ ***καὶ*** δ′.
>
> If we take together all the diameters, their squares are really double,
> [as, for example, if we receive the square 9 of the diameter 3 *together with* (***μετὰ***) the square 49 of the diameter 7, they are really double of the square 25 of the side 5 *and* (***καὶ***) the square 4 of the side 2]
> *of which* (hon) squares of diameters
> each is greater or less of the double square of the side by a unit. 2,25,9–12

As with all good heuristic ideas, this one is really a step in *analysis*, going backward in the chain of deduction: In order to prove what is required, namely the Pell property of the side and diameter numbers, it is enough to prove that

> the square of the diameter *together with (μετὰ)* the square of the next diameter is really double the square of the side *and (καὶ)* the square of the next side.

Proclus tells us that the Pythagoreans were encouraged by this method:

> διὸ καὶ οἱ Πυθαγόρειοι ἐθάρρησαν τῇ μεθόδῳ. *Proclus* 2,25,12–13

Thus the Pythagoreans realized that it is enough to prove that

> for any *natural numbers* a, b, the square of $a + 2b$ *together with* ***(μετὰ)*** the square of a equals double the square of $a + b$ *and* ***(καὶ)*** of b.

But in fact the Pythagoreans carried the analysis one step further, going one more step bacward in the chain of deduction. As with Propositions II.4–8, the statements

are geometric, about lines, and so the Pythagoreans stated that it will be enough to prove that

> for any *lines* a, b, the square of $a + 2b$ *together with* ***(μετὰ)*** the square of a equals double the square of $a + b$ *and* ***(καὶ)*** of b.

Thus the initial heuristic idea of the Pythagoreans led them to the discovery, by analysis, of the geometric Proposition II.10 of the *Elements*:

for lines a, b, $(a + 2b)^2 + a^2 = 2((a + b)^2 + b^2)$.

Now it is the turn of synthesis/proof.

From Proposition II.10, by reversing the analytic steps, we are to obtain the required statement about the side and diameter numbers. However before going to the side and diameter numbers, the Pythagoreans, wishing to prove that II.10 is really a geometric statement, not equivalent to, but stronger than, the corresponding arithmetical one, they interposed (προετίθεσαν, 2,27,11) the *elegant theorem* (*θεώρημα γλαφυρὸν*, 2,27,12), which they proved geometrically (γραμμικῶς, linearly, 2,27,17), clearly turning II.10 into the statement of a (geometric) inductive step (if a is diameter and b side, then $a + 2b$ is diameter and $a + b$ side):

> διὰ τὸ θεώρημα [Proposition II.10] ἔσται
> τὸ ἀπὸ τῆς ΑΔ *μετὰ* τοῦ ἀπὸ τῆς ΔΓ διπλάσιον τοῦ ἀπὸ τῆς ΑΒ *καὶ* ἀπὸ τῆς ΒΔ.
> *ὧν*
> τὸ ἀπὸ τῆς ΔΓ διπλάσιον τοῦ ἀπὸ τῆς ΑΒ·
> καὶ λο[ιπὸν] *ἄρα* τὸ ἀπὸ τῆς ΑΔ τοῦ ἀπὸ τῆς ΒΔ διπλάσιον· 2,27,24-2,28,3,
>
> By the theorem [Proposition II.10] we have that
> the square of ΑΔ together with (*μετὰ*) the square of ΔΓ is
> double the square of ΑΒ and (καὶ) the square of ΒΔ,
> of which (*ὧν*)
> the square of ΔΓ is double the square of ΑΒ,
> hence *ἄρα* the square of ΑΔ is double the square of ΒΔ.

The wording of this argument is truly remarkable, because it preserves intact the linguistic peculiarity with which the Pythagorean heuristic idea was conceived (*μετὰ*, καὶ, *ὧν*), thus confirming fully the analytical nature of the argument, and revealing at the same time that the Pythagorean heuristics was for the purpose of an inductive argument.

T*he statement of the elegant theorem*:

> ἡ μὲν διάμετρος προσλαβοῦσα τὴν πλευράν, ἧς ἐστιν διάμετρος, **γίνεται πλευρά**,
> ἡ δὲ πλευρὰ ἑαυτῇ συντεθεῖσα καὶ προσλαβοῦσα τὴν διάμετρον τὴν ἑαυτῆς **γίνεται διάμετρος** 2, 27, 13–16
>
> the diameter, having received (προσλαβοῦσα) the side, of which it is diameter, becomes side (γίνεται πλευρά), and
> the side, being composed with itself (ἑαυτῇ συντεθεῖσα) and having received (προσλαβοῦσα) the side's diameter becomes diameter **(γίνεται διάμετρος)**.

In the final step of synthesis, Proposition II.10, in an arithmetic form, immediately deduced from the geometrical, is used for the proof of every inductive step of the Pell equation, stated in a manner linguistically identical with the statement of the elegant theorem (so that the latter serves as the model for identical language for every inductive step in the proof of the Pell equation). The first inductive step is as follows:

> λαβέτω οὖν ἡ διαμετρικὴ μονὰς πλευράν, ὅ ἐστι μονάδα (καὶ γὰρ αὕτη διάμετρος ἦν), **γίνεται** δυὰς καὶ **πλευρὰ** τετράδος·
> ἡ δὲ πλευρικὴ μονὰς ἑαυτῇ συντεθεῖσα λαβέτω διάμετρον ἄλλην μονάδα (ἦν γὰρ καὶ ἡ διαμετρική), **γίνεται** τριὰς [καὶ **διάμετρος**]
> καὶ ποιεῖ τὸν ἐννέα, μονάδι μείζονα τοῦ ἀπὸ δυάδος· 2,28,17–21
>
> The diametric unit receiving side . . . becomes side, and
> The side unit composed with itself and receiving diameter. . .becomes [diameter].

(the second step 2,28,22–24; the third step 2,28,27-29,1)

Thus the Pythagoreans proved the following:

Proposition P(*n*) Let n be a given natural number. The n-th side number p_n and diameter number q_n satisfy the Pell Diophantine equation

$q_n^2 = 2p_n^2 + (-1)^n$.

The Pythagorean proof, reconstructed according to above arguments, now runs smoothly as follows:

Proposition P(1) clearly holds.

We obtain a proof Proof (2) for Proposition P(2), by *applying the arithmetical version of Proposition II.10* with $a = p_1$, $b = q_1$, using the recursive definition, and using the fact that Proposition P(1) holds.

We next obtain Proof (3) for Proposition P(3) by applying Proposition II.10 with $a = p_2$, $b = q_2$, using the recursive definition, and using the fact that Proposition P (2) holds. It is clear that continuing in this way we can obtain Proof (n) for Proposition P(n).

The number of steps of these separate proofs Proof (n) is going to infinity as n is going to infinity (and thus ad infinitum, καὶ ἀεὶ οὕτως, 2,29,4).

So the ancients had a proof Proof (n) for Proposition P(n) for every n, but they had no proof for all n simultaneously, namely no proof for the Proposition $(\forall n)$P(n), because this proof would require an infinite number of steps.

We conjecture that the Pythagorean proof of the Pell property for $N = 2$ marked the *Birth of Induction*. It was *unfinitized* induction, Greeks never finitized mathematical induction (Plato's *Parmenides* 149a7-c3 has been proposed (Wedberg 1955 and Acerbi 2000) as a perfect specimen of ancient proof by mathematical induction; however our analysis in (Negrepontis and Farmaki 2021, Sect. 3.6) shows that Plato means this to be an argument involving only finite induction, since there are only finitely many "ἄψεις"/logoi in every true Being, forming a period.).

9 A Reconstruction of Theaetetus' Proof of the General Case of the Pell Property

Theaetetus had a strong motivation to study the Pell property for every non-square number, because of the Pythagorean discovery of the Pell property for $N = 2$ (Sect. 8). Once a proof of the palindromic periodicity theorem has been obtained (Sect. 7), the proof of the general case of the Pell property, namely for every non-square natural number, is straightforward.

9.1 The Tools for the Proof of the Pell Property in Book X of the *Elements*

There are strong internal signs that the Pell problem is a central concern in Book X.

One such sign is the classification of the apotome lines in six classes in X.84/85, which for the simple apotome lines is intimately related with whether their Pell number is square or not.

The second sign is Proposition X.97 stating that the square of every apotome line can be made equal to a rectangle one of whose sides is a rational line and the other an apotome with square Pell number.

A natural extension of X.97 that the product of two (simple) apotome lines is equal to a rational line times an (simple) apotome line with Pell number the product of the Pell numbers of the two initial lines, not stated explicitly in the *Elements*, is all that is needed on top of the palindromic periodicity theorem, to provide a complete proof of the Pell equation.

9.1.1 The Pell-Related Classification of the Apotome Lines in Six Classes in X.84/85

The classification of all apotome lines in six kinds in the definitions X.84/85, which has played no role for the proof of the palindromic periodicity, is according to two criteria.

The first criterion is *external* and concerns the commensurability or incommensurability of the assumed line in relation to the whole part or to the annex part of the apotome. This criterion does not have to do with the internal structure of the apotome, since *the same apotome line* can have assumed line commensurable to the whole part, or to the annex part, or to neither of the two. This criterion is introduced for making the apotome lines compatible to each other, by having the same/commensurable assumed line.

The second criterion is *internal*, has to do with the structure of the apotome line, and can be described as follows: If g–h is an apotome line then we form the right triangle with hypotenuse g and one vertical side h, and we define π to be the second vertical side: $\pi^2 = g^2 - h^2$. The criterion for classification is whether the lines π and the whole g are commensurable or not. At a formal level it is a rather opaque criterion, but it is immediately illuminated if we apply it on the simple apotome lines, which, as we have seen with the constructions in Propositions X.85–90 and

with the proof of the palindromic periodicity theorem (Sects. 5 and 7), are the main object of interest in Book X. A simple apotome line γ has the form either $\gamma = (qb - pa)/\lambda$ or $\gamma = (pa - qb)/\lambda$, where p, q, λ are natural numbers, with $a^2 = Nb^2$, where N a non-square number.

We introduce the following crucial **Definition**. The *Pell number* of a simple apotome line γ, denoted by Pell(γ), is the number $(q^2 - Np^2)/\lambda^2$.

For $\gamma = (qb - pa)/\lambda$, Pell($\gamma$) is a positive rational number, for $\gamma = (pa - qb)/\lambda$ negative.

It becomes evident that the second, internal criterion for the classification of the simple apotome lines is intimately related with the Pell problem, in fact can now be stated *solely in terms of the Pell number of the apotome* and in fact with whether the *Pell number of the apotome line is square or not*.

Classification of the simple apotome lines according to X.84/85.

γ first apotome	either $\gamma = (qb - pa)/\lambda$	Pell(γ) square and b assumed line [X.85]
	or $\gamma = (pa - qb)/\lambda$	$-$Pell(γ)·N square and a assumed line
γ second apotome	either $\gamma = (qb - pa)/\lambda$	Pell(γ) square and a assumed line [X.86]
	or $\gamma = (pa - qb)/\lambda$	$-$Pell(γ)·N square and b assumed line
γ third apotome	either $\gamma = (qb - pa)/\lambda$	Pell(γ) square and assumed line not commensurable to b, or to a [X.87]
	or $\gamma = (pa - qb)/\lambda$	$-$Pell(γ)·N square and assumed line not commensurable to b, or to a
γ fourth apotome	either $\gamma = (qb - pa)/\lambda$	Pell(γ) positive non-square and b assumed line
	or $\gamma = (pa - qb)/\lambda$	$-$Pell(γ)·N non-square and a assumed line [X.88]
γ fifth apotome	either $\gamma = (qb - pa)/\lambda$	Pell(γ) positive non-square and a assumed line
	or $\gamma = (pa - qb)/\lambda$	$-$Pell(γ)·N non-square and b assumed line [X.89]
γ sixth apotome	either $\gamma = (qb - pa)/\lambda$	Pell(γ) positive non-square and assumed line not commensurable to b or to a
	or $\gamma = (pa - qb)/\lambda$	$-$Pell(γ)·N non-square and assumed line not commensurable to b, or to a [X.90]

If $\gamma = (qb - pa)/\lambda$, then $\pi^2 = (q^2b^2 - p^2a^2)/\lambda^2 = ((q^2 - p^2N)/\lambda^2)b^2 = \text{Pell}(\gamma)b^2$, hence

qb and π are commensurable if and only if $\text{Pell}(\gamma)$ is a square number.

If $\gamma = (pa - qb)/\lambda$, then $\pi^2 = (p^2a^2 - q^2b^2)/\lambda^2 = ((p^2N - q^2)/\lambda^2)b^2 = -\text{Pell}(\gamma)b^2 = -\text{Pell}(\gamma)a^2/N = (-\text{Pell}(\gamma)\cdot N/N^2)a^2$ hence,

pa and π are commensurable if and only if $-\text{Pell}(\gamma)\cdot N$ is a square number.

The simple verifications of equivalence of the definitions X.84/85 with the corresponding conditions in the table above.

The table shows that the classification of the (simple) apotome lines γ is most closely related to the Pell number $\text{Pell}(\gamma)$, and in fact to whether $\text{Pell}(\gamma)$, or the modified expression $-\text{Pell}(\gamma)\cdot N$, is a square or non-square number, in case γ is of the form $qb - pa$, or of the form $pa - qb$, correspondingly.

We note that an even remainder $\gamma_{2n} = q_{2n}b - p_{2n}a$ of the quadratic anthyphairesis a to b, $a^2 = Nb^2$, N non-square, is

a first apotome if its Pell number $q^2 - Np^2$ is a square number,

a fourth apotome otherwise.

9.1.2 The Pell-Related Proposition X.97 of the *Elements*

Proposition X.97, stating that the "square" of every apotome line is a first apotome line, is crucial for the proof of the Pell property.

Proposition X. 97 The square on an apotome applied to a rational straight line produces as breadth a first apotome.

[If γ is an apotome with respect to the assumed line b and $\gamma^2 = \chi\ b$, then χ is a first apotome]

Proposition X.97 reveals its true content when applied to simple apotome lines related to the quadratic incommensurability $a^2 = Nb^2$, N non-square, namely to the apotomae of the form either $\gamma = (pa - qb)/\lambda$ or $\gamma = (qb - pa)/\lambda$, for which the assumed line is the line b. The proof of Proposition X.97 in fact shows that for those lines γ,

$\text{Pell}(\chi) = (\text{Pell}(\gamma))^2$.

The close connection of Proposition X.97 with the Pell property is evident.

9.2 The Crucial Step for a Reconstruction of Theaetetus' Proof of the General Pell Property, Employing the Palindromic Periodicity Theorem and Proposition X.97

The principal application of Proposition X.97 is with respect to the reduced remainders $\varphi_n = (a - m_nb)/\lambda_n$.

Proposition If φ_n is a reduced remainder in the initial semi-period of the period of the anthyphairesis of a to b, and ω_n is its corresponding conjugation line in the final semiperiod, then

$$\text{Pell}\,(\varphi_n) = -\lambda_{n+1}/\lambda_n, \text{Pell}\,(\omega_n) = -\lambda_{\text{n}}/\lambda_{n+1}, \text{and}$$

$$\text{Pell}\,(\varphi_n \cdot \omega_{\text{n}}/b) = 1$$

Proof By direct computation

$$\varphi_n = (a - m_n b)/\lambda_n,$$

hence Pell $(\varphi_n) = -(N - m_n{}^2)/\lambda_n{}^2 = -\lambda_n\,\lambda_{n+1}/\lambda_n{}^2 = -\lambda_{n+1}/\lambda_n$, and

$$\omega_n = (a - m_n b)/\lambda_{n+1},$$

hence Pell $(\omega_n) = -(N - m_n{}^2)/\lambda_{n+1}{}^2 = -\lambda_n\,\lambda_{n+1}/\lambda_{n+1}{}^2 = -\lambda_n/\lambda_{n+1}$.

Thus by Proposition X.97

$$\text{Pell}\,(\varphi_n{\cdot}\omega_n/b) = \text{Pell}\,(\varphi_n)\ \text{Pell}\,(\omega_n) = (-\lambda_{n+1}/\lambda_n)(-\lambda_n/\lambda_{n+1}) = 1.$$

But note that line $\varphi_n.\omega_n/b$ is *not* a solution to the Pell problem yet, because it is a fractional N-apotome, not an integral one.

9.3 The Reconstruction of Theaetetus' Proof of the General Case of Pell Property

Proposition

$$\text{Pell}\,\left(\gamma_{n+1}\right) = \text{Pell}\,(\gamma_n)\ \text{Pell}\,\left(\varphi_{n+1}\right).$$

Proof By definition $\gamma_{n+1}\ b = \gamma_n\ \varphi_{n+1}$, namely $\gamma_{n+1} = \gamma_n\ \varphi_{n+1}$/b. The conclusion follows by a natural extension of Proposition X.97 to a product of two apotome lines, rather than to the square of an apotome line, an extension not mentioned explicitly in Book X.

Proposition

$$\text{Pell}\,(\gamma_n) = \text{Pell}\,(\varphi_1)\ \text{Pell}\,(\varphi_2)\ldots\text{Pell}\,(\varphi_n).$$

If $a^2 = Nb^2$, then Anth$(a, b) = [m_1, \text{period}(I_1, I_2,\ldots, I_n, (I_{n+1}), I_n,\ldots,I_2, I_1, 2m_1)]$.

Then, with middle γ_{n-1} present, we have

$a = m_1 b + \gamma_1$	$\varphi_1 = \gamma_1$
$b = I_1\gamma_1 + \gamma_2$	$\varphi_2\,\gamma_1 = \gamma_2 b$

(continued)

$\gamma_1 = I_2\gamma_2 + \gamma_3$	$\varphi_3\ \gamma_2 = \gamma_3 b$
...	...
$\gamma_{n-2} = I_{n-1}\ \gamma_{n-1} + \gamma_n$	$\varphi_n\ \gamma_{n-1} = \gamma_n b$
$\gamma_{n-1} = I_n\ \gamma_n + \gamma_{n+1}$	$\varphi_{n+1}\ \gamma_n = \gamma_{n+1} b$
$\gamma_n = I_n\ \gamma_{n+1} + \gamma_{n+2}$	$\omega_n\ \gamma_{n+1} = \gamma_{n+2} b$
...	...
$\gamma_{2n-3} = I_3\ \gamma_{2n-2} + \gamma_{2n-1}$	$\omega_3\ \gamma_{2n-2} = \gamma_{2n-1} b$
$\gamma_{2n-2} = I_2\ \gamma_{2n-1} + \gamma_{2n}$	$\omega_2\ \gamma_{2n-1} = \gamma_{2n} b$
$\gamma_{2n-1} = I_1\ \gamma_{2n} + \gamma_{2n+1}$	$\omega_1\ \gamma_{2n} = \gamma_{2n+1} b$
$\gamma_{2n} = 2m_1\ \gamma_{2n+1} + \gamma_{2n+2}$	

Hence, the Pell number of the integral N-apotome $\gamma_{2n+1} = p_{2n+1}a - q_{2n+1}b$, equal by definition to the number $(N p_{2n+1}{}^2 - q_{2n+1}{}^2)$, is equal to 1, since

$$\mathrm{Pell}\left(\gamma_{2n+1}\right) =$$

$$\mathrm{Pell}(\omega_1\ \gamma_{2n}/b) = \mathrm{Pell}(\omega_1)\ \mathrm{Pell}(\gamma_{2n}) =$$

$$\mathrm{Pell}(\omega_1)\ \mathrm{Pell}(\omega_2\ \gamma_{2n-1}/b) = \mathrm{Pell}(\omega_1)\ \mathrm{Pell}(\omega_2)\ \mathrm{Pell}(\gamma_{2n-1}) =$$

$$\mathrm{Pell}(\omega_1)\ \mathrm{Pell}(\omega_2)\ \mathrm{Pell}(\omega_3\ \gamma_{2n-2}/b) = \mathrm{Pell}(\omega_1)\ \mathrm{Pell}(\omega_2)\ \mathrm{Pell}(\omega_3)\ \mathrm{Pell}(\gamma_{2n-2}) =$$

$$\ldots$$

$$\mathrm{Pell}(\omega_1)\ \mathrm{Pell}(\omega_2)\ \mathrm{Pell}(\omega_3) \ldots \mathrm{Pell}(\omega_\mathrm{n})\ \mathrm{Pell}\left(\varphi_{n+1}\right)\ \mathrm{Pell}(\varphi_n) \ldots \mathrm{Pell}(\varphi_3)\ \mathrm{Pell}(\varphi_2)\ \mathrm{Pell}(\varphi_1) =$$

$$(\mathrm{Pell}(\omega_1)\mathrm{Pell}(\varphi_1))\ (\mathrm{Pell}(\omega_2)\mathrm{Pell}(\varphi_2))\ (\mathrm{Pell}(\omega_3)\mathrm{Pell}(\varphi_3)) \ldots (\mathrm{Pell}(\omega_\mathrm{n})\mathrm{Pell}(\varphi_\mathrm{n}))\ \mathrm{Pell}\left(\varphi_{n+1}\right)$$
$$= 1{\cdot}1{\cdot}1{\cdot} \ldots {\cdot}1{\cdot}(-1) = -1.$$

If we continue with one more period, the Pell number of the last remainder of the second period will clearly be +1.

If the middle term γ_{n-1} is not present, then the middle(-1) term in the product for the Pell number of the last remainder of the first period is missing, and the last remainder of this period, already has Pell number + 1.

Note. We might conclude by saying that Tannery's (1882) and van der Waerden's (1976) intuition was right, that the Greek geometers had somehow proved the general Pell property, but they definitely did not possess the decisive arguments, namely an understanding of the deep mathematical secrets hidden in Plato's philosophy and the Pell content of some key Propositions and the classification of apotome lines in Book X.

9.4 The Third Purpose of Book X of the *Elements* Is the Extension of the Quadratic Anthyphairetic Periodicity to the Canonical Solids by Means of Application of Areas, in an Attempt to Counter the Successes of the Non-Anthyphairetic Approach by Archytas and Eudoxus

We have argued that the principal two purposes of Theaetetus in Book X is the proof of the theorem on palindromic periodicity and the proof of the Pell problem.

9.4.1 The Question on the Role of the Pythagorean Application of Areas in Book X

There are still several Propositions in Book X that have not been used as tools for the proof of these two results. This is essentially the hexad of Propositions X.91–96 and its conjugate X.54–59, distinguished by the fact that they employ the *Pythagorean application of areas, always in defect*, together with several Propositions X.17–21, 33–36, that are preparatory for the two hexads.

The question is: What is the purpose of the introduction of the Pythagorean application of areas in Book X? We will outline our interpretation as this is not the main subject of our present work. It will be the subject of a separate more detailed publication.

9.4.2 In Order to Answer the Question in 8.4.1 We Concentrate on the Only Use of the Application of Areas Introduced in Book X, the Study of the Canonical 20heron in Book XIII, Especially in Propositions XIII.11 and 16 of the *Elements* by Means of Proposition X.94

It seems reasonable to try to find the answer to the Question set in 8.4.1 by analyzing the only use of the group of propositions of Book X that employ application of areas. It is only Proposition X.94 employed for the proof of Proposition XIII.16 on the canonical solid 20hedron, with use of XIII.11.

Definition (Proposition X.76) A line Ω is a *minor* line
if there are two lines Φ, Ψ, such that
$\Phi > \Psi$, $\Omega = \Phi - \Psi$,
$\Phi^2 + \Psi^2$ is a *rational* area (namely commensurable to b^2), and
$\Phi\Psi$ is a *medial* area (namely equal to a rectangle with sides commensurable in square).

Proposition XIII.16 The side, edge of the 20hedron is a *minor* with respect to the diameter of the sphere in which the 20hedron is comprehended.

Proposition XIII.16 is a simple consequence of Propositions XIII.11 and X.94.

Proposition XIII.11
Let Ω be the side of a canonical 5gon, comprehended by a circle of radius b, and let γ be the simple apotome $\gamma = (5b - a)/4$, with $a^2 = 5b^2$.

Then

$$\Omega^2 = \gamma \cdot 2b.$$

Proposition X.94. If the line γ is is a *fourth (simple) apotome* and a rational line r, such that $\Omega^2 = \gamma \cdot r$, then Ω is a *minor* line.

Here is an *outline of the proof* of Proposition X.94.

We employ the special Pythagorean application of areas in defect, a special form of the application of areas, as follows.

[1] Let γ be a *(simple) apotome*, $\gamma = qb - pa$, where q, b are rational numbers, and a, b are lines commensurable in square,

namely there are natural numbers M, N, such that $a^2/b^2 = M/N$.

[2] We employ *Pythagorean application of areas in defect with data qb and pa*/2.

Since $qb > pa$, it follows that $qb/2 > pa/2$, and hence an application of areas in defect with these data is possible.

[3] We form *the circle* with diameter qb, we take the height $pa/2$, and

form *the right triangle*, with hypotenuse the diameter qb,

and third point the point where the height $pa/2$ meets the circumference.

[4] We set Φ to be one of the sides of the right triangle, so that $\Phi^2 = (qb - x)qb$, and

Ψ the other side, so that $\Psi^2 = qbx$.

We then verify all required conditions,

$(\Phi - \Psi)^2 = \gamma \cdot qb$,

$\Phi^2 + \Psi^2 = (qb)^2$, a rational area,

$\Phi\Psi = qb \cdot pa/2$, a medial area.

Proof of XIII.11 We verify that γ is a fourth apotome, and we apply the fundamental Proposition X.94 on γ.

9.4.3 The Special Application of Areas Introduced by Theaetetus in Book X, with Givens qb and pa/2, in Notation of Sect. 9.4.2, Is Such That the Anthyphairesis of the Solution x to b Is Eventually Periodic

The following proposition clarifies the role played by the *special* Pythagorean application of areas appearing in Proposition X.94,

namely a Pythagorean application of areas in defect with data two lines qb and $pa/2$ that are not in arbitrary relation, as in a general application of areas, but are *commensurable in square*.

The effect of this condition is to produce an equation of the form

$$Ax^2 + Cb^2 = Bxb,$$

with natural numbers A, B, C as coefficients.

Finally, such an application of areas produces an anthyphairesis of x to b that is eventually periodic.

Proposition If γ is a *fourth (simple) apotome*, $\gamma = qb - pa$,

where q, p are rational numbers, and a, b are lines commensurable in square, namely there are natural numbers M, N, such that $a^2/b^2 = M/N$, then the *Pythagorean application of areas in defect* with data qb and $pa/2$

(a) leads to the construction of a line x, such that

$$x(qb - x) = p^2a^2/4 = \left(p^2M/4\,N\right)b^2, \text{namely}$$

$$x^2 = qxb - \left(Mp^2/4\mathrm{N}\right)\cdot b^2;$$

(b) the *discriminant* Δ of this application of areas is equal to

$$\Delta = \left(q^2 - M/4Np^2\right)b^2; \text{and}$$

(c) the anthyphairesis of x to b is *eventually periodic*.

We note that because of the commensurability in square of a, b, the application of areas has *natural numbers* as coefficients.

(corresponding, by setting $\omega = x/b$,

to a second degree equation $\omega^2 - q\omega + Mp^2/4N = 0$ with integer coefficients).

The *proof of the proposition* is a straightforward consequence of

the invariance of the discriminant under anthyphairetic substitution (no use is made of the conjugation theory) with a pigeonhole argument. The details are omitted.

9.4.4 The Interpretation of the *Anonyma Scholia X.135, 185* to the *Elements*

In turn the proposition, establishing the periodicity of anthyphairesis, produced by this special application of areas, provides a satisfactory interpretation of the hitherto mysterious philosophically phrased *Scholia X.135, 185* to the *Elements*.

Scholion in Euclid's Elements X.135, 1–9.
It is worthy of admiration (Θαυμάζειν ἄξιον), that
the ruling, controlling power (κρατητικὴ δύναμις) of the triad (τῆς τριάδος)
finitises (ἀφορίζει) the alogos power (ἄλογον δύναμιν) and
reaches (διήκει) till the extremes (μέχρι τῶν ἐσχάτων),
because each kind of alogia (ἀλογίας) is *finitised (ἀφορίζεται)* by some mean (μεσότητος),
one by the geometric (γεωμετρικῆς) mean, the other by the arithmetical (ἀριθμητικῆς) mean,
the other by the harmonic/musical (μουσικῆς) mean;
and it seems that the substance of the soul sittting upon (ἐπιβατεύουσα) the substance of the magnitudes according to the "logoi" of the soul (κατὰ τοὺς ἐν αὐτῇ λόγους)
finitises (ὁρίζειν) everything indefinite (ἀόριστον) and the infinite of the alogia (τὴν τῆς ἀλογίας ἀπειρίαν)
by means of these three bonds (δεσμοῖς).

Scholion in Euclid's Elements X.185
holding together (συνέχουσα) its scattered and divided quality (τὸ σκεδαστὸν αὐτῆς)

According to these *Scholia*, phrased in the language of platonic philosophy, some power controls and *finitizes* the anthyphairetic infinity present in each of the 13 (1 medial, 6 additive, 6 subtractive) *alogoi lines*, by means of the three bonds (of addition, subtraction, and geometric mean). The finitization can only refer to some form of *anthyphairetic periodicity.*

The only anthyphairetic periodicity present in the alogos line minor is the anthyphairetic periodicity produced by the special Pythagorean application of areas in defect provided by X.94, according to the proposition above.

9.4.5 The Answer to the Question in 8.4.1: The Purpose of the Introduction of Application of Areas in Book X Is the Extension of the Quadratic Anthyphairetic Periodicity to the Canonical Solids

Since, according to Proposition XIII.16, the side, edge of the 20hedron is a minor wrt the diameter of the sphere in which the 20hedron is comprehended; it follows that the finitizing power of periodic anthyphairesis is present and dominates the canonical solids. This is precisely our interpretation of the purpose of the introduction of application of areas in Book X.

9.4.6 The Answer Given in Sect. 9.4.5 Should Be Understood in Context to the Successes of the Non-Anthyperetic Approach by Archytas and Eudoxus in Various Basic Questions

Despite a claim to the contrary in the *Theaetetus* 148b2 ("καὶ περὶ τὰ στερεὰ ἄλλο τοιοῦτον"), Theaetetus failed to extend the quadratic, plane periodic anthyphairesis to a cubic stereometry, since in fact it does not hold. Theaetetus' anthyphairetic method of proof on quadratic incommensurabilities does not extend to cubic incommensurabilities.

Soon after, an alternative, antagonistic *non-anthyphairetic approach to incommensurabilities* took place, proposed by *Archytas* and his student Eudoxus.

Archytas succeeded in achieving arithmetical, non-anthyphairetic proofs, not only of quadratic incommensurabilities, first shown in terms of periodic anthyphairesis by Theaetetus, but also of cubic incommensurabilities, as Theaetetus could not do. The proofs were based on Proposition VII.27 (if a, b are relatively prime numbers, then a^n, b^n are relatively prime for any number n as well), and its derivative Proposition VIII.14, on the existence of an arithmetical mean proportional for the plane case, and two *arithmetical mean proportionals* for the cubic incommensurabilities.

Archytas' incommensurability proofs were criticized by Plato in the *Philebus* 16c5-17a5 as "eristic," "non-dialectical" proofs.

Soon after, *Eudoxus,* a student of Archytas, developed a *non-anthyphairetic approach to the theory of ratios of magnitudes*, replacing the limited anthyphairetic theory by Theaetetus, exposed in Book V of the *Elements*, foreshadowing Dedekind

cuts. Eudoxus theory was sharply criticized in *Anonymon Scholion X.2* to the *Elements* by circles close to Plato.

The new theory of ratios by Eudoxus made possible *Archytas'* ingenuous *non-anthyphairetic approach to duplication of the cube* by means of constructing two mean proportionals (as initially conceived by Hippocrates).

Archytas' duplication of the cube was clearly criticized by Plato in the *Politeia* 527d-528d (Plato 1969) and by Plutarch, in *Quaestiones Convivales* 718 B8-F4.

(In this section we follow Negrepontis 2019, pp. 83–86, where the reader can find more details).

All these successes by Archytas and Eudoxus have put Theaetetus and Plato in the defensive, and in need of some success of the anthyphairetic approach in solid geometry. Propositions X.94 and XIII.16, interpreted as in Sects. 9.4.4 and 9.4.5, are such results.

9.4.7 Passage *Meno* 86e-87b Shows Plato's Strong Interest for Theaetetus' Special Application of Areas in Defect in Book X

The *Meno* passage 86e-87b, generally considered mysterious, was shown in Negrepontis and Farmaki 2019, Sect. 7, to go from an application of areas in defect with data a and m, with $a/2 > m$, into a circle with diameter a and an inscribed (*right*) *triangle* with hypotenuse a and height $m/2$ (and not an isosceles one, as claimed there), establishing a close relation of the *Meno* passage with Propositions X.18 and X.33, preparatory for Proposition X.94. Plato is of course interested in Theaetetus' introduction of application of areas, since via them a finitization is achieved by means of periodic anthyphairesis.

9.4.8 Reappraisal of the Old Dispute About Geometric Algebra: Pre-Euclidean Application of Areas Is Mostly About Periodic Anthyphairesis and Secondarily Geometric Algebra

Our interpretation of the purpose of the application of areas in Book X forces a rather drastic reappraisal of the dispute on geometric algebra. This is the principal pre-Euclidean application of areas, and while Theaetetus is certainly practicing some geometric algebra, nevertheless his main interest is the periodic anthyphairesis of the application of areas. The purer occurrence of geometric algebra in the application of areas must perhaps wait until periodic anthyphairesis is no longer a main concern, e.g., in Apollonius.

9.4.9 The Purposes of Book X of the *Elements*

Book X is thus revealed to have a most exciting purpose: Supplying the tools for the statement and proof of the palindromic periodicity of the anthyphairesis of the quadratic irrationals and of the closely related solution of the Pell problem, and still further attempting to extend the anthyphairetic periodicity to space and the canonical solids. These purposes were hitherto unsuspected, as can be seen by opinions expressed by authors who have studied Book X, such as:

van der Waerden (1950, p 172), who writes:

> "Book X does not make easy reading. . .The author succeeded admirably in hiding his line of thought".

Mueller (1981, pp. 270–271), who writes:

> "One would, of course, prefer an explanation that invoked a clear mathematical goal intelligible to us in terms of our own notions of mathematics and which, under analysis, would lead univocally to the reasoning in book X. Unfortunately, book X has never been explicated successfully in this way nor does it appear amenable to explication of this sort. Rather, book X appears to be expedient for dealing with a particular problem and at the same time a mathematical blind alley";

Taisbak (Taisbak 1982, p 58), who must be credited with demystifying the mathematical structure of Book X., writes:

> "We are prepared to face the possibility that there was no other point than to entertain us with good logic";

Knorr (Knorr 1983, p 60), who writes:

> "The true merit of Book X, and I believe it is no small one, lies in its being a unique specimen of a fully elaborated deductive system of the sort that ancient philosophies consistently prized";

The first two purposes (palindromic periodicity, Pell) show that these and such statements must be rejected.

On the other hand, Weil thinks that its purpose is not to prove the strong palindromic periodicity theorem, but *only* to be useful for Book XIII. But Weil's thesis does not take into account the imitation by Plato of the Theaetetus' palindromicity Theorem in the *Politicus*, and our reconstructed proof. Weil's thesis is also rejected by the *Scholia X.135, 185* to the *Elements.*

The purposes of Book X are then the following:

(a) The proof of the strong Theaetetus' parindromic periodicity theorem

(tools needed include apotome X.73–78, binomial X.36–41, conjugacies X.112–114, uniqueness X.79–84, and invariance under commensurability X.103)

(b) The solution of the Pell problem for every non-square N

(tools needed include the classification for apotome X.84/85, constructions X.85–90, X.97 square of an apotome, and possibly X.91)

(c) The proof that some key three-dimensional, space constructions, such as the constructions of canonical polyhedra in Book XIII, have some connections with periodicity, and can be considered finitized, such as

(i) The side of the 20hedron is a "minor line" with respect to the diameter of the sphere in which the 20hedron is comprehended, defined in X.76, constructed in Proposition X.94

(ii) The side of the 12hedron is a "double" apotome (hence the need for a definition of the apotome more general than that of the simple apotome). The details of (c) (i) can be found in Negrepontis, Farmaki, Kalisperi, 2021.

10 The Problem of Pell in Hindu Mathematics

In this final section we will examine the nature of the Hindus' contribution to the solution of the Pell problem (A relevant preliminary study can be found in Brokou 2014). This contribution appears to have come in two stages, first by Brahmagupta in the seventh century AD who developed the *bhavana*, a technique of composition or squaring, and secondly by Bhaskara II in the twelfth century who was associated with the *cakravala* method, practiced with the auxiliary technique of *kuttaka* (Accounts of the method have been given by Singh (1983), Srinivasiengar (1988), Bhanu Murthy (1992), Emch et al. (2005), and Bhattacharyya (2009)). However, according to Weil (1984), *kuttaka* is entirely unnecessary, while various global and local shortcuts, while ingenious, nevertheless obscure the basic periodic nature of the *cakravala* method. The pure form of *cakravala* shows strong similarities to our reconstructed Theaetetus' periodicity proof of quadratic anthypairetic periodicity. We want to emphasize that we have no way of knowing if the origin of the methods developed by the Hindu mathematicians are in some way connected with Theaetetus' reconstructed proofs.

10.1 Reception of the Hindus' Solution to the Problem of Pell in Europe

We can imagine the astonishment of the European mathematicians with the circulation of Colebrooke's book in 1817. Pierre de Fermat in 1657 had solved the problem of Pell specifically for $N = 61$ and, with a letter to Frenicle had challenged him to solve, claiming "misleadingly, or rather mischievously" that he chose small numbers "pour ne vous donner pas trop de peine" (so you don't have too much pain) (Weil 1984, p 97), now it turned out that the very case of $N = 61$ was known to Bhaskara II at about 1150 (Colebrooke 1817, pp. 176–178)!

Hankel, a mathematician and historian of Mathematics, (Hankel 1874) would hail *bhavana* and *cakravala* as "the climax of all Hindu science," a method which "is beyond all praise; [and] is certainly the finest thing achieved in the theory of numbers before Lagrange."

> "der Glanzpunkt ihrer gesammten Wissenschaft ... Diese Methode ist über alles Lob erhaben; sie ist sicherlich das Feinste, was in der Zahlentheorie vor Lagrange geleistet worden ist." (Hankel 1874, pp. 200–202)

However, a little later, Tannery (Tannery 1882, p 325) hypothesized that the Hindu indeterminate analysis had Greek origin, and that with the aid of the Greek rules for approximation one could "by simple steps" pass to the Indian method. Weil writes (Weil 1984, p 19):

> Tannery seems to have... entertained the hope that the solution would some day re-appear with the lost books of Diophantus; so far no evidence for this has been forthcoming.

> Equations of the type $x^2 - Ny^2 = 1$ do occur in Diophantus (e.g. in *Dioph*.V.9 and 1 l), but it is a rational solution that is asked for, even when accidentally a solution in integers is obtained (e.g. in *Dioph*.V.9, where N is of the form $m^2 + 1$, giving $y = 2\ m$, $x = 2\ m^2 + 1$).

Van der Waerden (1976) argues in favor of the Greek origin of Brahmagupta's astronomy:

> "The main subject of Brahmagupta's treatise is astronomy. His astronomical system is based upon the epicycle hypothesis, which is a Greek invention. As one of his tools, Brahmagupta uses a table of sines. The Greeks had tables of chords, which can easily be transformed into tables of sines.
> Some eighty years before Brahmagupta, Varaha Mihira (see Selenius 1975, p 173) presented excerpts from five Siddhantas, one of which, the "Romaka-Siddhanta" was based on the solar and lunar theory of Hipparchos, while another Siddhanta is ascribed to "Paulisa the Greek" (Shukla 1954, p 10). Hence the astronomy and the mathematical tools of the Hindus in the time of Brahmagupta and before were largely derived from Greek sources.
> This makes it even more probable that the Hindu methods of solving Pell's equation also go back to Greek sources."

The arguments by Tannery and van der Waerden were not considered convincing.

We saw in Sect. 5 that Weil did not believe that the conjugation Propositions X.112–114 of Book X of the *Elements* were used for the proof of the periodicity of the quadratic continued fractions/anthyphairesis, and that therefore the Hindu contribution should be considered original. Weil further commented on the "experimental," as he thought, nature of the method of the Hindus, without any proofs, marking nevertheless a "no mean achievement."

> *Firstly,* the facts for which we have just given proofs may have been known to the Indians only experimentally; there is nothing to indicate whether they had proofs for them, or even for part of them.
> For the Indians, of course, the effectiveness of the *cakravala* could be no more than an experimental fact, based on their treatment of a great many specific cases, some of them of Considerable complexity and involving (to their delight, no doubt) quite large numbers.
> As we shall see, Fermat was the first to perceive the need for a general proof, and Lagrange the first to publish one.
> Nevertheless, to have developed the *cakravala* and to have applied it successfully to such difficult numerical cases as $N = 61$ or $N = 67$ had been no mean achievement.
> (Weil 1984, p 24)

10.2 Brahmagupta's *Bhavana*/Composition

10.2.1 Brahmagupta's *Bhavana*/Composition in Colebrooke 1817

Brahmagupta introduces the subject of the resolution of the *varga-prakṛti* (rendered as "affected square" by Colebrooke 1817, or "square-nature" by Weil 1984 p 21, to refer to the general Diophantine equation $q^2 = Np^2 + \lambda$, where N: non-square integer > 1, λ integer and (q, p) a pair of desired integer solutions – cf. Raghavan 1997, p 1008) by presenting an interesting rule (*bhavana* in Sanskrit), according to

which two pairs of already known solutions not necessarily of the same λ are composed and as a result a new pair of solutions is produced, having $\lambda\lambda'$ as the constant term:

> RULE §39–40:
> A root [is set down] two-fold: and [another, deduced] from the assumed square multiplied by the multiplier, and increased or diminished by a quantity assumed.
> The product of the first [pair], taken into the multiplier, with the product of the last [pair] added, is a "last" root.
> The sum of the products of oblique multiplication is a "first" root.
> The additive is the product of the like additive or subtractive quantities.
> The roots [so found], divided by the [original] additive or subtractive quantity, are [roots answering] for additive unity. (Colebrooke 1817, p 363)

The correspondence between the terminology of Coleberooke translating Brahmagupta and the one we are going to use is presented below:

N: "multiplier" (gunaka in the Sanskrit text)
q: "last root"
p: "first root"
λ: "additive or subtractive" (ksepa, praksepa, or praksepaka for Brahmagupta)

10.2.2 Brahmadupta's *Bhavana*/Composition in Modern Notation

Definition. If N is a non-square number and (q, p) a dyad of natural numbers, the *Pell number* of (q, p) with respect to N is $\lambda = q^2 - Np^2$

We note that the Pell number of a dyad is either positive or negative.

The Pell number of the dyad (q, p) coincides with the Pell number Pell(γ) of the simple apotome $qb - pa$ if $qb > pa$ or $pa - qb$ if $pa > qb$.

*Definition of the Brahmagupta's general bhavana/composition rule * for non-square N.* If (q, p) is a dyad with N-Pell number $\lambda = q^2 - Np^2$ and (q', p') a dyad with N-Pell number $\lambda' = q'^2 - Np'^2$, then the dyad $(q'' = qq' + Npp', p'' = qp' + pq')$ has N-Pell number $\lambda'' = \lambda\lambda'$. We write $(q, p)*(q', p') = (qq' + Npp', qp' + pq')$.

*Definition of the Brahmagupta's square bhavana/composition rule * for non-square N.* For the special case where $q' = q$, $p' = p$ and $\lambda' = \lambda$, the dyad resulting from the rule takes the form $q'' = q^2 + Np^2, p'' = 2pq$, with N-Pell number $\lambda'' = \lambda^2$. We write $(q, p)*(q, p) = (q^2 + Np^2, 2pq)$.

10.2.3 The Close Connection of Brahmagupta's General *Bhavana*/Composition and Square *Bhavana* Rule with the Composition and Squaring of Simple Apotome Lines in Book X and Especially Proposition X.97 of the *Elements*

It is difficult to see how Brahmagupta came up with the *bhavana* definition

$$(q,p)*(q',p') = (qq' + Npp', qp' + pq').$$

But the definition becomes natural if we consider it as the arithmetical version of the extended to non-squares geometric Proposition X.97 of the *Elements* for simple apotomae lines:

$$(qb - pa)(q'b - p'a) = ((qq' + Npp')b - (qp' + pq')a)b.$$

The *bhavana*/composition rule plays a basic role in Bhaskara's *cakravala* process, as we shall see in the next section.

10.2.4 Some Examples Worked Out by Bragmagupta

[1]. The Pell problem for $N = 83$: to find natural numbers q, p, such that $q^2 - 83p^2 = 1$.
Brahmagupta starts with the dyad (9, 1).
Then he composes the dyad (9, 1) with itself according to square *bhavana* (Sect. 10.2.2), and finds
(9, 1) * (9, 1) = (164, 18), whose Pell number is 164^2–$83 \cdot 18^2 = 4$.
Then, dividing by 4, the dyad (82, 9), has Pell number $82^2 - 83 \cdot 9^2 = 1$, solving the equation $q^2 = 83p^2 + 1$. Therefore, setting $q = 82$, $p = 9$, he obtained $q^2 - 83\mathrm{p}^2 = 1$.

[2]. The Pell problem for $N = 92$: to find natural numbers q, p, such that $q^2 - 92p^2 = 1$.
Normally the initial step would be the dyad (9, 1), since 9 is the greatest number whose square 81 is less than $N = 92$, but, thanks to a shortcut (explained in Sect. 10.2.5 below), since $10^2 - 92 = 8 < 11 = 92$–9^2, Brahmagupta goes to the dyad (10, 1), whose Pell number is 10^2–$92 \cdot 1^2 = 8$.
Brahmagupta composes the dyad (10, 1) with itself according to square *bhavana* (9.2.2), and finds
(10, 1) * (10, 1) =
(192, 20), with Pell number 192^2–$92 \cdot 20^2 = 8^2 = 64$.
Dividing by 8^2 we get 24^2–$92 \cdot (5/2)^2 = 1$.
We have arrived at a dyad with Pell number 1, but this is not an integral, but a fractional, dyad, (24, 5/2) that has Pell number 1.
Brahmagupta again composes the dyad (24, 5/2) with itself according to square *bhavana* (9.2.2), and finds
(24, 5/2)*(24, 5/2) =
$(24^2 + 92 \cdot (5/2)^2, 2 \cdot (5/2) \cdot 24) = (576 + 575, 120) = (1151, 120)$.
Therefore, setting $q = 1151$, $p = 120$, he obtained $q^2 - 92p^2 = 1$.

10.2.5 Some Reductions by Brahmagupta Employing Square *Bhavana*/Composition

If, for some non-square number N, a dyad can be found with Pell number either
-4, or $+4$, or -2, or $+2$, or -1,
then by repeated use of Brahmagupta's square rule,

it is possible to find a dyad with Pell number +1, thus solving the Pell problem.

We will verify the Brahmagupta's reduction rules, by employing Proposition X.97.

[1] *Reduction from Pell(d) = − 4 to Pell(e) = 4, employing Proposition X.97.*

Let $d = pa - qb$ be an integral simple apotome, with $a^2 = Nb^2$, N non-square, and with assumed line b, such that $\text{Pell}(d) = q^2 - p^2N = -4$.

We note that the line d is a fifth apotome (in the sense of the definitions X.84/85 of the *Elements*).

Set f be the line such that $d^2 = fb$.

By Proposition X.97 of the *Elements*, we have,

since $p^2N + q^2 = 2q^2 + 4 = 2(q^2 + 2)$, that

$$d^2 = (pa - qb)(pa - qb) = \left(\left(p^2N + q^2\right)b - 2pqa\right)b$$
$$= \left(2\left(q^2 + 2\right)b - 2pqa\right)b, \text{hence}$$
$$f = 2\left(q^2 + 2\right)b - 2pqa, \text{and}$$
$$\text{Pell}(f) = (\text{Pell}(d))^2 = \left(p^2N + q^2\right)^2 - 4p^2q^2N = \left(p^2N - q^2\right)^2 = 16.$$

Set $e = f/2$.

Then e is an integral simple first apotome, with $\text{Pell}(e) = 4$.

[2] *Reduction from Pell(d) = −2, to Pell(e) = 1, employing Proposition X.97.*

Let $d = pa - qb$ be an integral simple apotome, with $a^2 = Nb^2$, N non-square, and with assumed line b, such that and $\text{Pell}(d) = q^2 - p^2N = -2$.

We note that the line d is a fifth apotome (in the sense of the definitions X.84/85 of the *Elements*).

Set f be the line such that $d^2 = fb$.

By Proposition X.97 of the *Elements*, we have,

since $p^2N + q^2 = 2q^2 + 2 = 2(q^2 + 1)$, that

$$d^2 = (pa - qb)(pa - qb) = \left(\left(p^2N + q^2\right)b - 2pqa\right)b$$
$$= \left(2\left(q^2 + 1\right)b - 2pqa\right)b, \text{hence}$$
$$f = 2\left(q^2 + 1\right)b - 2pqa, \text{and}$$
$$\text{Pell}(f) = (\text{Pell}(d))^2 = \left(p^2N + q^2\right)^2 - 4p^2q^2N = \left(p^2N - q^2\right)^2 = 4.$$

Set $e = f/2$.

Then e is an integral simple first apotome, with $\text{Pell}(e) = 1$.

[3] *Reduction from Pell(d) = 4 to Pell(e) = 1, employing Proposition X.97 and its generalization for different apotomae.*

Let $d = qb - pa$ be an integral simple apotome, with $a^2 = Nb^2$ and with assumed line b such that $\text{Pell}(d) = q^2 - p^2N = 4$.

We note that the line d is a first apotome (in the sense of the definitions X.84/85 of the *Elements*).

Set g be the line such that $d^2 = gb$.

By Proposition X.97 of the *Elements*, we have,

since $p^2N + q^2 = 2q^2 - 4 = 2(q^2 - 2)$, that

$$\begin{aligned} d^2 = (qb - pa)(qb - pa) &= \big(\big(q^2 + p^2N\big)b - 2pqa\big)b \\ &= \big(2\big(q^2 - 2\big)b - 2pqa\big)b, \text{hence} \end{aligned}$$

$$g = 2\big(q^2 - 2\big)b - 2pqa, \text{and}$$

$$\text{Pell}(g) = (\text{Pell}(d))^2 = \big(q^2 + p^2N\big)^2 - 4p^2q^2N = \big(p^2N - q^2\big)^2 = 16.$$

Set $h = g/2$.

Then h is an integral simple first apotome, with $\text{Pell}(h) = 4$.

Employing the generalization of the Proposition X.97 for the apotomae d and h, we have

$$\begin{aligned} dh &= (qb - pa)\big(\big(q^2 - 2\big)b - pqa\big) \\ &= \big(\big(q\big(q^2 - 2\big) + Np{\cdot}pq\big)b - \big(q{\cdot}pq + p\big(q^2 - 2\big)\big)a\big)b = \\ &= \big(\big(q\big(q^2 - 2\big) + \big(q^2 - 4\big)q\big)\big)b - \big(q^2p + p\big(q^2 - 2\big)\big)a\big)b \\ &= \big(q\big(2q^2 - 6\big)b - p\big(2q^2 - 2\big)a\big)b = \\ &= \Big(4q\big(q^2 - 3\big)^2b - 4p\big(q^2 - 1\big)a\Big)b. \end{aligned}$$

$$\begin{aligned} \text{Pell}(dh/b) &= q^2\big(2q^2 - 6\big)^2 - Np^2\big(2q^2 - 2\big)^2 \\ &= q^2\big(2\big(q^2 - 3\big)\big)^2 - \big(q^2 - 4\big)\big(2\big(q^2 - 1\big)\big)^2 = \ldots = 16. \end{aligned}$$

Set $e = q(q^2–3)^2b - p(q^2 - 1)$a; then e is a simple first apotome, with $\text{Pell}(e) = 1$.

The remaining *bhavana* rules are shown in a similar way.

10.2.6 Brahmagupta's Reduction Rules and Palindromicity

Although all the Brahmagupta's Reduction rules follow essentially from Proposition X.97, it is nevertheless not easy to explain the mathematical reason that makes these rules work.

The rules for the dyads with Pell numbers +4, or −2, or 2, or −1 appear to rely on the *palindromic* periodicity, since the first semiperiod determines completely the full period, exactly because of palindromicity.

The rule from a dyad with Pell number -4 to a dyad with Pell number 4 is interesting because a Pell number -4 can occur early in the anthyphairesis of $a^2 = Nb^2$ (e.g., as we shall see below the third step of the anthyphairesis for $N = 61$ has Pell number -4, while the length of the whole period is 11). The argument of the case [1] in Sect. 10.2.5, together with the rule from Pell number 4 to Pell number 1, shows that the whole quadratic anthyphairesis is determined by the time we find a dyad with Pell number -4.

Thus the Brahmagupta reduction rules, for a non-square number N, rely on the palindromic periodicity of the anthyphairesis of a to b, with $a^2 = Nb^2$.

10.3 The Unknown Origins of *Cakravala*

The greatest known contribution to the *cakravala* method is due to Bhaskara II, a Hindu mathematician of the twelfth century AD. But he is not the originitator of this method.

Bhaskara II in his *Lilavati* and *Bija-ganita* (1150 AD) ascribed the solution of *varga-prakrti* to earlier writers (Selenius 1975, p 168).

Indeed, the "principle of composition" or *bhavana* goes back to Brahmagupta's *Brahmasphuta-siddhanta* (628 AD) (Colebrooke 1817, p 363). As for the *cakravala* method, its first known occurrence is found in the work of *Acarya Jayadeva*, who, according to Selenius (1975, p 168):

> "lived about 1000 or earlier, at least 100 years before *Bhaskara II.* His work is quoted and explained with illustrations in the Sundari [Shukla 1954, p.1-4], written in 1073 by Srimad Udayadivakara as a commentary on the *Laghu-Bhaskariya* of Bhaskara I (629)."

However, Bhaskara II does not explicitly mention Jayadeva (Dutta 2010, p 156), who, was anyway an "otherwise unknown author," as pointed out by Weil (1984, p 22). Thus, the originator of such a momentous mathematical discovery, as the *cakravala* method (that in principle is powerful enough to solve the general Pell problem), is considered as not yet known:

> With this, one is still far short of the general solution; since Colebrooke it has been known that such a one is to be found in the work of Bhaskara (twelfth century; Col. pp.170–184; cf. Datta and Singh, 1oc.cit. pp. 161–172), but an
> almost identical presentation has now been found, attributed to an otherwise unknown author Jayadeva, in a commentary of the eleventh century (cf. K. S. Shukla, Ganita 5 (1954), pp. 1–20). Both authors describe the method as "the cyclic process" (cakravala, from cakra, a wheel). Its true *originator remains unknown*. (Weil 1984, p 22)

Dutta (2010), agreeing with Weil that the originator of *cakravala* is not known, writes on the subject:

> The discovery [of cakravala] took place sometime during the 7th−11th century... However, the true originator is not known. (p 148)

> The *Bijaganita* of Bhäskara II contains – apart from basic results of algebra - a lucid exposition of the *kuttaka, bhavana* and the *cakravala,* and mentions several other indeterminate equations. Bhäskara II attributes the *cakravala* to ancient authors without specifying any name. At the end of his treatise, Bhäskara II makes a general acknowledgement of the prolific algebra works of Brahmagupta, Sridhara and Padmanabha as his chief sources. There is therefore a strong possibility that the lost treatises of Sridhara and/or Padmanabha too contain an account of the *cakravala* algorithm. The history of cakravala became more mysterious with the discovery (in 1954) of a work dated 1073 CE which quotes verses from a preceding algebraist Jayadeva describing the cakravala algorithm (along with the bhavana). Curiously, Jayadeva is not mentioned by Bhäskara. (p 156)
> In 1954, K.S. Shukla discovered the text *Sundari* (1073 CE) of Udaydivakara, a commentary on the *Laghu-Bhaskariya* of Bhaskara and found that it contains quotations from a hitherto unknown mathematician called Jayadeva on the *bhavana* and the *cakravala.* He published the verses in [Shul]. (p 159)

10.4 A Simple Key Proposition, Deduced from the Reconstructed Proof of the Theaetetus' Periodicity Theorem, Shows Its Connection with *Cakravala*

Before examining the *cakravala* method we will state and prove a simple proposition that follows from the reconstructed anthyphairetic proof of the Theaetetus' periodicity theorem (Sect. 5). It will be the key to clarify the link between the reconstructed Theaetetus' proof and the Bhaskara's II approach.

Proposition Let N be a non-square number, $a^2 = Nb^2$, and
γ_n, I_n, λ_n, m_n as in Sect. 5. Then
[1] $\lambda_n + m_n > m_1$, hence $(\lambda_n + m_n)^2 > N$;
[2] if $(m_n + \lambda_n)^2 - N < N - {m_n}^2$, then $I_n = 1$, and hence $m_{n+1} = \lambda_{n+1} - m_n$.

Proof [1] Since $m_1 \geq m_{n+1}$,
we have $m_n + m_1 \geq m_n + m_{n+1} = I_n \lambda_{n+1} \geq \lambda_{n+1}$,
[using *Theaetetus' conjugation* (Sect. 5),
or the weaker statement that $m_n + m_{n+1} = a$ multiple of λ_{n+1}]
hence $\lambda_n\lambda_{n+1} > \lambda_n\lambda_{n+1} - \lambda_2 = (N - {m_n}^2) - (N - {m_1}^2) = {m_1}^2 - {m_n}^2 = (m_1 - m_n)(m_1 + m_n) \geq (m_1 - m_n)\lambda_{n+1}$,
hence $\lambda_n > m_1 - m_n$.
[2] We have $m_{n+1} + m_n = I_n \lambda_{n+1}$
[again employing *Theaetetean conjugation*]
$(\lambda_n + m_n) + m_n < 2\ \lambda_{n+1}$.
[Elementary computation employing $N - {m_n}^2 = \lambda_n\lambda_{n+1}$.
By the arithmetical form of Proposition II.4 of the *Elements*,
it follows from the assumption that

$$(m_n + \lambda_n)^2 - N = {m_n}^2 + {\lambda_n}^2 + 2\, m_n\lambda_n - N < N - {m_n}^2, \text{hence}$$

$$\lambda_n(\lambda_n + 2m_n) = {\lambda_n}^2 + 2\, m_n\, \lambda_n < 2\left(N - {m_n}^2\right) = 2\, \lambda_n\, \lambda_{n+1}, \text{hence}$$

$$\lambda_n + 2m_n < 2\, \lambda_{n+1}, \text{hence}$$

$$(\lambda_n + m_n) + m_n < 2\, \lambda_{n+1}.]$$

We now employ [1]: $m_{n+1} \leq m_1 < m_{n+1} + \lambda_{n+1}$
to obtain

$$m_{n+1} + m_n < 2\, \lambda_{n+1}.$$

It now follows that

$$I_n = 1, \text{and } m_{n+1} = \lambda_{n+1} - m_n.$$

Corollary 1 If $(m_1 + 1)^2 - N < N - {m_1}^2$,
then $I_1 = 1$, $\gamma_2 = b - \gamma_1 = b - (a - m_1 b) = (m_1 + 1)b - a$ and $m_2 = \lambda_2 - m_1$.

Corollary 2 (*characterization of* m_{n+1}). m_{n+1} is the greatest natural number m, such that $m \leq m_1$ and m is of the form $-m_n + k{\cdot}\lambda_{n+1}$ for some natural number k.

10.5 The Initial Step of the *Cakravala* Process

Weil 1984, pp 23–24: cakravala for non-square N invariably starts with a dyad (q, 1) such that q^2 is the closest square to N below or above. Thus in effect cakravala starts with the first or the second anthyphairetic remainder of the anthyphairesis of a to b, $a^2 = Nb^2$.

It is very important to make sure that the initial step of the *cakravala* method for a non-square number N always corresponds to the first remainder of the anthyphairesis of a to b, with $a^2 = Nb^2$.

10.5.1 Weil: The Initial Step of *Cakravala* Is Invariably Anthyphairetic

This calls for several observations.
"Secondly, in order to carry out the *cakravala* [for the non-square number N], one must have a starting point; *invariably* they [the Hindus] choose as such the triple $[(q, p_1 = 1; \lambda_2)]$ for which $[q^2]$ is the closest square to N, above or below.
it is easy to see that $[\lambda_2]$ is then $<2\sqrt{N}$. (Weil 1984, p 23)

[the words and symbols in brackets are added by the authors]

10.5.2 The Starting Dyad of the *Cakravala* Method

We set $a^2 = Nb^2$ and denote by γ_n the nth anthyphairetic remainder of the anthyphairesis of a to b.

It is clear that if q^2 is the closest square to N *below*, then $a - qb = \gamma_1$

(e.g., $N = 67$, $a - 8b = \gamma_1$).

But in case q^2 is the closest square to N *above*, then Bhaskara II takes the dyad $(q, 1)$, (e.g., $N = 61$, (8,1)). This appears to be a violation of the classical anthyphairesis (since, e.g., for $N = 61$, $a - 7b = \gamma_1$). The natural way would be to start with the pair (7, 1), whose Pell number is $7^2–61\cdot1^2 = -12$. However, Bhaskara II had a shortcut that allowed him to go automatically to the next step of the anthyphairesis, by noting that 61 is closer to 8^2 than to 7^2: $8^2–61 = 3 < 12 = 61–7^2$. In such a case the shortcut, described and shown in Sect. 10.4, Corollary 1, allows them to proceed immediately to the second stage with the dyad (8, 1). But in fact there is no violation of the classical anthyphairesis, only a shortcut. Thus, if q^2 is the closest square to N *above* then $qb - a = \gamma_2$, and the Bhaskara II dyad $(q, 1)$ is in fact anthyphairetic.

In order to solve the Pell problem for $N = 61$, Bhaskara II starts with the dyad (8, 1), which has positive Pell number $8^2 - 61\cdot1^2 = 3$.

If N is closest to the square number below, the first step of the anthypairesis is employed

($N = 67$ with initial triple (8, 1, −3), where $a^2 = 67b^2$, $\gamma_1 = 8a - b$)),

if N is closest to the square number above, the second

($N = 61$, with initial triple (8, 1, 3), where $a^2 = 61b^2$, $\gamma_1 = 7a - b$, $\gamma_2 = 8b - a$).

Thus Bhaskara II is careful to start with a triple corresponding to an anthyphairetic pair.

10.6 The Third Step of the Bhaskara's II *Cakravala* Process for *N* = 61 and Its Relation to the Reconstructed Theaetetus' Method

Before examining the general step of the *cakravala* method, it will be instructive to consider the third step of the *cakravala* method by Bhaskara II for the case of $N = 61$.

10.6.1 The Third Step of the Bhaskara's II Cakravala Process for N = 61

According to the Bhaskara's II *cakravala* process, we compose, with the Brahmagupta's *bhavana* process, the dyad (8, 1), with $\lambda = 8^2–61\cdot1^2 = 3$, with the dyad $(m_3/3, 1/3)$, where m_3 is to be determined by the *kuttaka* method:

$(8, 1)*(m_3/3, 1/3) = ((61 + 8\, m_3)/3, (m_3 + 8)/3)$.

The Diophantine equation for the "smallest root" is $3P = M + 8$.

Bhaskara II employs *kuttaka* method, Bachet-Bezout method (Bachet (1612)), based on the Euclidean algorithm Propositions VII.1 & 2 of *Elements*, an application that does not appear explicitly in Greek Mathematics, in order to find at least one integer solution. The *kuttaka* method is explained below in Sect. 10.7.2.

One solution by inspection, omitting *kuttaka*, is $M_0 = 1$, $P_0 = 3$.

Then every integral solution of the equation has the form:

$$M = 3k + 1,$$

$$[P = k + 3]$$

where $k = 0, \pm 1, \pm 2, \ldots$.

We find m_3 to be the solution m the makes $N - m^2$ minimum, the m such that $N > m^2$ and m greatest. It is clear that $k = 2$, $m_3 = 7$ is the required solution.

We find $p_3 = k + 3 = 2 + 3 = 5$, and $q_3 = 39$. Then Pell(39, 5) $= -4$

Now Bhaskara II follows the old *bhavana* rules by Brahmagupta, going from the dyad with Pel number -4 to a dyad with Pell number +4, and then further to the dyad ($q = 1\ 766\ 319\ 049$, $p = 226\ 153\ 980$) with Pell number +1.

By *bhavana*/composition of this pair with itself ad infinitum, we get an infinite multitude of pairs with Pell number 1.

10.6.2 The First Three Steps of the Reconstructed (in Sect. 5) Theaetetus' Method for $a^2 = 61b^2$

Computation of γ_1: $m_1 = 7$, $\gamma_1 = a - 7b = \varphi_1$

$$\text{Pell}(\gamma_1) = -12 = -\lambda_2$$

Computation of φ_2 by means of the conjugation form of anthyphairesis, $\varphi_1(I_1 b + \varphi_2) = b^2$.

We find that $\varphi_1(a + 7b) = a^2 - 7^2 b^2 = 61b^2 - 49b^2 = 12b^2$, hence

$$I_1 b + \varphi_2 = (a + 7b)/12 = b + (a - 5b)/12.$$

Thus $\varphi_2 = (a - 5\text{b})/12$.

$$\text{Pell}(\varphi_2) = -36/12 \cdot 12 = -1/4 = -\lambda_3/\lambda_2.$$

Computation of γ_2 by means of the formula $\gamma_1\ \varphi_2 = \gamma_2 b$:

$$\gamma_1\ \varphi_2 = (a - 7b)\ (a - 5b)/12 = \left(a^2 + 35b^2 - (12ab)\right)/12 = ((96b - 12a)/12)b = (8b - a)b.$$

Thus $\gamma_2 = 8b - a$.

$$\text{Pell}(\gamma_2) = \lambda_3 = 3.$$

Computation of φ_3 by means of the conjugation form of anthyphairesis, $\varphi_2(I_2 b + \varphi_3) = b^2$.

We find that $\varphi_2(a + 5b) = (61b^2 – 25b^2)/12 = 3b^2$, hence

$$I_2 b + \varphi_3 = (a + 5b)/3 = 4b + (a - 7b)/3.$$

Thus $\varphi_3 = (a - 7b)/3$.

$$\text{Pell}\,(\varphi_3) = -4/3.$$

Computation of γ_3 by means of the formula $\gamma_2\,\varphi_3 = \gamma_3 b$:

$$\gamma_2\,\varphi_3 = (8b - a)\,(a - 7b)/3 = \left(15ab - \left(a^2 + 56b^2\right)\right)/3 = ((15a - 117b)/3)b = (5a - 39b)b.$$

Thus $\gamma_3 = 5a - 39b$.

$$\text{Pell}\,(\gamma_3) = -4.$$

The close connection of the two approaches is evident.

10.7 The General *Bhaskara II Cakravala* Step

10.7.1 Description of the *Cakravala* Process by Bhaskara II/Colebrooke

Colebrooke (Colebrooke 1817, p. 175) quotes Bhaskara II in the extract below that describes the *cakravala* process:

> §83–86 Rule for the cyclic method:
> Making the "least" and "greatest" roots and additive, a dividend, additive and divisor,
> let the multiplier be thence found.
> The square of that multiplier being subtracted from the given coefficient, or this coefficient
> being subtracted from that square, (so as the remainder be small;)
> the remainder, divided by the original additive, is a new additive;
> which is reversed if the subtraction be [of the square] from the coefficient.
> The quotient corresponding to the multiplier [and found with it] will be the least root:
> whence the "greatest" root may be deduced.
> With these, the operation is repeated, setting aside the former roots and additive.
> This method mathematicians call that of *the circle* (Colebrooke 1817, p 175)

10.7.2 The General *Cakravala* Process with *Kuttaka* by Bhaskara II and Its Relation to the Reconstructed Theaetetus' Method

The starting point is a (q, p) N-dyad, with absolute value of its Pell number $q^2 - Np^2$ the natural number λ. As we have seen the initial choice of this N-dyad is not a random one, but an anthyphairetic, corresponding to the anthyphairetic remainder γ_1 or γ_2 of the anthyphairesis of a to b, where $a^2 = Nb^2$. We will prove that the resulting N-dyad is the one corresponding to the next anthyphairetic remainder. Thus we assume that $q = q_n, p = p_n$, where $\gamma_n = (-1)^n(q_n b - p_n a)$. In such a case $\lambda = \lambda_{n+1}$, the absolute value of

$$q_n{}^2 - Np_n{}^2.$$

The basic step of the Bhaskara's II *cakravala* process is a Brahmagupta-type composition with the dyad $(m/\lambda_{n+1}, 1/\lambda_{n+1})$, as follows:

$$(q_n, p_n)^* (m/\lambda_{n+1}, 1/\lambda_{n+1}) = ((mq_n + Np_n)/\lambda_{n+1}, (q_n + mp_n)/\lambda_{n+1}),$$

where m is a natural number to *be determined*.

The number m is determined by solving the Diophantine equation for the "smallest root," namely

$$\lambda_{n+1} P = Mp_n + q_n.$$

Bhaskara II employs first the *kuttaka* method, in order to find at least one integer solution, say P_0, M_0, so that we have $\lambda_{n+1} P_0 = M_0 p_n + q_n$. As already mentioned, the *kuttaka* method is based on the Euclidean algorithm (Propositions VII.1 & 2 of *Elements*), and constitutes an ingenious application that does not appear explicitly in Greek mathematics and is equivalent to the Bachet-Bezout method.

Then

$$\lambda_{n+1}(P - P_0) = (M - M_0)p_n$$

and employing Proposition VII.19 of Euclid's *Elements* we obtain

$$(P - P_0)/(M - M_0) = p_n/\lambda_{n+1}.$$

Since, the generalized side and diameter numbers p_n, q_n are relatively prime, it immediately follows that the numbers p_n, λ_{n+1} are relatively prime, and hence it follows, from the fundamental Proposition VII.22 of Euclid's *Elements*, that

$$P - P_0 = k\, p_n,$$

$$M - M_0 = k\, \lambda_{n+1}$$

for k any integer. Thus the general solution of the Diophantine equation is

$$P = P_0 + k\, p_n,$$

$$M = M_0 + k\, \lambda_{n+1}$$

for $k = 0, \pm 1, \pm 2, \ldots$.

Now let m be the *greatest* number that satisfies

$N - m^2 > 0$, $\lambda_{n+1}\, p = mp_n + q_n$.

(for simplicity we avoid the absolute values, a "local" shortcut employed by Bhaskara II, as Weil points out)

> ("Thirdly, the Indian prescription for choosing $\boldsymbol{x}$ within its congruence class modulo m is not quite what we have indicated above, since the rule is to make $N - \boldsymbol{x}^2$ 'small' (i.e., in actual practice, as small as possible), but, as the context shows, *in absolute value*; in other words,

one should substitute $\boldsymbol{x}_1 = \boldsymbol{x} + |\boldsymbol{m}|$ for x if ${x_1}^2 - N$ happens to be less than $N - x^2$. It can be shown that this *has merely the effect of abbreviating the procedure somewhat* when that is the case." (Weil 1984, p 24)).

But we now see, by Proposition of Sect. 10.5, that the number m satisfies

$$N - m^2 > 0,$$

$$\lambda_{n+1} p = m\, p_n + q_n,$$

but the immediately greater natural number m satisfying $\lambda_{n+1} p = m p_n + q_n$, namely the number $m + \lambda_{n+1}$, fails to satisfy $N - (m + \lambda_{n+1})^2 > 0$.

This proves that the *cakravala* number m coincides with the anthyphairetic number m_{n+1}, and thus the N-dyad produced by the *cakravala* process is precisely the dyad (p_{n+1}, q_{n+1}), corresponding to the anthyphairetic remainder γ_{n+1}.

10.7.3 *Cakravala*, Without *Kuttaka*, According to Weil 1984

But Weil shows that the *kuttaka* method is not an essential tool of the *cakravala* method, and it can be avoided (This was in fact shown earlier by Krishnaswamy Ayyangar (Krishnaswamy 1929–30).).

Weil: The Knowledge of the Rules

$m_{n+1} + m_n =$ multiple of λ_{n+1} and $m_{n+1} \leq m_1 < m_{n+1} + \lambda_{n+1}$,
which are used anyway in Bhaskara's II kuttaka approach to cakravala, makes kuttaka unnecessary

That being so, the *kuttaka* is of course *not needed* at the first step, since $q_0 = 1$;
but it is also *not needed* in any further operation,
since, if notations are as above, we have $p' - q'x = -qm'$,
so that at the next step one has to take $x' = -x \pmod{m'}$.
Strangely enough, this does not seem to have been noticed by any of our Indian authors (nor even by their later commentators, down to the sixteenth century); they make no mention of it, and invariably refer to the *kuttaka* for the choice of x, even though their abundant numerical evidence could easily have convinced them that *this was unnecessary.*
(Weil 1984, pp. 23–24)

Kuttaka Is Not Necessary for the *Cakravala* Process, According to Weil

We provide below the details of Weil's simple proof that the use of *kuttaka* is not necessary for the determination of the crucial number m_{n+1}. Both the *kuttaka* method and Weil's argument rely on the formulae $m_n + m_{n-1} = T_n \lambda_n$, a multiple of λ_n (1), and $m_n \leq m_1 < m_n + \lambda_n$ (2), which were derived in Sect. 5 and in Sect. 10.4.

Let N be a non-square number.

As we have seen the method of *cakravala* starts "invariably" with

$$\lambda_1 = 1, m_1, \text{such that}, {m_1}^2 < N < (m_1 + 1)^2, \text{and } q_1 = m_1, p_1 = 1.$$

[Consider above remarks, for the seemingly different choice e.g. for $N = 61$]

Inductively assume that for 1,2,. . .,*n*, λ_n, m_n, q_n p_n are natural numbers such that

$$m_n + m_{n-1} = T_n\lambda_n, \text{a multiple of } \lambda_n \ (1),$$

$$m_n \leq m_1 < m_n + \lambda_n \ (2),$$

$$\lambda_n q_n = m_n q_{n-1} + Np_{n-1}, \lambda_n p_n = q_{n-1} + m_n p_{n-1} \ (3).$$

$$\lambda_n \leq 2\, m_1 \ (4),$$

Defiition of λ_{n+1}. λ_{n+1} is the absolute value of the Pell number ${q_n}^2 - N{p_n}^2$ of the dyad (q_n, p_n).

Claim 1 $N - {m_n}^2 = \lambda_n\lambda_{n+1}$.[*Proof.* (q_{n-1}, p_{n-1})*$(m_n/\lambda_n, 1/\lambda_n) = (q_n, p_n)$.
By the multiplicative property of Pell numbers we have
$\lambda_n \cdot (N - {m_n}^2)/{\lambda_n}^2 = \lambda_{n+1}$, hence $N - {m_n}^2 = \lambda_n\lambda_{n+1}$].

Definition of m_{n+1}. We define m_{n+1} *the unique number* such that

$$m_{n+1} + m_n = T_{n+1}\lambda_{n+1}, \text{and}$$

$$m_{n+1} \leq m_1 < m_{n+1} + \lambda_{n+1}.$$

[With this definition of m_{n+1}, *kuttaka* is avoided, and according to Proposition of Sect. 10.4 this definition coincides with the dyad q_{n+1}, p_{n+1} in our reconstructed Theaetetus' proof of periodicity (Sect. 5)]

Definition of q_{n+1}, p_{n+1}. Define q_{n+1}, p_{n+1} by

$$\lambda_{n+1}q_{n+1} = m_{n+1}q_n + Np_n, \text{and}$$

$$\lambda_{n+1}p_{n+1} = q_n + m_{n+1}p_n.$$

[It is clear that this definition, on the one hand coincides with the Brahmagupta's *bhavana*

$$(q_n, p_n)*(m_{n+1}/\lambda_{n+1}, 1/\lambda_{n+1}) = \left(q_{n+1}, p_{n+1}\right), \text{and}$$

on the other hand coincides with the reconstructed Theaetetus' proof of periodicity (Sect. 5).

$$\gamma_n\varphi_{n+1} = (q_n b - p_n a)((a - m_{n+1}b)/\lambda_{n+1}) =$$

$$[((q_n + m_{n+1}\, p_n)a - (m_{n+1}\, q_n + Np_n)b)/\lambda_{n+1})b$$

$$= \left(\left(p_{n+1}a - q_{n+1}b\right)/\lambda_{n+1}\right)b = \gamma_{n+1}b].$$

Claim 2 q_{n+1}, p_{n+1} are natural numbers.

[Proof. $\lambda_{n+1}\, p_{n+1} = q_n + m_{n+1} p_n$

$$= (m_n q_{n-1} + N p_{n-1})/\lambda_n + m_{n+1}\, (q_{n-1} + m_n p_{n-1})/\lambda_n$$

$$= (m_n + m_{n+1}) q_{n-1}/\lambda_n + (N + m_{n+1}\, m_n) p_{n-1}/\lambda_n =$$

$$= T_{n+1}\, \lambda_{n+1}.q_{n-1}/\lambda_n + \left(N - {m_n}^2 + {m_n}^2 + m_{n+1}\, m_n\right) p_{n-1}/\lambda_n =$$

$$= T_{n+1}\, \lambda_{n+1}.q_{n-1}/\lambda_n + (\lambda_n\, \lambda_{n+1} + m_n\, (T_{n+1}\, \lambda_{n+1}))\, p_{\mathrm{n}-1}/\lambda_n$$

$$= \lambda_{n+1}\, (T_{n+1}\, q_{n-1}/\lambda_n + (\lambda_n + m_n\, T_{n+1})\, p_{n-1}/\lambda_n).$$

Hence, $p_{n+1} = T_{n+1}\, q_{n-1}/\lambda_n + (\lambda_n + m_n\, T_{n+1})\, p_{n-1}/\lambda_n$,
a natural number].
Similarly for q_{n+1}.

Claim 3 $\lambda_2 \leq 2\, m_1$.

[*Proof.* $N < (m_1 + 1)^2 = {m_1}^2 + 2\, m_1 + 1$,
hence $\lambda_2 = N - {m_1}^2 < 2\, m_1 + 1$,
hence $\lambda_2 \leq 2\, m_1$.]

Claim 4 $N - {m_n}^2 \leq 2\lambda_n m_1$.

[Proof. $N - {m_n}^2 < (m_1 + 1)^2 - {m_n}^2 = {m_1}^2 - {m_n}^2 + 2\, m_1 + 1$,

hence

$$N - {m_n}^2 \leq (m_1 + 1)^2 - {m_n}^2 - 1 = {m_1}^2 - {m_n}^2 + 2\, m_1.$$

By (2) $m_1 < m_n + \lambda_n$, hence $m_1 - m_n < \lambda_n$, hence $m_1 - m_n \leq \lambda_n - 1$.
Thus, by Claim 3,

$$N - {m_n}^2 \leq {m_1}^2 - {m_n}^2 + 2\, m_1 = (m_1 - m_n).(m_1 + m_n) + 2m_1 \leq$$

$$\leq (\lambda_n - 1)\, 2m_1 + 2m_1 = 2\lambda_n m_1].$$

Claim 5 $\lambda_{n+1} \leq 2m_1$.

[Proof. By Claims 1, 4, $\lambda_n\, \lambda_{n+1} = N - {m_n}^2 \leq 2\lambda_n\, m_1$,
hence $\lambda_n\, \lambda_{n+1} \leq 2\, \lambda_{n+1}\, m_1$, hence $\lambda_{n+1} \leq 2m_1$].

10.8 On the Cyclical Meaning of the Term *Cakravala*

The *cakravala* of Jayadeva and Bhaskara II is a general method for solving the *varga-prakrti*, the Pell problem. Why is it called by such a term implying *circularity,*

periodicity? Jayadeva or Bhaskara II do not give a reason for this terminology. Modern scholars have suggested that the method is called *cakravala* because of its *iterative* character:

> **"***Bhāskara II* provided *chakravāla* or *cyclic* process for the solution. *Chakravāla* means '*circle*'. It is observed that the same set of operations being applied again and again in a *continuous round* so the method is called *chakravāla*." (Datta and Singh 1938, p 162).

But this cannot be accepted as a satisfactory justification. For example, infinite anthyphairesis has an iterative character, but will never be described as cyclical unless it is periodic, a condition far stronger than infinite. In the same manner, the approximation of the area of a circle by say inscribed canonical polygons with number of vertices that doubles at every stage is clearly an iterative procedure, repeating itself ad infinitum, that would never be described as circular.

Weil suggests that the shortcuts employed by the Hindus, such as Brahmagupta's *bhavana*/composition rules (or those minimizing the absolute value of the distance of m^2 to N, we might add), ingenuous as they certainly are, tend to obscure the underlying periodicity; and that the periodicity to which *cakravala* refers is the anthyphairetic/continued fraction periodicity:

> Finally, we are told to iterate the process only till we find an "additive"
> m with one of the values $\pm 1, \pm 2, \pm 4$, and then to make use of the *bhavana*,
> i.e., of *Brahmagupta*'s procedure for that case.
> Actually this is no more than a shortcut,
> since it can be shown that the *cakravala*, applied in a straightforward manner,
> would inevitably lead to a triple (***p, q; 1***) as desired;
> while this shortcut is quite effective from the point of view of the numerical solution,
> it destroys the *"cyclic"* character of the method, which otherwise would appear from the fact
> that the "additives" ***m***, ***m', m''*** . . . would repeat themselves *periodically*,
> corresponding to the *periodicity* of the continued fraction of $\sqrt{N}$. (Weil 1984, p 24)

10.9 The *Cakravala* Method Appears to Have Similarities with the Reconstructed Theaetetus' Conjugacy Method

Weil has succeeded in presenting the *cakravala* method in pure form, stripped of the mathematically unnecessary *kuttaka* (Sect. 10.7.3), and unencumbered by ingenious shortcuts (that are in fact consequences of the reconstructed Theaetetus' conjugation method) that nevertheless obscure the periodic nature of *cakravala*.

The *cakravala* method in its pure form reveals close similarities with the reconstructed Theaetetus' conjugacy method presented in Sect. 5. Indeed, for a non-square number N, the *cakravala* process:

(a) Invariably starts with an arithmetized version ($q_1 = m_1, p_1 = 1$), [or else if N is nearer to $(m_1 + 1)^2$, with ($q_2 = m_1 + 1, p_2 = 1$)],

of the initial anthyphairetic remainder(s) $\gamma_1 = a - m_1 b$, or $\gamma_2 = (m_1 + 1)b - a$, respectively,

of the anthyphairesis of a to b, for $a^2 = Nb^2$ (Sect. 10.5).

(b) Proceeds inductively from the given dyad (q_n, p_n), whose Pell number ${q_n}^2 - N{p_n}^2$ has absolute value equal to λ_{n+1}, to the next dyad (q_{n+1}, p_{n+1}), with a Brahmagupta-type composition of the given dyad with the dyad $(m_{n+1}/\lambda_{n+1}, 1/\lambda_{n+1})$:

$$(q_n, p_n) * (m_{n+1}/\lambda_{n+1}, 1/\lambda_{n+1}) = \left(q_{n+1}, p_{n+1}\right),$$

where m_{n+1} is the greatest number satisfying the rule $m_n + m_{n+1} =$ multiple of λ_{n+1} and $m_{n+1} \leq m_1$.

This procedure appears close to the arithmetized version of the geometric rule $\gamma_n \varphi_{n+1} = \gamma_{n+1} b$, namely

$$(-1)^n (q_n b - p_n a)\, \varphi_{n+1} = (-1)^{n+1} \left(q_{n+1} b - p_{n+1} a\right) b,$$

where φ_{n+1} has been determined by the conjugation relation $\varphi_n (I_n b + \varphi_{n+1}) = b^2$, into which the anthyphairetic relation $\gamma_{n-1} = I_n \gamma_n + \gamma_{n+1}$ has been transformed and thus shown by conjugacy to have the form $\varphi_{n+1} = (a - m_{n+1}\, b)/\lambda_{n+1}$, where m_{n+1} is determined by the rule $m_n + m_{n+1} = I_n \lambda_{n+1}$, according to the Theaetetus' conjugacy method, as reconstructed in Sect. 5 (cf. Sects. 10.6, 10.7).

(c) Employs the term "*cakravala*," unmistakably indicating periodicity (and not just iteration).

This makes sense only as referring to the periodicity of the geometric anthyphairesis of a to b, for $a^2 = Nb^2$, and non-square number N. (Sect. 10.8)

11 Summary

In Sect. 2, the concept of geometric anthyphairesis is introduced as well as the consequent pre-Eudoxian, in fact Theaetetean, anthyphairetic definition of equality of ratios for magnitudes. The Logos Criterion for the periodicity of an anthyphairesis is also presented, as a natural consequence of the pre-mentioned definition.

In Sect. 3, the anthyphairetic base of the platonic philosophy is highlighted. Through the examples of the One of the second hypothesis in the *Parmenides* and the Divisions of the Angler and Sophist in the *Sophistes*, the following argument is supported: the basic entity in Plato's philosophical system, the intelligible Being, is a philosophical imitation of a dyad in periodic anthyphairesis.

In Sect. 4, the influence of Theaetetus' mathematical discoveries on Plato's later work is outlined. This influence is pointed out by Plato himself ("*πειρῶ μιμούμενος*"), in the *Theaetetus* 148d4-5. The philosophical statements closely

imitating Theaetetus' periodicity theorem are detected in both the *Politicus* 283a-287b (according to which intelligible Beings are generated by a double measurement: finite measurement and infinite generation) and the *Philebus* 16c, 23a-25e (where an intelligible Being is presented as the mixture of an anthyphairetic infinite/incommensurable and a finite/commensurable). It should be noted that Theaetetus' periodicity theorem, which is traced in semi-philosophical language in the *Theaetetus* 147c-148d, is the following: "if a, b are lines commensurable in power only, in particular if $a^2 = Nb^2$ for some non-square number N, then the anthyphairesis of a to b is periodic."

In Sect. 5, the reconstruction of the proof of Theaetetus' periodicity theorem takes place, by using tools found in the Theaetetean Book X of the *Elements* and more specifically the apotomae (Propositions X.73–107), the binomial lines (Propositions X.36–72), and their conjugation (Propositions X.112–114). The reconstruction is based on the realization that the anthyphairetic remainders γ_n of the anthyphairesis of a to b, for $a^2 = Nb^2$, N non-square, are simple apotome lines of the form $\gamma_n = (-1)^n(q_n b - p_n a)$, and that the anthyphairetic relations of the remainders ($\gamma_{n-1} = I_n\gamma_n + \gamma_{n+1}$) can be transformed into relations of conjugation $\varphi_n(I_n b + \varphi_{n+1}) = b^2$, with the necessary introduction of the reduced remainders φ_n defined by $\gamma_n\, \varphi_{n+1} = \gamma_{n+1}\, b$. It is noted that for the reconstruction, the *pigeonhole principle* is additionally needed, which is provided by Plato in the *Politicus* (272d-e).

In Sect. 6, it is shown that the definition of the Statesman in the dialogue *Politicus* is an imitation not only of periodic but *palindromically periodic* anthyphairesis. It is argued that Theaetetus had established the stronger palindromic periodicity theorem: "if $a^2 = Nb^2$, N non-square, then the anthyphairesis of a to b is palindromically periodic," a result that in modern era was gradually discovered by the work of Fermat, Brouncker, Lagrange, and Euler (seventeenth and eighteenth century).

In Sect. 7, the reconstruction of Theaetetus' strong theorem of palindromic periodicity takes place, using tools from the Book X of the *Elements* and the pigeonhole argument implied in the *Politicus*.

In Sect. 8, it is argued that Theaetetus had a strong motivation to deal with the Pell problem, since the case $N = 2$ was a venerated Pythagorean discovery not unnoticed by Plato (*Politeia* 546c), closely connected with their discovery of the periodicity of the anthyphairesis $a^2 = 2b^2$.

In Sect. 9, it is noted that the Pell property is actually included in the reconstructed proof of Theaetetus' palindromic periodicity theorem and thus the proof of the general Pell property (namely for every N non-square) is within easy reach. Hence it is assumed that Theaetetus had a proof for the general Pell property as well. It is argued that Theaetetus' preoccupation with the Pell problem can be indeed traced in Book X since the classification of apotome lines in six classes in X.84/85 makes sense only in relation to the Pell property. Specifically:

(i) The first and the fourth apotome are apotomae with *positive Pell number* (corresponding to the *even remainders* of the anthyphairesis of a to b for $a^2 = Nb^2$, N non-square, and b the assumed "one foot" line) while the second and the fifth with *negative Pell number* (corresponding to the *odd remainders*).

(ii) The first and the second apotome lines are those with *square Pell number*, the fourth and the fifth with *non-square Pell number*.

Moreover, Proposition X.97 produces an apotome with square Pell number from any apotome line.

Based on the above, a multidimensional but clear purpose can now be attributed to the Book X of the *Elements*: firstly, to provide the tools needed for the statement and proof of the palindromic periodicity of the anthyphairesis of quadratic irrationals and the closely related proof of the general Pell problem and secondly, to try to extend the anthyphairetic periodicity to space and the canonical solids.

In Sect. 10, the contribution of the Hindus to the Pell problem is presented and similarities between their methods and the reconstructed proof of Theaetetus are denoted. Specifically:

(i) The *bhavana* method of composition of Brahmagupta bears similarities to the arithmetized version of the geometric rule of "multiplying" simple apotomae or binomial lines, which is closely related to the Proposition X.97 of the *Elements*. *Bhavana* is applied as a rule of reductions for the solution of the Pell problem in cases where the Pell number is equal to -4 or $+4$, or -2 or $+2$, or -1.
(ii) The *cakravala*/circle method, mostly advanced by Bhaskara II, when studied stripped from the interfering (and mathematically unnecessary, as Weil remarks) method of *kuttaka* and from other (ingenious but disorientating) shortcuts, appears as the arithmetized version of the reconstructed conjugacy method used in the proof of the Theaetetus' palindromic periodicity theorem presented in Sect. 5.

Acknowledgments We express our warm thanks to Athanase Papadopoulos for encouragement and extensive and essential discussions that have led to a substantial improvement of our work.

Abstract

Śulbasūtras, which are compositions from the first millennium BCE, related to the activity of construction of *vedis* (altars) and *citis* (fireplaces) for the performance of *yajñas* (fire sacrifices), constitute a unique historical resource from India from the ancient times, with explicit mathematical content. They manifest familiarity with various geometric constructions and also geometrical principles, including what is now commonly known as Pythagoras theorem. The converse of the Pythagoras theorem played an important role in many of their practical constructions. The task of interrelating the square and the circle in terms of areas was also addressed by them, though in a limited practical context, and the pursuit also seems to have led them to quite an accurate approximation of $\sqrt{2}$.

Study of the Śulbasūtras in the modern framework began in the second half of the nineteenth century, with the work of George Thibaut. Since then four Śulbasūtras, Baudhāyana Śulbasūtra, Āpastamba Śulbasūtra, Mānava Śulbasūtra, and Kātyāyana Śulbasūtra, have been studied by various scholars, to varying degrees of detail. While on the one hand there have been several illuminating findings, on the other hand a variety of poorly substantiated claims and theories have also emerged in historical writings on them.

This chapter aims at presenting a reasonably comprehensive account of the mathematical contents of the Śulbasūtras, together with a critical review of

various inferences drawn in the literature, and bringing out the issues calling for further studies and clarifications. We highlight also the differences between the different Śulbasūtras and comment on their significance in various respects, an aspect which has not received much attention so far.

1 Introduction

Around the beginning of the first millennium BCE performance of *yajñas* (ritual fire sacrifices) seems to have acquired tremendous importance among the Vedic people in India. The *nitya* (literally meaning "perpetual" or "regular") *yajñas* performed by normal householders (from the priestly class) would have had a longer tradition, presumably going back to the Ṛgvedic period. Following the rise of the ritualism associated with the *yajurveda* (cf. Bloomfield 1908, p. 31), eventually the *kāmya yajñas* became one of the salient features of the Vedic culture. Here "*kāmya*" refers to being undertaken in pursuit of "desires," and the desires involved could relate to both spiritual objectives as well as material gains, and the latter could in turn be in terms of health and physical strength, wealth, political power, etc. The schemes for *kāmya yajñas* evolved as ambitious large-scale projects, with the involvement of the kings and the rich, and brought a great deal of material as well as intellectual resources into the activity. This led, on the one hand, to elaborate formulation of intricate operational details for the performance of *kāmya yajñas*, both in terms of the associated littany, ritual elements, as well as physical structures and arrangements to be adopted. On the other hand, it gave a fillip to the development of know-how in various respects, as an enabling factor in the projects contemplated. The *vedis* (altars) for the *yajñas* were raised areas, in specified shapes, of sizes often over 50 feet in length and breadth. There were designated spots marked on the vedis for performance of various ritual events involved. The *citis* (fireplaces) to be erected for the main sacrificial event were often in intricate shapes, of various birds, turtle, etc., with sizes of the order of 20 feet in length and 30 feet in width. The preoccupation with drawing figures on the ground on these scales seems to have brought in an understanding of various principles in planar geometry, as also some miscellaneous mathematical ideas. The Śulbasūtras form our main, and almost exclusive, source of this mathematical content; in respect of geometry, they constitute the earliest corpus from India (in absence of any significant inputs relating to the Indus valley civilization in this respect).

The Śulbasūtras form a section of the *Śrautasūtras*, which in turn are parts of *Kalpasūtras* belonging to the *Vedāṅga* (appendages of Vedas) literature. The

Śrautasūtras deal with various aspects of the performance of the *yajñas* including, in particular, the *mantras* to be chanted in the course of various rituals, while the Śulbasūtras are concerned primarily with various aspects of laying of the *vedis* and *citis* for the purpose. Apart from the details with regard to plotting and erecting the *vedis* and *citis*, the Śulbasūtras also include enunciation of the geometric principles and constructions involved. Also, aside from the explicitly articulated knowledge, there are various ideas discernible in other parts, which also form an integral part of the study of the mathematical contents of the Śulbasūtras.

The Vedic people were a heterogeneous community with numerous branches (*śākhās*), and while they shared a common body of knowledge, the individual branches had their respective compositions that they followed. Thus, it is quite plausible that there may have been numerous Śulbasūtras.[1] There are at present four Ślbasūtras that have been edited, translated into western languages, and have been studied to varying degrees: Baudhāyana Śulbasūtra, Mānava Śulbasūtra, Āpastamba Śulbasūtra, and Kātyāyana Śulbasūtra; three more have been named in Datta (1932), as being extant, which are by Maitrāyaṇa, Varāha, and Vādhula, and two others *Maśaka śulba* and *Hiraṇyakeśi śulba*, among those that are lost; and one other, *Satyāṣaḍha śulba,* is named in Kulkarni (n.d., p. III).[2]

The studies and writings on the mathematical contents of the Śulbasūtras have largely focused on the body of knowledge contained in them as a whole, a typical question addressed being whether one or other mathematical idea is found in (any one of) them. While some statements involving comparisons do come up in the literature, and also there are some tabular concordances produced (the latter notably in Kulkarni n.d.), a serious comparative study of them as independent compositions, and whether and what it may signify with regard to the activity as a whole, seems lacking so far. This aspect seems especially important on account of the fact that they belong to widely differing time periods, and the differences between them may relate, in one or more ways, to the overall developments and changes over the time period involved. In this context, our objective here will be twofold: One is to give a comprehensive introduction to the mathematical content of the Śulbasūtras, and the second is to provide a comparison between the four Śulbasūtras, with comments on the similarities and differences.

We begin in Sect. 2 by recalling some general details concerning the Śulbasūtras. The later sections are devoted to thematic description on various topics covered in the Śulbasūtras, paying attention also to the distinctive features of the individual Śulbasūtras.

[1] An estimate of over a thousand is cited in Datta (1932, p. 1) as the number of "schools," each one "with its own Śrautasūtra and hence probably its own Śulba" – it is however unclear how many of them would have been substantially distinct from each other.

[2] It is also mentioned in Kulkarni (n.d., p. III) that while they come from different *Kalpasūtra*s, thereby inheriting their names, the Satyāṣāḍha śulba is the same as the Āpastamba śulba and similarly Maitrāyaṇīya śulba is the same as Mānava śulba (though the larger works may have differences).

2 A General Introduction to Śulbasūtras

The four Śulbasūtras to be discussed, Baudhāyana Śulbasūtra, Mānava Śulbasūtra, Āpastamba Śulbasūtra, and Kātyāyana Śulbasūtra, we shall refer, for brevity, as BSl, MSl, ASl, and KSl, respectively. In this section, we recall various general details which will set the context for the discussion in the later sections.

2.1 Their Period and the Available Corpus on Them

Determination of the period of the Śulbasūtras has been a problematic issue, with no intrinsic clues available other than their style of language and grammar,[3] and the estimates of various scholars differ considerably. According to Plofker (2009), their approximate chronological order corresponds to what we have adopted in the listing above; this is also consistent with the discussion on the issue by Sen and Bag (1983). In the wider range of scholarly works involved, there is no consensus even about the century of individual compositions and also on the chronological precedence between MSl and ASl. A broad date-range is introduced in Kulkarni (n.d.), citing C. G. Kashikar (1966), as Baudhāyana (800–500 BCE), Āpastamba and Mānava (650–300 BCE), and Kātyāyana (300 BCE–400 CE), which it seems worthwhile to keep in mind, except that in the case of Kātyāyana, from the extended range suggested, the early part seems more appropriate, in the context of estimates from various other works (cf. Sen and Bag 1983, page 3, in particular).[4] These differences in the estimates with regard to their period will not be of consequence for our discussion in the following sections.

There have been several commentaries on these compositions. Their dates, especially of the notable ones, are uncertain however, for want of adequate inputs. Based on the works they cite, or allude to, most of them are inferred to be from the

[3] The reference to "style of language and grammar" here is in terms of the contents of the respective *Śrautasūtras* containing the respective śulbas, as a whole, and not just the śulbas. While this provides an advantage in terms of comparability, it brings in an issue whether the inferences drawn would apply equally to the corresponding śulbas. In the overall context, the śulbas which were typically the last sections of the Śrautasūtras, comparable to Appendices in modern works, and played largely a facilitating role, which may not have been considered as sacrosanct as the core body, and could have been subject to flexible updating. It may be noted that there has been at least one suggestion, by a commentator, Rāma of the *Kātyāyana Śrautasūtra*, believed to be from the fifteenth century, that the śulba in that work was perhaps composed by a different person (cf. Datta 1932, p. 12, where however the possibility has been discounted).

[4] It may however be recalled here that according to many early scholarly works, from the nineteenth and early twentieth century, the Śulbasūtras are from a somewhat later period than those indicated above; see the account on the question in Seidenberg (1975, Sect. 10), where the author recalls the estimates of various scholars. It may also be mentioned that the Chronology Committee of senior historians of science, formed in the 1950s following a symposium on History of Sciences in South Asia organized by the Indian National Science Academy (INSA) at Delhi, under the Chairmanship of R.C. Majumdar (Other members were A. S. Altekar, P. C. Bagchi, S. L. Hora, D. S. Kothari, and A. N. Singh) which considered dating of various historical stages in India, recommended 500 BCE and later as the period of the Śulbasūtras (cf. Gupta 1990, 2001).

second millennium CE, with a few possibly from the later part of the first millennium. The commentaries have played a very important role in the preparation of the modern editions of the works, it being a difficult task to make out the meaning and significance of various parts of the original texts, without the benefit of the interpretations in the commentaries; the reader is referred to Datta (1932) for a detailed discussion on the topic; see also (Delire 2003, 2009).[5] On the other hand, it needs to be borne in mind that the level of mathematics witnessed in the commentaries does not necessarily correspond to that of the originals, given especially the time gap. The commentators were not taking on the role of a historian but were acting as interpreters of the contents of the Śulbasūtras for the community engaged in pursuing the ritual activity, and their interpretations would naturally incorporate some of the mathematical knowledge accumulated by their time. The mathematical practices and trends had also seen major changes over the span of the millennium separating the originals and the commentators.[6] We shall however not go, in this review, into the details on these points, except for occasional references.

The first English edition of BSl was produced by George Thibaut, together with his commentary, in 1875 (cf. Thibaut n.d.-a). Thibaut also edited and translated into English the first two chapters of KSl (cf. Thibaut n.d.-b). The next to attract the attention of the global scholarship was ASl, of which a German edition, with commentary, was brought out by Albert Bürk in 1901 (cf. Bürk 1901). The first modern language edition of the Mānava Śulbasūtra arrived only in 1963, with Jeanette M. van Gelder's translation of (the larger work) *Mānava Śrautasūtras* (van Gelder 1963). English editions of BSl (including the commentary of Dvārakānatha Yajvan) and of ASl (with commentaries of Kapardisvāmin, Karavinda, and Sundararāja) were brought out in 1968 by Satya Prakash and Ram Swarup Sharma, in (1968a, b), respectively. A comprehensive edition on the four Śulbasūtras together, accompanied by translations and the authors' commentaries, was brought out by S.N. Sen and A.K. Bag in 1983 (Sen and Bag 1983).[7] A comprehensive edition of the four Śulbasūtras together with several useful tables and indices, and a concordance, was brought out by Raghunath Purushottam Kulkarni, in Marathi, which has subsequently been translated also in Hindi (Kulkarni n.d.). A critical edition with translation and commentary in French, of the Baudhāyana Śulbasūtra, together with the commentary

[5] In Delire (2009), comparing some parts of the text of *Śulbadīpikā*, Dvārakanātha's commentary on BSl, with Sundararāja's commentary on ASl the author infers that Dvārakānātha copied from Sundararāja (negating the view held by B. Datta that the latter copied from the former, and confirming R.C. Gupta's suggestion made earlier). Based on the conclusion the author revises David Pingree's estimate of *terminus post quem* for the former to the second half of the fifteenth century CE; we may also recall here that 1609 is argued as a *terminus ad quem*.

[6] It may be worthwhile to quote here the following from Thibaut (1875, p. 272): "Trustworthy guides as they are in the greater number of cases, their tendency of sacrificing geometrical construction to numerical calculation, their excessive fondness, as it might be styled, of doing sums renders them entirely misleading."

[7] It may be noted here, however, that while the commentaries on BSl and ASl are fairly detailed, those on the other two, especially MSl, have tended to be rather cursory, warranting a better treatment.

Śulbadīpikā of Dvārakānātha Yajvan, was brought out by Jean-Michel Delire in 2016 (Delire 2016).[8]

There have, of course, also been numerous descriptive accounts in various books (we may mention in particular (Srinivasiengar 1967; Amma 1979; Bag 1979; Kulkarni 1983; Plofker 2009; Puttaswamy 2012; Joseph 2016; Divakaran 2018), the summary accounts (Gupta 2001, 2006) on the topic) and several papers on themes related to the topic. The works that we refer to will be cited accordingly.

2.2 The Format

Like other *Vedāṅga* literature, the Śulbasūtras are composed mostly in the "sūtra" (aphorism) style prose, except for some parts in MSl, which are in verse form. "Sūtra" means thread, and the style involved endeavors to present the text through concise arrangements facilitating memorization and recitation, rather than adhering to a regular complete-sentence format for a narrative. It may be noted that the originals do not consist of individually numbered sūtras. The text of the respective originals has been divided in the modern expositions in convenient individual segments which have been enumerated as sūtras, and grouped into chapters; some of the original works also have divisions like chapters, but their scheme has not always been adhered to in the modern editions. Unfortunately there is considerable diversity in the schemes adpoted in the different expository works with regard to segmenting and numbeing of the sūtras, (Sen and Bag 1983; Prakash et al. 1968a; Kulkarni n.d.). For instance, Thibaut in (n.d.-a) adopted a division of BSl into three chapters, with 113, 83, and 323 numbered sūtras, respectively, adding to 519 sūtras, while on the other hand in (Sen and Bag 1983), which now serves as a standard reference, the material appears in 21 chapters adding to 285 sūtras; the authors however include with each sūtra the reference number from Thibaut, in parenthesis. To provide the reader an overall sense of the size of the works, let me also mention further that as presented in Sen and Bag (1983) MSl has 16 chapters adding to 228 sūtras, ASl has 21 chapters adding to 202 sūtras, and KSl has 6 chapters adding to 67 sūtras; except in a few cases, each sūtra is in one or two lines.

Here we shall primarily follow the numbering as in Kulkarni (n.d.), which from the author's point of view has the advantage that it provides the text of the Śulbasūtras in the Devanagari script. For BSl these numberings are according to Thibaut's, as may be referred from Sen and Bag (1983), and for MSl they correspond to van Gelder's numbering. The author hopes to publish in the near future a concordance between the numbering of the sutras in various sources of mathematical Śulbasūtras.

[8] Recently an edition of *Maitrāyaṇīya Śulbasūtra* was brought out by R.P. Kularia (Kularia 2016); the author however has not had an opportunity to access it, and as such its contents will not be reflected here.

2.3 The Role of Śulbasūtras

Equipping the people involved with constructions of *vedi*s and *citi*s, with the necessary skills, would have been the task before the composers of the Śulbasūtras. The śulbas however are not quite in the format of simply describing, sequentially and minimally, the steps to be taken toward the desired end output, in the style of manuals for assembling equipment etc., even though they have often been referred to as manuals, and though their basic purpose could have been served in this fashion as well. They are seen to take on a larger role; in the case of BSl and ASl, the presentation evidently manifests a certain purposefulness, with a pedagogical objective of disseminating also geometric understanding around the procedures described; and in the case of MSl, though one does not find any disciplined pursuit of a pedagogical objective, a good deal of geometrical knowledge is disseminated anyway, along with the operational details meant to be conveyed, in what seems like a chatty style. In KSl, one finds somewhat of a mixture of the two approaches. It may be noted that on the whole many of the geometric principles and constructions that have been articulated are not directly involved in following the procedures for laying out the *vedi*s and *citi*s. Thus, a more comprehensive approach is seen to be taken in the context, toward disseminating the accumulated knowledge, along with explication of the core operational part involved in the activity.

In BSl, an exposition of geometry is taken up systematically at the outset. The first two chapters, as set out in Sen and Bag (1983), with 25 sūtras (the number comes to 62 in Thibaut's edition), contain an exposition on geometry[9] (together with an introduction to units of measurement). This part could have, for instance, been adopted in the form of a textbook, by other sections of the society at the time, not concerned with the activity of laying out the structures involved in the rituals; whether this happened on any significant scale is something we may never get to know.

Much in the same way as BSl, ASl also includes a course on geometry, at the beginning, and while there are some significant differences between the two (which we will have occasion to discuss in the later sections here), the divergence is similar to what one would find between two textbooks on the same topic. The same however cannot be said of MSl and KSl. Indeed, a good fraction of the propositions appearing in BSl and ASl, and also some that are not part of them (as will be seen later), are found in MSl and KSl, but they turn up strewn across the narrative; significance of the spots where they appear would itself be an interesting issue for exploration. Many of these statements, though not all, also seem to be more brusque than the corresponding part in BSl and ASl. One may wonder whether this suggests that a

[9] A quick account of this part with translations of sūtras and a brief commentary may be found in Plofker (2007); I may add a small clarification that *nyañchana* refers to a mark made for the purpose of plotting points on the ground with respect to it, and is not a word for "mark," as may be suggested by the parenthetical reference there, on p. 388; also, it perhaps ought to have been highlighted that sutra BSl I.48 (in Thibaut's numbering as adopted here) corresponds to what is called the Pythagoras theorem.

degree of geometric understanding is viewed as a prerequisite, and the statements are being recalled briefly as recapitulation; the suggestion is not quite borne out consistently however, if one considers the details that the sutras go into in certain cases. We shall discuss this further when we get to the details.

2.4 Units of Measurement in the Śulbasūtras

Before proceeding further, it would be convenient to give an introduction to the units of measurements involved, to build up a basic familiarity with them. Interestingly, Baudhāyana Śulbasūtra begins, rather uniquely among the Śulbasūtras, with a detailed account of various units, which serves as a good reference for our context here; there are some variations involved in the usage of units in other Śulbasūtras, which also we will discuss briefly.

Among the principal units (in terms of their usage in the exposition as in BSl) are *aṅgula, prādeśa, pada, aratni*, and *puruṣa*. These are manifestly based on human anatomy; the terms, respectively, mean "finger," "span" (between the thumb and forefinger), "foot," "elbow," and "man"; the interrelation between them is set out in BSl as 12 *aṅgulas* to a *prādeśa*, 15 *aṅgulas* to a *pada*, two *pradeśas* to an *aratni*, and five *aratnis* to a *puruṣa*. A *puruṣa* would thus be 120 *aṅgulas*. Two other measures occurring frequently are *prakrama* (which literally means a step or stride), defined to be two padas, and *vyāyāma*, defined to be four *aratni*s.

While the interrelations described above would fix the relative sizes of the units mentioned, further inputs would be needed to make them more definitive, as the anatomical sizes would vary to an extent from person to person. This would seem to have been achieved to an extent, though it is unclear whether this was indeed intended (see below for some related comments), by Baudhāyana by describing *aṅgula* as being equal to 14 *aṇus* and also alternatively as 34 *tilas*; *aṇu* here stands for a certain seed – and not an atom (which is the now common meaning associated with the term) – and *tila* means sesame seed, and in either case what is meant is that the length measure *aṅgula* equals that many of the seeds placed sideways in a row, widthwise, next to each other. On the other hand, Baudhāyana also states that modifications may be applied in respect of measurement of certain units, which include *pada, prakrama,* and *aratni* from the abovementioned ones, "when desired" (BSl I.18). Baudhāyana's text does not specify what circumstance would call for such a modification, but as explained by commentator Dvārakanātha (see Prakash et al. 1968a, p. 43 – in Sanskrit) this is for making an allowance for traditions, and in particular a provision was called for to conform to the practice of taking the *puruṣa* measure dependent on the *yajamāna* (the person performing or sponsoring the *yajña*), as the distance from the tip of the middle finger to the ground when he stands with upstretched arms; this convention was commonly used for fixing the sizes of the bricks for tiling the *citi*s (cf. Kulkarni n.d., p. XXV). In such a case, the *aṅgula* measure is taken to be 120th of the *puruṣa* measure thus determined.

Taking the height of the *yajamāna* from toe to upstretched arms to be $7\frac{1}{2}$ feet, viz, 90 inches, the *aṅgula* measure would be $\frac{3}{4}$th of an inch, and *pada* would be $11\frac{1}{4}$ inches, or close to a foot.

As indicated, unlike BSl the other Śulbasūtras do not present a list of units, but various units appear along the texts. Of the abovementioned units, *aṅgula, aratnī*, and *puruṣa* are shared by all. *Prādeśa* takes a new but equivalent name *vitasti*. The unit *pada* appears later only in ASl and KSl, but in KSl it stands for 12 *aṅgulas*.

In the account on units of measure in BSl mentioned above, there are also various other units described, which do not bear a simple relationship with others; among these, I may especially mention *īṣā* which is 188 *aṅgulas*, *akṣa* equal to 104 *aṅgulas* and *yuga* which is 86 *aṅgulas*; all the three terms are related to chariots, meaning the shaft, axle, and yoke, respectively, with primarily a contextual significance and, interestingly, are shared by all the four Śulbasūtras. Though these have been listed by Baudhāyana along with various units that are involved in describing various lengths in the course of the constructions, they are in fact sizes associated with a specific *vedi*, styled as a chariot in the shape of an isosceles trapezium, with *īṣā*, *akṣa,* and *yuga* as its altitude, base, and face, respectively. While apparently the sizes were expected to be known all around, and accordingly disseminated in all the Śulbasūtras, they had no manifest role in measuring other lengths, in multiples or parts.

The relation one *aṅgula* being 34 *tilas* would also seem curious. It turns out that the choice is likely to have to do with an approximate numerical expression for $\sqrt{2}$ (see Sect. 8) in which 34 is involved in the denominator; this was noted by Thibaut in Thibaut (n.d.-a),[10] observing also that the subdivision may have been chosen to simplify calculations in that context – with the sesame seed serving as a matching choice; whether it matched the actual size of the seed to a substantial degree of accuracy or not may not have mattered. On account of this background, the conversion holds wider interest from a historical point of view. Both of these finer units are specific to BSl and absent from the other Śulbasūtras. It may also be noted that in BSl the division into 34 parts is related to the theoretical issues of squaring the circle (see Sect. 7), which have generally been skipped in the other Śulbasūtras. On the other hand, the finer units being dropped from the later Śulbasūtras also suggests that they had not been of practical consequence.[11]

[10] It is argued in Delire (2005) that similarly the unit *aṇu*, defined to be the 14th part of *aṅgula*, is motivated by another approximation of $\sqrt{2}$, viz, as $\frac{7}{5}$. Though there is no reference to this approximation in BSl, it is found in MSl and is likely to have a longer history in the tradition. According to Delire (2005), the *aṇu* being defined as the 14th part of *aṅgula* may be considered as "the fossilized remnant of it."

[11] It may be worth recalling here that the Mānava Śulbasūtra mentions, in MSl 1.4.2–4, a different set of fine measures. These are introduced in order to build up the *aṅgula* and other larger measures, in a context when the *yajamāna*'s height is stunted, due to genetic reasons or a disease, and hence inadmissible in setting the units. Mānava takes an *aṅgula* to be six *yavas* (barley seeds), each *yava* to be six *sarṣapa*s (flax seeds), which are further subdivided, with the latter described as six hairs of a "3-year-old calf," and the last one further equated to six of lotus pollen. The scheme however is very likely a notional make-believe formulation, rather than anything of metrological significance, especially there being nothing to indicate their having the practical means to make comparisons at that level. At any rate, it is doubtful if the finer measures alluded to played any role at all, as the seed units would have sufficed for the purpose at hand; more descriptions would only lead to more ambiguity and confusion in matching them. It is interesting however that *aṅgula* in this formulation equals 36 *sarṣapa*s, quite close to Baudhāyana's subdivision of *aṅgula* as 34 *tilas*. It is also interesting that the subdivisions are repeatedly into six parts of the previous one.

Finally, it may be mentioned here that in measuring areas, in the Śulbasūtras the same name as any linear measure is used for the area of the square whose side is one unit in that measure; thus, one *puruṣa area* is what we may refer to as one square *puruṣa*[12]; in the sequel, we shall adopt the same practice as in the originals, and only occasionally include "square" in parenthesis, for clarity.

2.5 *Vedis* and *Citis*

The performance of the *kāmya yajña*s involved elaborate arrangements, with multiple structures and designated spots for various functions that were part of the sacrificial event. The steps for these are prescribed in quite minute detail; they are however not all part of the Śulbasūtras; rather, they go back to the older *Brāhmaṇa* works,[13] and one of the cited sources in this respect is the *Śatapatha Brāhmaṇa*; to some extent, the details may also have been passed on from generation to generation orally, as a part of the tradition, without being part of any composition. The Śulbasūtras recall only some features that are immediately relevant to their narrative, and the other aspects, including notably the names of various components in the overall organization, are taken for granted as known. Let me recall here a few of the details which would be helpful in following the discussion in the forthcoming sections; the reader is referred, in particular, to Sen and Bag (1983, pages 169–173) for an exposition in greater detail.

2.5.1 The *Mahāvedi* and the Three *Agnis*

An important component of the layout for the *kāmya yajñas* is the *Mahāvedi* (literally "the great altar," also called *saumikī vedi*, the soma altar). It is in the shape of an isosceles trapezium, with its axis of symmetry along the east-west line (called *prācī*)[14]; the stretch along the axis is 36 *steps,* and the (mutually parallel)

[12] This can be a source of some confusion, since when two units are involved in a description, say two *puruṣas* and one *aratni*, it would not be clear whether the area refers to the sum of the two square measures, or the area of the square with the sum as the linear measure; see the discussion related to this in Seidenberg (1978, pp. 336–337); and the issue however will not concern us here.

[13] *Brāhmaṇas* are scriptures intermediate to the *Vedas* and the *Kalpasūtras* (which are parent bodies of the Śulbasūtras), and at several places Baudhāyana makes statements citing their authority, distinguishing along the way between teachings of the Brāhmaṇa to which he owes allegiance and those of the others.

[14] Baudhāyana does not mention how the cardinal directions were determined. It has been suggested that it was determined by the shadow of the pole on the equinox day, and verified by the rising and setting points of the star Kṛttikā (see Sen and Bag 1983, p. 264). In KSl 1.2, a procedure is described to determine the east-west line as the line joining the two points on a circle drawn around the base of a pole, where the shadow of the tip of the pole falls on the circle in the course of a day. The north-south line is then obtained by drawing a perpendicular to the east-west line, the instruction for which (as given in KSl 1.3) corresponds to what we refer to as the arrow method, described in Sect. 3.3. Even so, KSl 7.35 describes determining East as the direction of rising of the stars Kṛttikā, Śravaṇa, or Puṣya, or as the midway of the directions of rising of Citrā and Swàtī. Presumably both procedures coexisted and were used for confirmation of each other.

sides on the western and eastern sides are 30 and 24 steps, respectively; while the description in *Śathapatha Brāhmaṇa* in this regard is in terms of the number of step strides (see Sect. 6.4 for more details on this), BSl and ASl assign for them that many units in size, the unit chosen being either a *pada* or a *prakrama*, which correspond to $11\frac{1}{4}$ inches and $22\frac{1}{2}$ inches, respectively (it may be recalled that *prakrama* by itself also means a stride). The area defines the region for various special ritual activities, of which we will not go into the details (see Sen and Bag 1983 for an exposition). I may mention however that there is a rectangular annexe to this, on the western side, symmetric about the axis of the *Mahāvedi*, called *pragvaṃśa*, where the priests, the members of the family, and guests assemble.

Every *yajña* mandatorily involved also three *agni*s (sacred fires), viz, *āhavanīya*, *gārhapatya,* and *dakṣiṇāgni*, and these are also situated in the *prāgvaṃśa*, on eastern, western, and southern side, respectively. Three different schemes for locating the position of *dakṣiṇāgni*, in terms of the other two agnis, which are along the east-west line, are described in BSl I.67–69. In Datta (1932), the author assumes that identical spot is being described in the three, and deduces from it the implied values of $\sqrt{5}$ and $\sqrt{2}$; however, the assumption is erroneous, as we contend in detail in Sect. 8.5. Datta's assumption is all the more surprising in the light of the fact that two of the three methods proposed in BSl, and also analogous descriptions in Āpastamba and Kātyāyana, give two options each (in ASL 4.6–4.7 and KSl 1.26–1.27, respectively), in which it is evident that they do not purport to describe the same spot.

2.5.2 *Kāmya Citis*

Depending on the motive of the *yajamāna* (one performing the *yajña*) in performing the *yajña*, the ensemble for it includes an *agniciti* of a special design, like in the shape of a bird, turtle, etc.; one desiring heaven would have the *citi* in the shape of one of the birds, *Śyena* (falcon) or *Kaṅka*, in a flying mode, with wings outstretched. *Droṇaciti*, in the shape of a trough (used for serving food), is when the desire is for plentiful of food; the trough designs, in square or circular shape, come equipped with a handle. *Chandściti* is the *citi* to be adpoted when cattle is desired.[15] *Rathacakraciti*, in the shape of a chariot wheel, was erected when annihilation of rivals was the desire involved.[16] The turtle-shaped *Kūramāciti*, described only in BSl, is for vanquishing *Brahmaloka*! (BSl III.270).

The *citi*s typically consisted of five layers of tilings of bricks, together forming a knee-high structure, with the cross-section, and the top view, in the desired shape, specific to the *yajña*. The area of each *kāmya citi* was to be $7\frac{1}{2}$*puruṣa*, while performing the *yajña* for the first time, and was enhanced in successive repetitions (the process of enhancements is discussed in Sect. 2.6.4 and in further detail in Sect. 5.2; when not

[15] Cattle was one of the major items of acquisition in the Vedic times, and evidence from the vedic literature shows that people maintained huge herds of cattle.

[16] A tabular list of *citis* together with the motives associated with them, as described in the *Taittirīya Saṃhitā* of the *Yajurveda*, is provided in Sen and Bag (1983, p. 6).

specified otherwise, in our dicussion we shall restrict to the former, the primary context).

2.5.3 The Brick Layouts

The brick-tiling plans for the various designs of the *kāmya citi*s involve intricate designs (even when the outline of the *citi* is simple, like a rhombus), and specific patterns are provided by the Śulbasūtras for the *citi*s they discuss.

Each layer was to have 200 bricks, so the total number of bricks would be 1000, and there are also some special instances involving larger number of bricks, but we need not go into it here. The first, third, and fifth layers follow a common design for brick-tiling, and the second and fourth share another common design, and the two designs are such that the edges of the bricks would not overlap between the successive layers, except at the outlying edges of the figure of the *citi*. Apart from these general restrictions, the designs are seen to incorporate various esthetic considerations. The tiles involved are in multiple shapes, though a majority of them are in square shape. We will have further occasion later to elaborate on the shapes involved (see Sect. 3.6).

The *āhavanīya* and *gārhapatya agni*s, which were used domestically, as well as mandatory parts of the elaborate sacrificial rituals, had an area one (square) *vyāyāma*. The *gārhapatya* was tiled with 21 bricks, adhering also to the stipulation of non-overlapping of the edges, as above; see Sect. 9.2 for more on their design patterns.

2.6 Mathematical Highlights

Construction of various figures, fulfilling a variety of stipulations, is the main theme of the mathematical content of the Śulbasūtras; other aspects of geometrical understanding, presented or alluded to, are supplementary. Though the *citi*s were indeed three-dimensional objects, it is the planar designs of the shapes involved that play the crucial part, and as such the main geometrical content of the Śulbasūtras is about geometry of planar figures.[17]

2.6.1 Rectilinear Constructions and Related Geometry

The typical figure that one encounters most often in the Śulbasūtras is that of isosceles trapezia, including the various special cases consisting of squares, rectangles, and isosceles triangles.[18] Indeed, the isosceles trapezia seem to have held a great appeal to the ancient Indian geometers, as witnessed already by the choice for

[17] There is an isolated instance of a *citi*, the *śmaśānaciti* (cemetery-shaped *citi*), described in BSl 8.1–17, whose shape is of a frustrum of a pyramid, and there is a discussion in Datta (1932, pp. 101–103) involving a volume computation of the shape; however, the formulation and inferences do not seem convincing enough to be recalled here.

[18] The shapes of some of the bricks used in the construction of *citis* are asymmetrical; see Sect. 3.6. However, there is no discussion of geometrical issues involved in respect to them.

the shape of the *Mahāvedi*, presumably inspired by esthetic considerations, or also metaphoric or spiritual aspects, associated with the activity.[19]

These figures, as drawn in the context of construction of the *vedi*s, had a bilateral symmetry, with the axis of symmetry along the east-west direction,[20] with the face (the shorter of the parallel sides) toward the east and the base (the longer parallel side) on the west, as seen in the case of the *Mahāvedi*. The description of the steps in the constructions is typically with reference to the cardinal directions; this applies not only to description of practical constructions of *vedi*s and *citi*s, but also in the enunciation of the general theory, even where it is taken up separately. This is seen to have served as a crucial reference framework in absence of notation for points and lines drawn in the course of the constructions.

As may be expected, construction of perpendicular is one of the key ingredients in drawing these figures. However, the notion of a perpendicular line is not explicitly formulated in any of the Śulbasūtras. Moreover, the constructions described are restricted to closed geometric figures needed in practical constructions. As such, tasks like drawing a perpendicular to a line at a point do not figure in the exposition by themselves, even though they are involved as part of various procedures that are described in the construction of the individual figures. In this respect, the works resemble manuals and reflect their limited aim. It is nevertheless clear that the theorists were aware of them as primary tools, though they may not quite have abstracted them as principles that could be communicated directly. In a critical appreciation of the results, it would be important to bear this aspect in mind. Some details of how the steps are communicated in the basic constructions will be described in Sect. 3.

2.6.2 The Pythagorean Principle and Pythagorean Triples

One of the main highlights of the Śulbasūtras geometry relates to the Pythagoras theorem, or rather the physical principle involved.[21] It is explicitly stated in all the four Śulbasūtras as above; the statements appear in terms of diagonals and sides of a rectangle, rather than a right-angled triangle as in Euclidean geometry. These are arguably the earliest extant explicit statements of the principle, anywhere in the world. We shall discuss the statements as presented in the individual Śulbasūtras, and their nuances, in some detail; see Sect. 4. Apart from the statements themselves, we find numerous theoretical geometric as well as practical applications of the principle in the Śulbasūtras. These will be discussed in the later part of Sect. 4.

While the Śulbasūtras geometers were aware of various methods of drawing perpendiculars, as we shall see in detail in Sect. 3, their favourite method was

[19] Engagement with isosceles trapezium in fact goes back to more ancient works. It was pointed out by A. Bürk that it occurs as a shape of a *vedi* described in *Taittirīya saṃhitā* (cf. Seidenberg 1975, p. 510).

[20] This was followed in respect of the larger plan as well, except in a few respects, such as the location of *Dakṣiṇāgni*, or choice of tiling designs of some of the *kāmya citis*.

[21] In the context of the Śulbasūtras, I prefer to use the term "principle" in this context, the term "theorem" being associated closely to framework of deductive systems. The Sanskrit word *nyāya* that is commonly used for statements from this category also corresponds to "principle," than an equivalent of "theorem."

based on the converse of the Pythagoras principle, that a triangle in which the square of the largest side equals the sum of squares of the other two sides is a right-angled triangle; this was used along with Pythagorean triples (triples of integers in which squares of two of them add up to the square of the third), typically (3, 4, 5) and (5, 12, 13) by a procedure called *nyañchana* (see Sect. 3.2 for details).[22]

Curiously, though it is used extensively in both theoretical and practical contexts involved in the works, the converse of the Pythagoras principle is not stated explicitly anywhere in the Śulbasūtras. It may also be noted that the usage is seen to appear in constructions even before the statement of the Pythagoras principle itself, in the text of the Śulbasūtras. One may wonder if this means that they viewed it as an independent basic principle by itself, which it was adequate to illustrate through construction of figures.

Usage of the converse of the Pythagorean principle, as indicated above, brings in the notion of Pythagorean triples, viz, integer triples (a, b, c) such that $a^2 + b^2 = c^2$. Their interest in the latter (for which no name was introduced) was anchored on its usage in *nyañchana*. For that, the small-sized triples as above are the most convenient, so one may wonder if they would have had any motivation for exploring the multitude of Pythagorean triples. However, various such triples, other than the two recalled above, do appear in BSl and ASl, as we shall see in Sect. 6.3; there is also a sūtra in KSl which has been linked in literature to Pythagorean triples, on which also I shall comment in Sect. 6.3.

2.6.3 Transformation of Figures

Areas of figures played an important role; in a way, along with the significance of the design, its area would have been a guage of the stature associated with it. While multiple designs were possible, depending on the context, the areas involved were chosen to be the same. It is generally supposed that the practice stems from a scriptural injunction, but there is no evidence to that effect. This seems to have been a matter of convention as it came to be practiced by different groups.[23] When looking for a new or different design for a product, for one or other reason, it is natural to maintain some of the vital parameters associated with the components to be the same. The choice of the area of the *citi*s being retained the same is likely to have been in the same spirit. Presumably it would have been meant for balancing the

[22] Use of the converse of the Pythagoras theorem for obtaining perpendiculars on an extensive scale is unique to the Śulbasūtras tradition. It was earlier believed that the Egyptians used triangles with sides 3, 4, and 5 (in some units) for construction of perpendiculars, but this has now been discounted (see Gillings 1972, Appendix 5).

[23] As Thibaut puts in succinctly in Thibaut (1875, p. 232) (see also Thibaut n.d.-a, p. 145) "... according to the opinion of some theologians, the *gārhapatya* had to be constructed in a square shape, according to the opinion of others as a circle, the difference of the opinions referred only to the shape, not to the size, and consequently there arose the want of a rule for turning a square into a circle."

level of importance associated with the *citi*s.[24] We shall discuss this in some further detail in Sect. 2.6.4.

Whatever the genesis of the convention, it motivated the issue of transforming figures into one another, retaining the same area, and the methods introduced in this respect stand out as a major theme found in the Śulbasūtras. While some of the procedures are simple cut and paste prescriptions, others involve application of the Pythagoras principle. Transformation of a rectangle into a square with the same area may be one of the notable instances of such a geometrical application of this form[25]; see Sect. 5.5 for details.

2.6.4 Enhancement of Figures

It was well understood that for the figures drawn, scaling up a figure by a factor enhances the area by the square of the factor, irrespective of the specific design of the figure, and this played an important role in their constructions for redrawing the figures in larger sizes. In certain contexts, it was needed to redraw an earlier figure with an area larger by a given factor (see Sect. 5.1 for details), and for this they introduced the technique of scaling up the unit by a factor equal to the square root of the given enhancement factor for the area, and then following the same steps as before, with the new unit; producing the enhanced unit is achieved as an application of the Pythagoras principle; see Sect. 5.2.

In particular, for doubling the area, the diagonal of a unit square would be used as the enhanced unit; on account of this, the diagonal (and its measure) was called *dvikaraṇī* (one which doubles). There seems to be no direct application of this involved in the Śulbasūtras, but presumably it had a pedagogical role as the simplest case of enhancement by a factor. On the other hand, it is used in defining *trikaraṇī* (one which triples), as the diagonal of a rectangle with one side the *dvikaraṇī* and other side the unit. In turn, the latter is involved in defining *tṛtīyakaraṇī* (one which modifies by a factor of one-third), as the third of the *trikaraṇī*. These terms are actually involved, in particular, in describing the area of *Sautrāmaṇī vedi* in relation with the *Mahāvedi* (cf. BSl I.85–86).

Baudhāyana also has a numerical formula for $\sqrt{2}$ which is the doubling factor, as $1+\frac{1}{3}+\frac{1}{3}\times\frac{1}{4}-\frac{1}{3}\times\frac{1}{4}\times\frac{1}{34}$. In decimal expansion, this corresponds to 1.1424156 . . ., which is accurate to five decimal places (six significant digits). It has been a major highlight on Śulbasūtras, and subject of much discussion in the literature (see Sect. 8 for further details on this). In its numerical context, the magnitude is also given a separate name as *saviśeṣa*. The twin names for the entity seem to have led to some confusion in interpreting a sūtra from KSl, in Thibaut (1875) and some later works, which we shall discuss in Sect. 3.5.

[24] It is important to keep this perspective in mind, as in application it means that there should be no perceptible difference between the two areas, as far as the people around can judge, and there would be no emphasis on exact equality by any absolute standards, or even a quest for achieving it.

[25] This corresponds to Proposition 14 of Book II in Euclid's *Elements*; the arguments involved differ somewhat, though both use the Pythagoras principle.

2.6.5 The Circle

There are various *citi*s which involve circles in their design. The *gārhapatya agni*, which is a regular component of the setting of sacrificial events, was often circular in shape. There are also various *kāmya citi*s, *rathacakraciti* (chariot-wheel shaped), *droṇaciti* (trough-shaped), and *parimaṇḍala kūrmaciti* (rounded turtle-shaped) which have circles in their design. Their sizes followed the convention of having areas equal to the other *citi*s and, as such, were defined in terms of area, and not by specification of the diameter. In this context, we find procedures for constructing a circle with area (meant to be) equal to a given square.

For the converse problem, of squaring the circle, BSl gives two numerical formulae for the ratio of the side of the square to the diameter of the given circle, rather than a geometrical construction as given for the other way. One of these is a crude one, while another one is refined and elaborate, even though the accuracy achieved does not happen to be particularly good (see Sect. 7.6). Only the crude one is found mentioned in the later Śulbasūtras. The converse issue has no application or connection with their practical context, which could have led to the detailed formula of Baudhāyana not finding a mention later.

The elaborate numerical expression is apparently obtained as the inverse of the ratio that would correspond to the ratio in the other way transformation. While there is consensus among scholars on this point, the question of how it was computed, and why it is given as a combination of terms in the way it is (see Sect. 7.6), has been a matter of much debate and can hardly be said to have been resolved satisfactorily. We shall discuss some of the points that have emerged and highlight the difficulties in coming to any conclusion.

The computation of the reciprocal of the ratio as alluded to above involves understanding $\sqrt{2}$ in terms of familiar numbers, which seems to have inspired the formula recalled in Sect. 2.6.4. With regard to this formula also, there has been much discussion on how it was arrived at, though one may say it has not been as perplexing as the other number mentioned above. We recall some of the suggestions with regard to it in Sect. 8.

Apart from geometry, there are also some arithmetical and combinatorial aspects that turn up in the course of the constructions. We shall examine these in Sect. 9. There are often claims made with regard to the topic, of solutions of indeterminate equation being treated/considered in the Śulbasūtras. It turns out however that they are not well-founded (see Sects. 9.2 and 9.3). On the other hand, the works show good prowess in dealing with numbers which is noteworthy, as we shall illustrate in Sect. 9.

2.6.6 Proofs?

One question that often arises is whether the Śulbasūtras have proofs. While it is reasonable to have curiosity about such a question, in the context of the overall development, the question seems to have got needlessly loaded by extraneous considerations than properly as a question in the subject of the history of mathematics.

A simple and straightforward answer to the question would be a no. Seidenberg in Seidenberg (1975, p. 519) (see also Seidenberg 1978, p. 332) takes to task the writers who say that there are no proofs there, adding that "We can only suppose that these

writers have not bothered to examine the work," and goes on to give a "counter-example." It comes from the sūtra ASl 5.7. After noting the area of the *Mahāvedi* to be 972 square *padas*, it is mentioned in the original that by transporting a triangular part from the south of the vedi to the other side, a rectangle can be produced. To this part, Seidenberg adds another sentence, included within what is presented as a quotation, saying "In this form one computes its area."; no equivalent of such a sentence is found in the standard editions as in Sen and Bag (1983), Prakash et al. (1968a), and Kulkarni (n.d.), so one wonders where our author got it from – so much for careful examination of the text – and then (euphorically) adds "This is a proof. And there are others."; this same example is cited in Datta et al. (1980, p. 123), with no claim about others. How far such an occasional extra comment, thrown in to help the listener grasp the point, or just in a chatty vein, can be taken to be in the spirit of giving a proof, in the natural context of the query, is highly questionable.[26] At any rate, this is an isolated instance and a comprehensive survey of the literature to look for more would not make any dent in the overall status in the matter. The crucial point is that there are no proofs found at places where one would really wonder how they arrived at the statement being made, such as say the Pythagorean principle, squaring the circle, etc., nor does the general format suggest, in spite of the pedagogical import of the material, any inclination to convey also the reasoning involved, together with the material being communicated. In fact at many places, one finds statements such as "This is known," "This is the knowledge of areas," "This has always been prescribed by ancient teachers," etc., with emphasis on authority and trust in traditional knowledge, rather than reasoning or proof.

And why should we expect, in the first place, to find proofs there? A historian's task is to understand how things were, and see them in context. We know from the context that these are documents meant for equipping the people concerned with the aspects of brick-laying for erecting the sacrificial structures, people roughly in the role of architects. Nowhere do the Śulbasūtras give the impression of aiming to be fountainheads of all geometric knowledge of the time – unlike many other parts of the Vedic literature, they had a limited aim (and generally formed a chapter at or near the end). Why would they be bothered to give, to the architects involved, proofs for mathematical statements, beyond an occasional explanation of how the area of a trapezium could be computed by relating it to a rectangle? We need to see the matter in perspective. Beyond their limited objective, there is also the point that while there are various mathematical statements involved, they are essentially in the nature of facts about the physical world. Once discovered, by some wise men, the trust in them

[26] In Datta et al. (1980, p. 123), the authors also recall "after describing the constructions necessary in a proposition the early Hindu geometers are found to have remarked *sa samādhiḥ*" and liken it to the expression Quod Erat Faciendum in Euclid's *Elements,* hinting at a proof-like structure for the narrative. The comparison is however not valid, since the clause mentioned (or its variants) occurs only occasionally in the Śulbasūtras, apparently highlighting some specific points, and not in the nature of announcing accomplishing any preplanned objective, unlike in the latter case. The mention as noted is significant from a pedagogical point of view but does not represent adoption of any formal discipline in the narrative.

would be based on the statements being consistent with physical observations and experiences and did not warrant any additional "proof" in terms of reasoning. It may be recalled here that even as late as the twelfth century Bhāskarācarya commented that "proofs" were for the dim-witted!

None of this means that they did not *have* proofs. Arriving at various results of course needed a thought process. The wise men who found them had to have a way of convincing *themselves* of various things being true, even if no one else. A statement like that of the Pythagorean principle cannot come out of nowhere. Though it seems to have been known in more ancient times elsewhere, like to the Babylonians, no credible route of possible transmission from outside has ever been suggested or conceived. How did it come up then? One possibility that is often suggested is that it was guessed or extrapolated from the examples of the Pythagorean triples that are found in the Śulbasūtras (see Sect. 6.3). This reasoning however seems flawed. Knowing a Pythagorean triple, viz, a triple (a, b, c) with a, b, c integers such that $a^2 + b^2 = c^2$, does not by itself point to that it corresponds geometrically to a right-angled triangle – making the connection, or looking for such triples, already involves knowing the Pythagorean principle. At any rate, there are several geometric ways they could have been convinced of the validity of the Pythagorean principle, based on the kind of constructions they were used to; while these would not be on the same footing as the Euclidean axiomatic proofs, they would be adequate for carrying conviction of their validity; and it would constitute a *proof* which is valid in a way that we are quite used to in our day-to-day practices, though not in a modern mathematical framework. We shall not go into the details of the possible proofs here, but refer the reader to Dani and Limaye (2021), Datta (1932), and Divakaran (2018); the last one presents a series of possibilities.

3 Constructions for Basic Rectilinear Figures

In this section, we recall the constructions of various basic rectilinear figures as described in the Śulbasūtras. Exposition of these procedures are contained in the preparatory mathematical sections in BSl and ASl.

3.1 Construction of a Square by the "Compass" Method

Baudhāyana's course on geometry begins, after an introduction to various length measures and their interrelations (see Sect. 2.4), with a systematic construction of a square, a basic task that everyone connected with the subject should be able to carry out. The method, introduced in sūtras BSl I.22–28, may be described as follows. The original description is in terms of a cord of length equal to the side of the desired square, and ties made at its ends. It would however be convenient here to recall it in terms of abstract geometric steps.

One starts with a point, say P (see Fig. 1), which is to be the midpoint of the desired square, and a line segment AB, set along the east-west line, with P as its midpoint; it

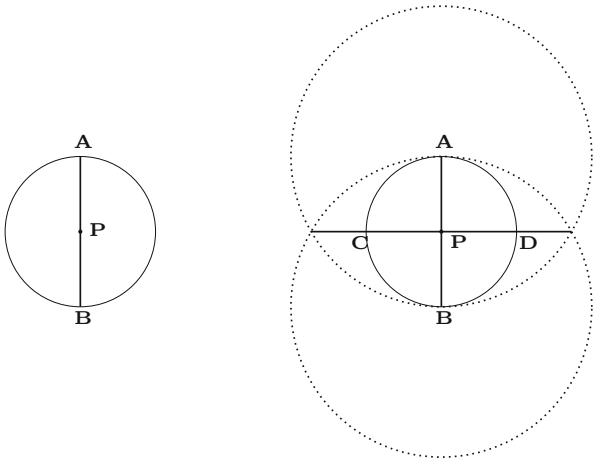

Fig. 1 First steps in Baudhāyana's construction of a square

may be borne in mind that A and B are to be the midpoints of the sides of the square on the east and west sides, respectively. A circle is drawn with P as the center, passing through A and B. The midpoints of the south and north sides are going to be identified on this circle. This is done by drawing two circles through A and B, passing through the other (B and A, respectively), and a line is drawn through their two points of intersection. This line is along the north-south direction, and the points C and D where it meets the first circle are the midpoints on the north and south sides. The vertices of the square are now identified as the points of intersection of circles drawn with adjacent midpoints (east and south, etc.) as centers, passing through P. It may be noted that the procedure essentially relies on the method for drawing a perpendicular to a line L at a given point P on it, by taking two points on L equidistant from P on either side, drawing circles through them with equal (sufficiently large) radius that would meet on either side of the line, and joining the two points of intersection. Here, however, specific choices for the circles are prescribed in terms of the length of the side, and the entire construction is presented as a package, a feature in which the exposition resembles a manual. In the light of the compass-like construction involved, we shall refer to this method in our discussion below as the compass method, though in their context it would be executed with poles and cords.[27]

[27] The original refers to "drawing circles," though the purpose involves only locating the relevant points by means of the intersecting segments of the circles. In literature, sometimes one finds quite adulatory comments on gratifying features of the figure that emerges from drawing all the full circles (e.g., Amma 1979, p. 29; Joseph 2016, p. 81); such comments however seem rather odd, as it would be pointless to draw the entire figure for getting the square, and one would be content identifying the relevant points of intersection! Surely for drawing nice figures they had other means and contexts!

3.2 Producing Perpendiculars by *Nyañchana* Method

The preceding construction is followed, in BSl I.30–35, by another method for construction of a square, which relies on the fact that in a triangle whose sides are in the proportion 3:4:5 the angle opposite to the longest side is a right angle. To construct a square of a given size, along the cardinal directions, one proceeds as follows: Taking a cord with twice the given length, say with endpoints P and Q as in Fig. 2, successively its midpoint R, the midpoint S of the half part RQ, and the midpoint X of RS are marked. The last one, which is called the *nyañchana*,[28] holds the key to the desired construction.

The *nyañchana* mark clearly divides the length of the cord in the proportion 3: 5. Tying the ends of the cord to poles at two points, say A and B, along the east-west line, at a distance equal to the desired side-length and stretching the cord on the ground, by holding it at the *nyañchana* mark, the corresponding point on the ground, C as in Fig. 2, is marked. This produces a right-angled triangle ABC, with the right angle at B. A similar one is produced with a right angle at A. Plotting the points on these perpendiculars at distance equal to half of AB, from the points A and B on both sides, produces the vertices of the desired square.

The reader would readily recognize that the fact used above about the proportion 3:4:5 is a particular case of the converse of the Pythagoras principle, and that (3, 4, 5) is a Pythagorean triple, viz, a triple (a, b, c), with a, b, c positive integers such that

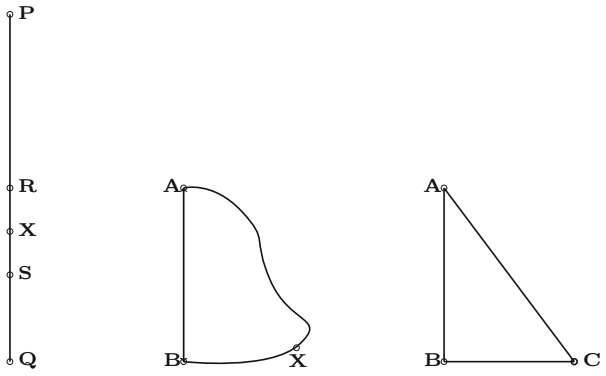

Fig. 2 The *nyañchana* method

[28] This term is reproduced here as in Thibaut's edition of BSl, which is also followed in Prakash et al. (1968) and Kulkarni (n.d.). In Sen and Bag (1983), the authors use *nyañcana*, which is a later-day Sanskrit equivalent of *nyañchana*. Etymologically the word is seen to have its root in the verb *nyañc*, which means "lying with face downwards." In MSl and KSl, it is called *nirañchana*. Curiously, in ASl though use of such a mark is involved in similar constructions, it is not given any name but is only referred to as "the mark" (*lakṣaṇaṃ*). For convenience, we shall uniformly use the term *nyañchana*.

$a^2 + b^2 = c^2$. An analogous method for drawing perpendicular using the Pythagorean triple (5, 12, 13) is adopted in a construction of rectangles that follows, in BSl I.42–44. In this instance, to draw perpendiculars to a segment PQ as above a cord with $1\frac{1}{2}$ times the given length is used, and on the additional part the *nyañchana* mark is made at $\frac{1}{6}$th from the separating mark, thus dividing the cord in the proportion 5:13. Tying the ends of the cord and stretching it by holding at the *nyañchana* mark produces the requisite perpendiculars; the construction is then completed by marking the vertices at the appropriate distances on them.

3.3 Perpendiculars by the "Arrow" Method

Interestingly, a method for producing perpendiculars which relies on the same geometric principles as the compass method, but is operationally different, is described in the course of the construction of rectangles and isosceles trapezia, in BSL I.36–40 and BSl I.41, respectively. Here, to draw a perpendicular to a line L at a point P, two points on L equidistant from P on the two sides are taken, say Q and R; see Fig. 3. A cord of length longer than that of QR is then tied to poles at P and Q, and points are plotted on the two sides of L by stretching the cord, holding it at its midpoint – joining the two points produces the desired perpendicular. The rectangle is drawn by plotting two points on the east-west line at the desired distance between the transversal sides, drawing perpendiculars to them by the method as above, and plotting points on them from the east-west line at half the size of the desidered width. For the isosceles trapezium, adopting the same procedure, the vertices are drawn at half the distance, from the east-west line, as the desired sizes of the base and face, respectively.

We note that while it shares its geometric basis with the compass method, it does not involve tracing the pairs of circular loci and taking points of intersection, but only on stretching a cord and marking a point on it on the ground. Equality of the distances of points as required is achieved through midpoint marks on the cords.

In the Āpastamba Śulbasūtra, the method is involved in the procedure described, in ASl 1.13–1.18, for construction of a square; here the method is further elaborately

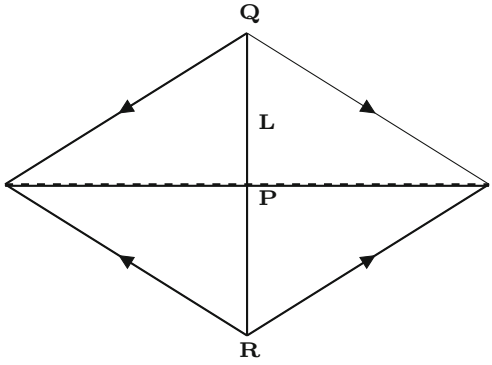

Fig. 3 Drawing perpendiculars by the "arrow" method

packaged, involving repeated application, to plot the vertices of the desired square. It may be worth recalling here for its interesting "packaging" feature.

Taking a cord of the given length a for the side of the square, markings are made at its midpoint, and the midpoints of the two halves. Poles are set along the eastwest direction at points A, B at distance a, at the midpoint M of AB, and at points P and Q which are midpoints of AM and BM, respectively; see Fig. 4. Tying the ends of the cord at P and Q, the midpoint on it is marked, after stretching on the ground, at R as in the figure. Next, tying both the ends of the cord to the pole at M and stretching the cord passing over R, the midpoint of the cord is marked, as C. In the same way, the point D is marked on the other side. Thus, C and D are the midpoints of the sides of the desired square, apart from A and B. Now, tying the ends of the cord at A and C and marking the midpoint, after stretching the cord on the ground (away from the midpoint M), yields the vertex in which the sides with A and C as midpoints meet; similarly the other vertices are determined.

Like in BSl, in ASl also an initial portion of the text is devoted to exposition of theory, and one finds interesting asides, as seen in the above construction. ASl however does not repeat the elaborate construction of the square by the compass method described in the beginning of BSl, as in Sect. 3.1. This does not amount to any loss in terms of ability of the intended learners to draw a square, for which an alternative, and relatively slick, method is provided, but with that the exposure to the compass method and the geometric understanding associated with it would no longer be a part of the knowledge of the learner.

3.4 Toward Conceptualization of Perpendicularity

It should be clear from the above discussion that in the underlying thought process, Baudhāyana implicitly had the idea of a perpendicular to a line at a given point,

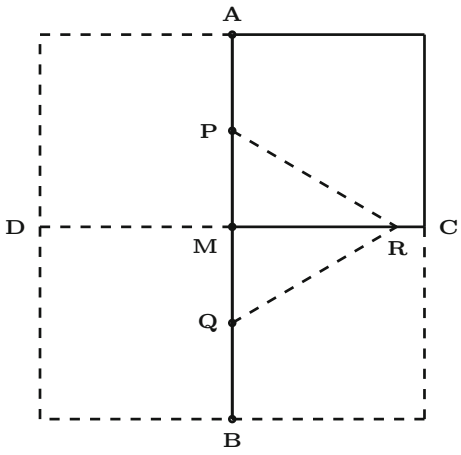

Fig. 4 A step in Āpastamba's construction of a square

together with various ways of constructing it. However, somehow the notion of perpendicular does not get formulated into a mathematical concept; or if it did in his mind, it was considered too abstract for the intended audience.

The idea of conceptualizing the perpendicular seems to have eluded the later Śulbasūtras as well, and nowhere does one find a direct instruction to draw a perpendicular (by first having a name for it) to a line at a given point; it comes only as a part of elaborate instructions for drawing the familiar *shapes* such as the squares, rectangles, and more generally, trapezia, typically with reference to the given dimensions of the figure individually. The closest they seem to have come in this respect is, as I pointed out in Dani (2010, p. 19), to use a common clause in certain contexts: The *vedi*s described in ASl 6.3–6.4 (*nirūḍhapaśubandha vedi*), ASl 6.6, ASl 6.7 (*paitṛkīvedi*), ASl 6.8 (*uttarāvedi*), and ASl 7.1 involve varied shapes (two trapezia of different dimensions, two squares, and a rectangle), but the construction of each of them refers to "Having stretched (the cord) by the mark at fifteen" (*pañcadaśikenaivāpāyamya*), and from the context it is clear that the clause refers to a process of drawing a perpendicular.

One may wonder what "stretching the cord by the mark at 15" has to with drawing a perpendicular. The answer is not far to seek. It may be recalled that one of the methods discussed, using the converse of the Pythagoras principle with the triple (5, 12, 13), consisted of using a (*nyañchana*) mark dividing the cord in the proportion 5:13. Actually it was more common to think in terms of its threefold multiple (15, 36, 39) because of its association with the *Mahāvedi*. Recall that the *Mahāvedi* is in the shape of an isosceles trapezium with a base of 30 units, height of 36 units, and face (side opposite to the base) of 24 units (see Sect. 2.5.1). Thus, the (right-angled) triangle formed by one of the vertices at the base together with the midpoints of the base and the face has sides 15, 36, and 39, and this is in fact used in one of the constructions of the figure; see Sect. 3.5. On account of this association with the *Mahāvedi,* the triple seems to have had an importance by way of tradition.[29] In this case, the cord involved would have the measure $54 = 15 + 39$ units, with the *nyañchana* mark at 15; thus, stretching by the mark at 15 is the key step in this way of drawing the perpendicular, and lent the name for the act of performing it, as mentioned earlier, in Sect. 3.2. Āpastamba does not have a term corresponding to *nyañchana*, so the name here directly refers to the mark at 15. This *operational* standardization led to associate "stretching by the mark of fifteen" with the process of drawing a perpendicular.[30]

[29] It may also be noted here that the triple is included in Baudhāyana's list, even though it is in a way redundant, being a multiple of another triple in the list, (5, 12, 13); see Sect. 4.1.

[30] It may be mentioned here that the altitude of an isosceles triangle (the segment joining the midpoint of the base to opposite vertex) had a name, *avalambaka*; mention of the term is found in MSl, including in particular in MSl 3.2.10. Etymologically its root is *avalamba*, which means "hanging down." The segment would readily have been known to be "perpendicular" to the base (say in terms of being like the sides of a rectangle), and this may well relate to the fact that in later Sanskrit literature the term *lambaka* stood for perpendicular, in a broader context. The connection however does not seem to have led to any insight toward the issue of conceptualizing the perpendicular, as discussed above.

3.5 Āpastamba's Varied Applications of *Nyañchana*

Āpastamba also takes forward the idea of using the converse of the Pythagoras principle, deploying other Pythagorean triples, as also through a triple like $(1, 1, \sqrt{2})$. Availing of the context of the *Mahāvedi,* he introduces various ways, in ASl 5.3–17, of constructing it, using the *nyañchana* method.

In terms of Fig. 5, starting with the east-west line segment of 36 units the trapezium ABCD is constructed, in various ways, as follows: The first construction which he notes to be an *ekarajjuvidhi* ("one-rope process") uses a cord of length 54 units, with a mark at 15 (as the *nyañchana* mark), to determine the vertices A and B by drawing the triangles EWA and EWB (see Fig. 5); the same marked cord is used to produce the direction of ED, and the vertex D itself is produced through a mark at 12 on the cord.

We note that the point M where the diagonals of the trapezium meet is at distance 16 units from E and 20 units from W. Availing of this, Āpastamba introduces a method for plotting A and B by drawing the triangles AMW and BMW by *nyañchana*, using the triple (15, 20, 25), and similarly C and D are plotted by drawinngs triangles ECM and EDM, using the triple (12, 16, 20).

The third construction is based on the triples (5, 12, 13) and (15, 36, 39); with P chosen as the point on the segment EW at distance five units from E, the vertices C and D are obtained by drawing the triangles ECP and EDP by *nyañchana*, with (5, 12, 13); the point P is of course of no significance to the main figure itself. The vertices A and B are obtained using (15, 36, 39) as in the first construction.

A fourth construction involves the triples (8, 15, 17) and (12, 35, 37); see (Dani 2010, pp. 16–17 for details). Taking a point Q on the segment EW at a distance 8 units from W, the vertices A and B are produced by drawing the triangles QWA and

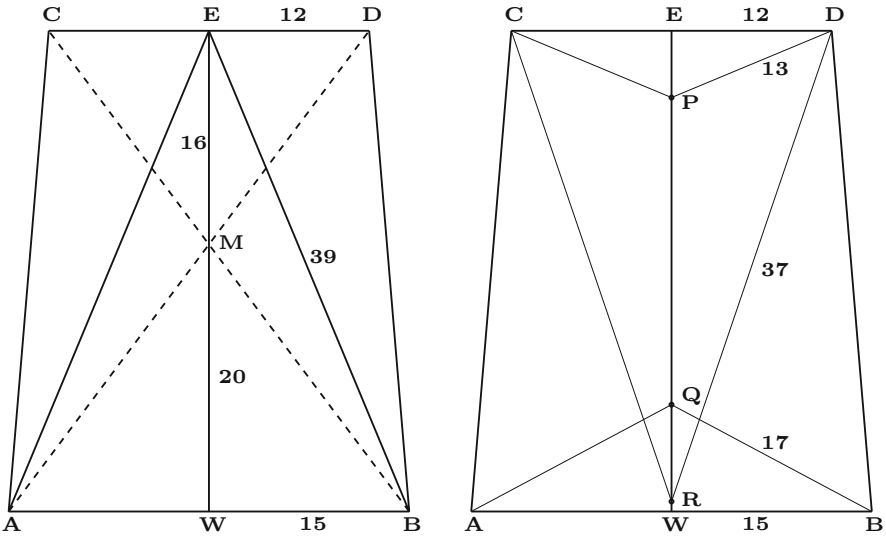

Fig. 5 The *Mahāvedi*

QWB with the triple (8, 15, 17), and with a point R on EW at a distance 35 units from E (equivalently, distance 1 from W), vertices C and D are obtained by drawing the triangles REC and RED using the triple (12, 35, 37).

It may be noted that having multiple ways of constructing the perpendicular had no practical relevance (nor has any been claimed in the original), but it is fun enough, and would serve as an exercise to enhance comprehension of the learner, of the basic idea involved.

There is also an application found in ASl 2.1–5, in a similar spirit, involving use of the nonintegral triple $\left(1, 1, \sqrt{2}\right)$. For this, a cord of length $1 + \sqrt{2}$ units would be used, with a *nyanchana* mark dividing it in the proportion $1 : \sqrt{2}$ (see Dani 2010, pp. 18–19); the mark for $\sqrt{2}$ on the cord would have to be preconstructed; thus, in effect one is replicating a previous construction of right angle, but this is very meaningful from a practical point of view. Unfortunately there seems to be a rather serious misunderstanding relating to this construction, going back all the way to Thibaut (1875), and persisting through some later works (cf. Heath 1926, p. 361, where the author refers it to papers of Bürk), and Seidenberg (1975, p. 511 – footnote 66). Quoting the sūtras ASl 2.1–5, Thibaut gives a translation as "Fix poles on both ends and the middle of the prishthya line, add to a cord of half the length (of the prishthya) its visesha, *i.e. its third plus fourth part of the third minus the thirty-fourth part of that fourth part*, . . . " (emphasis added). By recalling a meaning of visesha (*viśeṣa*) here, in the part noted with emphasis, the author means to be helpful, but it is misleading. First, it may be noted that the part does not correspond to anything in ASl 2.1–5, and the meaning is brought in from elsewhere, viz, ASl 1.10. While the latter gives a numerical value for *viśeṣa*, that term and *saviśeṣa* were also understood in terms of marks on a cord. In the context of the Śulbasūtras, where the thinking was largely geometrical, that would be the relevant meaning, and not the numerical value. In absence of any specific evidence to that effect, it would be incorrect to impute, and criticize them for it, that they were using the cumbersome way of adding indiviaually the components as described in the numerical value.[31]

3.6 Other Rectilinear Figures

One notable figure other than squares, rectangles, trapezia, and triangles appearing in the Śulbasūtras is of a rhombus. Interestingly, it figures also as the shape of a *citi*. In Baudhāyana's geometry such a figure, called *ubhayataḥ prauga* (literally "both ways triangle"), is constructed (cf. sūtra 1.57) starting with a square, by what we may call a cut and paste method, which we shall discuss in a Sect. 3.8. This method of

[31] As an illustration of the point being made, let me point out that if I tell my student to add e to an expression, even though by definition $e = 1 + \frac{1}{2} + \frac{1}{6} + \cdots$, I would not mean that she should add the terms $1, \frac{1}{2}, \frac{1}{6}, \cdots$, one by one; depending on the context, a readymade approximation may be used, or perhaps the expression absorbs adding of e in another way.

construction of a rhombus is also described in KSl (cf. sūtra 4.6). In either of the cases, the diagonals of the rhombus are in the proportion 2:1 (with the longer side along the east-west direction). Tiling of the *citi* in that shape in terms of rectangular and triangular tiles is described in BSl III.172–173; it is not indicated in the sūtra how the rhombus is constructed, but it is generally presumed that this is by the procedure taught in BSL I.57.[32] It is also described in ASl, but with a different tiling configuration, with most bricks also in the shape of a rhombus; the others are quarter portions, or halves in a few cases, of a rhombus, cut along the diagonals. MSl also mentions, in MSl 3.6.4–5, the construction as above (applicable to the outline) and aludes to the *citi,* but there does not seem to be any detailed description of the tiling design.

In KSl, the description in KSl 4.6 for transforming a square into a rhombus is followed by an analogous transformation into triangles, and also the converse aspect of transforming various figures to a square, which we shall take up in Sect. 3.8. There is no detail of what pentagons are meant, but the later commentators have postulated that it was in the shape of *haṃsamukhī* bricks (see the next paragraph).

Shapes of the bricks tiling the *citi*s would be another source of figures with which they were engaged. Actually in the construction of the *citi*s, most of the bricks are of square shape. However, they also used bricks whose shape is a triangle (arising as two of four parts of a square, cut along one or both diagonals); these are referred to as *ardhā* and *pādyā*. Note that in the former there are two sides equal to that of the original one while in the latter there is a unique one with the property. Triangular bricks arising from similar division of rectangles are also involved in the construction of certain *citi*s (specifically, in the tiling of *śyenaciti* described in BSl 119–124). Apart from these, they also used bricks of shapes which consist of adjoining with rectangular half-piece of the original square to one of these triangular shapes along a side equal to that of the original square. In the case of the *ardhā,* this yields an asymmetical trapezium, called *adhyardhā,* while with the *pādyā* it gives a pentagonal shape, called *haṃsamukhī* (see Sen and Bag 1983, pages 190–191 for various details in this respect – there however seems to be some confusion involved with regard to the sizes of the sides in Fig. 37 on page 191). The triangular and pentagonal bricks are used in producing the desired pointed parts in the outlines of the desired figure, such as for the tail or the beak of a falcon, as also for adjusting the total count of bricks in each layer, which was stipulated to be 200; we find many places in the layer designs where two or more triangular bricks are used in a layer covering a square, evidently for the purpose of enhancing the number of bricks laid in the layer. We will have an occasion to dwell on this point again in Sect. 9.3.

Interestingly the construction of *śyenaciti* in ASl involves bricks in the shape of a parallelogram, used in the wing part of the *citi* (see ASl, Chapters 15 – 20 in Sen and Bag 1983). There is however no description of how the parallelogram figure was constructed geometrically. The sizes involved being 24 *aṅgulas* (18 inches) and

[32] As pointed out in Seidenberg (1975, p. 330), use of the Pythagorean principle comes directly into play in this, unlike in the case of *citis* like *śyenaciti* or other complicated figures involving bricks of many shapes, in the construction of a square of area 15 (square) *puruṣa*.

20 *aṅgulas* (15 inches), the shape was presumably achieved by the masons through visual adjustments to fit the inclination desired for the designs involved in specific contexts. It may be noted that there is no notion of angle, or of a quantitative notion of slope in terms of ratios of sides etc., appearing in the Śulbasūtras. Achieving a given inclination would therefore be in terms of matching with given pair of lines set at an angle between them (say in the form of sticks clamped to each other suitably, or a metallic frame, etc.); the statement involved in item 9 in Datta et al. (1980, p. 130), listing construction of "a parallelogram having given sides and a given inclination" in the Śulbasūtras, needs to be read in this light.

3.7 Dividing Line Segments into Parts

Various geometric constructions described in the Śulbasūtras involve division of line segments, or figures such as rectangles, into a certain number of (equal) parts[33]; typically Śulbasutras mention only "parts" and the equality is implicit, and sometimes not mandatory. How a segment may be divided into two equal parts with the help of a cord is obvious; taking a cord (or a marked part on a cord) with the given length, one can simply fold it over and mark its midpoint. How this was done for larger number of parts is not clear. In Seidenberg (1978), Seidenberg mentions that at his request Frits Staal enquired with a priest performing a *yajña*,[34] and the reply was that they would fold the cord that many times over, adjusting it along the way. Seidenberg (1978, p. 336) comments that they might have solved the problem transforming the square with the given length as the side, into a rectangle whose one side is n times that, where n is the number by which division is sought; the other side will give the desired length-size of each of the equal parts. However, as he notes, there is no word on this, and it seems unlikely that they would have done it in that way.[35]

It is also conceivable that the length of the segment, taken in specific units, was numerically divided, converting into smaller units at each stage of remainders, down to the smallest unit, or one small enough for the context; that it would not be mathematically accurate is unlikely to have made a difference to them – the Śulbasūtras practices are seen to be quite open to approximations, making this a plausible explanation.

[33] Producing the *savišeṣa* (see Sect. 2.6.4) involves subdivision into 34 parts, and the procedure for the converse operation described involves dividing into 29 parts; these could however be theoretical or notional subdivisions. For more concrete examples, one may recall that in the construction of various *citis,* sides of squares or triangles are needed to be divided into a variety of number of parts like 7 (*Gārhapatya*, in BSl II.64), 12 or 13 (*praugaciti*, in ASl 12,7–11), etc.. Also, application of *nyañchana* with the triple (5, 12, 13) involves division of the additional part of the cord into six parts. It may also be recalled that the procedure for enhancement of citis of $7\frac{1}{2}$ *puruṣa citis* size into larger ones (cf. Sect. 5.2) involves division into 15 parts.

[34] Apparently a Vedic style *yajña* was performed during Staal's stay in India, and it was filmed by him.

[35] In Datta et al. (1980, p. 131, footnote 2), it is suggested that the division "was probably done by drawing parallels, as in Euclid"; the authors refer to sūtras concerning division of triangles as indicating that "surmise to be correct." However, the reasoning, which has not been elaborated, seems to be circular.

One may similarly ask about the division of a circle into equal radial parts. Division into two parts would result from plotting a diameter, and into four would follow from two diameters perpendicular to each other. They could also presumably bisect angles by considering the isosceles triangle formed by the two corresponding radii and taking the ray joining the midpoints of its base to the origin. In particular, it would be possible to divide the circle into 2^n parts for $n = 2, 3\ldots$. The design of the version of the *Rathacakraciti* with spokes involves radial division into 32 parts, to fit 16 spokes, with gaps of the same size as the spokes (see Sect. 9.4 for details). Whether the requisite division was indeed done by such a geometric process or by visual adjustments is not clear from available inputs. Also, division into six radial parts (and hence also three parts, and further into $3 \cdot 2^n$ parts for $n = 1, 2, \ldots$) of the circle would have been possible by drawing equilateral triangles; equilateral triangles, and the procedure for producing it, are found in the construction of the *Dārśapaurṇamāsikāvedi* (see Sect. 9.1). There are no instances of radial divisions of the circle outside these possibilities; it is unlikely they seriously considered the general issue.[36]

3.8 Transformation of Figures by Elementary Methods

One finds considerable preoccupation in the Śulbasūtras with transforming figures from one shape to another, retaining the same area, especially transforming a square into a figure with a desired shape and conversely transforming a given figure to a square shape with the same area. The methods introduced, though simple in many cases, have an intresting pedagogical dimension and have been discussed in Dani and Limaye (2021) in that light. In the case of rectilinear figures, the methods proposed are exact, while in the case of figures like circle or semicircle the methods

[36] In Joseph (2016, Sect. A.3.1.1, p. 79), there is a bulleted mention to the effect that Śulbasūtras have construction(s) to "Divide a circle into any number of equal areas by constructing diameters," with parenthetic reference to BSl II.73–74 and ASl 7.13–14; as is well-known, an accurate division of this kind is not possible geometrically, but even if one grants that approximate divisions in the overall spirit of the Śulbasūtras are meant, the above statement involves gross inaccuracies; the author has apparently relied, unfortunately, on some secondary source material aimed at lay public, not conforming to scholarly standards. First, the division in either of the instances cited is specifically into nine parts (and not "any number"), and second, and more importantly, the parts are not suggested or meant to be radial; the *Dhiṣṇya citis* which are the subject of BSl II.73–74 can be in the shape of a square or a circle; for the square version, the division is into nine square parts and is by a three-row grid, and the part in the center marked for being substituted by a stone in place of a brick; while the brief sūtra does not specify the division (in either case), in the case of the circle the context does not fit a radial division at all, and traditionally in the circular version the corresponding ninth part is taken to be a concentric circle with specified (eight *aṅgulas*) diameter, and the remaining annular part is divided into eight equal radial sectors (see Prakash et al. 1968, p. 101; Sen and Bag 1983, p. 184; Kulkarni n.d., p. 44); and the central part does not quite equal the rest. The sūtras ASl 7.13–14, in the other citation, are not about division of circle, at all, but of a square inscribed in a circle; the sutras concern tiling of the circular *Gārhapatya*, into 21 tiles, with 9 tiles in the inscribed square and 3 each in the four segments outside the inscribed square (see Prakash et al. 1968, p. 100; Sen and Bag 1983, pp. 183–184; Kulkarni n.d., pp. 43–44).

are approximate; these will be discussed in later sections. Some conversions involve the Pythagoras principle which we shall describe in Sect. 5.

In the descriptions below, we shall assume that the figures have their axis of symmetry along the east-west direction.

3.8.1 Transforming a Square into an Isosceles Trapezium

Given a square, an isosceles trapezium having the face of a desired size less than the side of the square is instructed, in BSl I.55, to be produced as follows: Mark out a rectangle at one end in the square along one of the sides, with the other side of length equal to the excess over the desired size of the face, cut the rectangle into two along the diagonal, take away one of the parts, and join it on the other side (the diagonal is chosen so that the shorter side that would be produced is toward the east).

3.8.2 Transforming a Square into an Isosceles Triangle

This could be done as a special case of the previous construction, but there is a different method described in BSl I.56, giving a diffrent triangle, with the base of the isosceles triangle equal to the diagonal of the square (and not twice the side of the square as one would get by the other method). A square is formed with the diagonal of the original square as the side. The isosceles triangle is formed by joining the vertices of one side to the midpoint of the opposite side; the latter would be situated toward the east.

3.8.3 Transforming a Square into a Rhombus

For this purpose, the sūtra BSl I.57 describes the following construction: Given a square, a copy of it is adjoined on the western side, forming a rectangle with the east-west sides twice the size of the north-south sides; the midpoints of the sides of the rectangle are joined cyclically to get the desired rhombus. (The way this is formulated, it is not just "cut and paste," on account of the introduction of a copy of the square to be adjoined, but it is in the same spirit and may still be considered a cut and paste method.)

3.8.4 Transforming a Square into a Rectangle: A Special Case

BSl I.54 is a sūtra for transforming a rectangle into a square with the same area, which involves usage of the Pythagorean principle, and will be discussed later in Sect. 5.5. Ahead of that, there are two sūtras on the issue of transforming a square into a rectangle, in the spirit of considering the converse issue. The resolution is based on elementary considerations in the same way as the above construction. Of the two sides of a rectangle with a given area, one could be chosen freely, so the converse issue as above needs an additional input of choice of the size of one side. BSl I.52 deals specifically with the case where one side of the rectangle is chosen to be the diagonal of the given square. The rectangle in this case is instructed to be produced by cutting the square along one of the diagonals and cutting one of the parts into two halves along the other diagonal; the three pieces can then be reassembled into a rectangle, with one side equal to the diagonal and the other

side half the diagonal. The same rule is also given KSl 3.4; it is not found in ASl and MSl.

Constructing the rectangle from a square having the diagonal as one of the sides would have been a novelty (and in fact may have motivated the *dvikaraṇī*) and hence explained systematically, while the practical case which comes next, with simple proportion of sides, may not have seemed to warrant an elaborate treatment.

3.8.5 Transforming a Square into a Rectangle: General Case

In the next sūtra BSl I.53, Baudhāyana moves on to the general question, but the response seems rather casual or informal. The instruction simply says "move the extra part to the side(s)." There have been many comments to the effect that the solution is unsatisfactory (see Prakash et al. 1968a, p. 56; unintelligible according to Seidenberg 1978 – p. 334; etc.). A slightly more elaborate instruction on the issue is found in ASl 3.1 (Kātyāyana does not discuss the general case, though the special case as above is included – MSl does not deal with the issue). Thibaut (1875, p. 246) comments "Āpastamba's rule helps us somewhat further"; this author however does not find any substantive difference. Rather than fully interpreting the sūtra in the light of the clarity claimed to have been attained, Thibaut then proceeds to discuss a special example, taking the side of the square to be 5 and the prescribed side of the rectangle to be 3, and describes (geometric) steps arriving at the other side to be $8\frac{1}{3}$ (as to be expected).[37]

Keeping the Śulbasūtras context in mind, where apart from imparting geometrical content at theoretical level, they aimed informing about steps to be taken in practical contexts, the following seems a plausible explanation, for both BSl I.53 and ASl 3.1, though the wording is not clear enough in either case; the explanation is for square with integer sides, which is the case they would have aimed to explain in these sūtras, for the practical contexts. In a way, the explanations of Thibaut and Bürk fit with this general version. Given a square with side m and the prescribed side for the rectangle being n (both integers – describing measures with respect to some unit), the procedure would be as follows: For simplicity, we shall assume $n < m$; the other case can be reduced to this by elementary considerations, which we shall not go into. We divide the quare into two rectangles one with sides m and n and the other with sides m and $m - n$. It now suffices to transform the second rectangle into one with one side n, so that it can be put alongside the first to get the desired rectangle. For this, we divide the side of size m into mn equal parts and the side of length $m - n$ into unit size parts and form a corresponding grid of rectangles. The resulting $mn(m - n)$ rectangles, with sides 1 and $\frac{1}{n}$, can be reassembled to get a rectangle with side n as desired, by stacking them into $m(m - n)$ columns of n each, alongside each other. More efficient plans involving fewer parts would be possible, but this is a

[37] As cited in Sen and Bag (1983, p. 157), Bürk also gives, in his 1902-paper (cf. Bürk 1901; the page number given in Sen and Bag 1983 seems incorrect, and this author has not accessed the original paper) a similar illustration with a square of side 6 and the prescribed side of the rectangle to be 4, leading to the other side being 9.

straightforward scheme which would be accessible to them, at least for small values of the integers that they would be concerned with. These kind of rectangular grids are witnessed, for instance, in the plan for tiling for the *gārhapatya agni* (cf. BSl II.64–65); similar grids are involved also in the tilings of *ubhayataḥ prauga citi*, the rhombus-shaped *citi* (cf. ASl 12.12–13).

4 The Pythagoras Principle

In Baudhāyana's scheme, the next topic to learn is the theorem now known after Pythagoras. It ought to be borne in mind that the notion of a theorem in the sense of Euclidean geometry, deduced from a set of axioms, etc., is not involved in the context of the Śulbasūtras. The statements made in the Śulbasūtras are in the nature of stating facts about the physical world, and no particular distinction was made between statements coming from empirical knowledge (those that could serve as "axioms" and those that may be deduced), though undoubtedly some of the statements would have emerged through a deductive process or cogitation, rather than through empirical observation.[38] It would therefore be more appropriate to discuss it as a principle known to them rather than as a "theorem," and we shall generally adopt the nomenclature accordingly. For convenience, we shall however continue to associate the name of Pythagoras, though the latter would be a later figure historically. In this section, we shall discuss the contents of the Śulbasūtras related to the principle.

The Pythagoras principle is stated in all the four Śulbasūtras, and it would be worthwhile to go over the formulations and the nuances involved in the different Śulbasūtras in some detail.

4.1 The Formulation in Baudhāyana Śulbasūtra

In BSl, the presentation on the topic begins with a sūtra, BSl I.45, which in close translation corresponds to "the diagonal of a square makes double the area"; it is implicit that the comparison is with the original square, and a linear size *making* a certain area means that the latter is the area of the square whose side is the given linear size. This is presumably meant as a warm-up toward the statement of the Pythagoras principle which is to follow, after one more intermediate observation. Based on the preceding observation, Baudhāyana refers to the size of the diagonal of the square as "*dvikaraṇī* (the doubler); the term is not introduced in the form of a definition, or nomenclature, but its usage in the next sūtra and linguistic considerations make this obvious.

The next statement is "when the transverse side is one unit and the stretch (*āyāma*) is its doubler, the diagonal is the tripler." While the first instance about

[38] An attempt is made in Datta (1932) to place the Śulbasūtras geometry on an axiomatic footing, but the effort does not seem to have led to any further development on the theme.

the diagonal of a square would be visually clear to a learner from a tiling, this second one is not so. Baudhāyana goes into one more digression, stating that one also gets from this a side-length which produces a third part of the area, by dividing the tripler (length) into three equal parts, and the division of the sides into three equal parts divides the square into nine equal parts. Following the preliminary observations, we come to the statement of the principle, in BSl I.48, which may be translated as:

> The diagonal of a rectangle makes the area that is made separately by the transverse and flank sides.

This is unmistakably a statement of the Pythagoras principle, though it is made in the framework of rectangles, and not right-angled triangles.[39] I may mention that the term used for the diagonal is *akṣṇayārajju*, which literally means "the cord that goes across."

The sūtra containing the statement of the principle is followed by one (BSl I.49) which states:

> Three-four, twelve-five, fifteen-eight, seven-tentyfour, twelve-thiryfive, fifteen-thirtysix, are pairs in which this is obtained.

The pairs of numbers described clearly correspond to the first two entries of the Pythagorean triples (3, 4, 5), (12, 5, 13), (15, 36, 39), (15, 8, 17), (7, 24, 25), (12, 35, 37), and (15, 36, 39). There is no clue as to how the triples were arrived at. They are apparently given as examples illustrating the principle, without involving surd magnitudes. The inclusion of the triple (15, 36, 39) here, though it is just a multiple, is very likely related, as commented in Sect. 3.5, to its association with the *Mahāvedi*.

4.2 The Statement in Āpastamba and Kātyāyana Śulbasūtras

While Baudhāyana comes to the statement of the Pythagoras principle in steps, ASl on the other hand goes straight to it, after introducing the methods for constructions of squares that used the converse of the principle, with the triples (3,4,5) and (5,12,13); the special case of the square is stated after that statement, and *dvikaraṇī* is introduced through it. The statement in ASl is the same except for a minor difference that the rectangle is referred simply as *dīrgha*, rather than *dīrghcaturasra* as in BSl.

Following the statement of the Pythagoras principle, ASl has a sūtra amounting to a remark that the constructions of squares described earlier are based on the knowledge of this principle. The clause involved is *tābhirjñeyābhiruktaṃ viharaṇaṃ*, and it translates as "the constructions noted above are known

[39] In certain books, one finds a statement that BSl gives only a restrictive statement of the theorem, and there is a complete one in ASl, which is not true; the statements in the two, as we shall see, are essentially equivalent.

(or knowable, or deducible) from this" (Kulkarni n.d.).[40] Such a remark is rather unique, with no analogous interconnections found elsewhere in the Śulbasūtras. It may be observed that strictly speaking the constructions are based on the *converse* of the Pythagoras principle. On the other hand, the converse statement, though used extensively in various constructions, is not stated explicitly in any of the Śulbasūtras. Apparently the converse statement was conflated with the statement of the principle itself, and the remark as above supports such an inference. The converse statement can of course be deduced from the principle through a simple argument, and visually it may have seemed to them a part of the statement itself.

KSl recalls the principle, as well as *dvikaraṇī*, *trikaraṇī, and tṛtīyakaraṇī* introduced in Sect. 2.6.4, in the second *kaṇḍikā* (Chapter) along with some aspects of construction of the *śamyā vedi*. The statement of the principle is same as in BSl. It is followed by the clause *iti kṣetrajñānaṃ*, "this is known about areas." One may wonder about the significance of such a clause. On the one hand, its being included especially in this context may signify some importance being associated to it being conveyed. On the other hand, it also suggests that the principle was being transmitted to the successive generations, providing no elaboration or reasoning toward its validity.

4.3 The Formulation in the Mānava Śulbasūtra

MSl, on the other hand, has a different take on the statement of the principle. The relevant sūtra there, MSl 3.1.10, translates as

> Multiply the length by the length, breadth by the breadth; it is known that adding them and taking the square root yields the diagonal.

It is noticeable that unlike in the other Śulbasūtras here the statement is not in terms of areas, but rather the lengths of the sides. Also, it is now seen to be presented more directly as a procedure for computing the size of the diagonal in terms of the sides. It is however not possible to ascertain whether these features reflect anything of significance, by way of change in mathematical practices, from a historical perspective. The concerned sūtra appears isolatedly, in a section with an assortment of others relating to bricks and brick-laying of the vedis, rather as one of the things that is especially selected for being remembered, and the scope for comparisons is limited on account of this.

[40] In Sen and Bag (1983), the authors recall (page 234) that according to Bürk the statement means that "the construction has been taught by means of these, of course, by means of such as are recognizable"; later authors have interpreted "recognizable" as referring to recognizable numbers (Sen and Bag 1983) or specifically to Pythagorean triples (Heath 1885, p. 146). Use of the verb "to know" in the clause relates the construction to the statement of the principle, and reference to "recognizable" numbers or triples is apparently based on a misunderstanding.

5 Applications of the Pythagoras Principle

The Pythagoras principle is applied in BSl and KSl for the construction of squares whose areas are prescribed in various ways, as we shall next discuss. In BSl, this part follows soon after the statement of the Pythagoras principle.

5.1 A Square Whose Area Is the Sum of Two Given Squares

The sūtra BSl I.50 describes how to construct a square whose area equals the sum of two given unequal squares; for equal squares, the issue is resolved by *dvikaraṇī* – the case could have still been included with the construction that is described, as given below, but is presumably excluded for the sake of maintaining clarity of some of the steps, where specializing could seem unnatural, or lead to some confusion.

The resolution, as may be expected, consists of plotting a rectangle with sides equal the sides of the given squares and taking the diagonal of the rectangle for the side of the desired square. In the sūtra, the rectangle is prescribed to be plotted within the larger square, based on one of its sides, marking the side length of the smaller one on the other side. See Fig. 6: PC is obtained as the side for the sum of squares whose sides are PA and PB.

The same procedure is described in ASl 2.10–12 and KSl 2.22. Mānava Śulbasūtra does not mention the proposition – it is however involved, and implicitly assumed to be known, in one of the applications of the proposition relating to enhancement of sizes of figures, which we discuss in the next subsection.

5.2 Enhancing the Size of Figures by Scaling the Unit

A rather unique practical application of the construction described in the last subsection, of combining two squares into one, is found in the Śulbasūtras; it is involved in MSl as well (in implementing the instruction as in MSl 3.3.6) though the

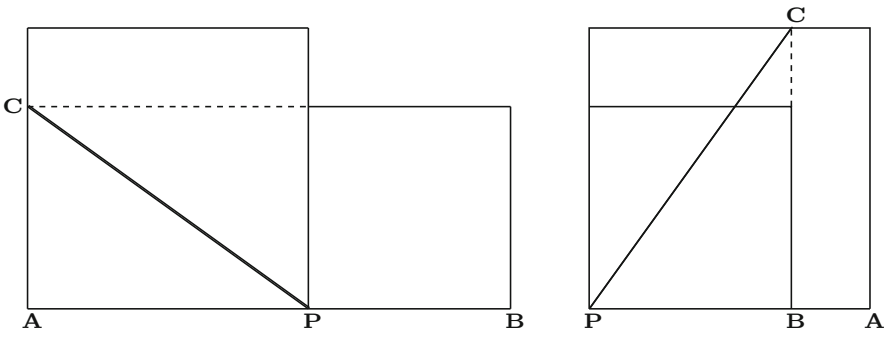

Fig. 6 The side for the sum of two squares

statement itself has not been recalled; apparently it is assumed as known; and the sūtra itself however pertains to a rather specific situation and is rather terse to be discussed here any further.

There was a certain practice or context to which this application has been linked. Certain *kāmya yajñas* were performed repeatedly, and there was a stipulation that on each successive occasion the *citi* should be in the same shape, but with area enhanced by one unit; the starting one would be $7\frac{1}{2}$ *puruṣa*, the second $8\frac{1}{2}$ *puruṣa*, the third $9\frac{1}{2}$ *puruṣa,* and so on (BSl II.1–5).[41] As the same figure was to be drawn each time, this was achieved by simply enhancing the basic measuring unit, as marked on the cords used, suitably, and following the same steps as before. Thus, to increase the area from $7\frac{1}{2}$ units to $8\frac{1}{2}$ units, the area needs to be enhanced by a factor of $\frac{2}{15}$, for which one would replace the original unit by the size of the side of the square obtained by augmenting the unit square by a square of size $\frac{2}{15}$; in this respect, BSl II.12 instructs that the unit area (*puruṣa*) be divided into 15 (equal) parts, 2 of which should be added with each unit area in the figure, to produce the enhanced figure of $8\frac{1}{2}$ *puruṣa*s.

Seidenberg (1975, p. 492) postulates that this stipulation may have been the motivation for the discovery of the above construction, and in turn of the discovery of the Pythagoras principle itself. While this may fit into the overall theme of "ritual origin" of ideas pursued there, there is no evidence to that effect. In fact it is quite in Indian tradition to incorporate modifications in the "requirements" for various rituals as newer possibilities arise through newly acquired knowledge. Thus, it is more likely that until some point in time the stipulation may have been only that on each successive occasion the area should be bigger, and the precise quantative version was introduced only after the principle, and the possible construction came to be discovered, in one or other general context. A few sūtras down the line from those mentioning the augmentation as recalled above, in BSl, there is a sūtra (BSl II.18) which says that according to some Brāhmaṇas, after performing a *yajña* with a *citi* of a certain size one should not perform it again with a *citi* of a smaller size; in terms of the overall requirement from a ritualistic perspective, this seems to be the key point, and the precise prescriptions would have been filled in when there were people around who had an idea of how to do it; it was accordingly followed by some Brāhmaṇas, which in this instance includes Baudhāyana's.

Curiously there is a variation in the application of the scaling scheme described above found in the Śulbasūtras, which seems to have gone without much notice in the literature. In the Āpastamba Śulbasūtra, in ASl 8.6 where the issue is dealt with, we see a variant as follows: It instructs to add $\frac{1}{7}$th (square) *puruṣa* per iteration to the unit square to get the new unit in the manner as above (the number of iterations is conveyed in the sūtra by words equivalent to "what is added to seven"). This in effect amounts to

[41] As described by Baudhāyana (BSl II.1–4) the sequence is supposed to go up to $101\frac{1}{2}$ *puruṣa*; one may wonder whether they would actually have continued that far, or it is simply a metaphor of some kind; anyway up to where it went does not make a difference to the mathematical content and will not concern us here.

adding $1\frac{1}{14}$ (square) *puruṣa* to the net area at each iteration. In the Kātyāyana Śulbasūtra, while some of the instructions on the issue of enhancements (specifically, those appearing in *kaṇḍikā* (Chapter) 5) are in conformity with Baudhāyana's formulation, in KSl 6.2 (in *kaṇḍikā* 6) this is seen not to be the case: For the *ekaśatavidha* (101-fold), *citi* the (original) *prakrama* unit is instructed to be replaced by the side of a square with area $14\frac{3}{7}$ (square) *prakramas*, thus implying that the area should be arranged to be $14\frac{3}{7}$ times that of the original *citi*. It can be seen that this does not match with the general scheme involving addition of one *puruṣa* to the area at each iteration, described earlier; the area works out to about 108.2 *puruṣa*s, considerably in excess of $101\frac{1}{2}$ *puruṣas* associated with the *citi*. On the other hand, it is seen to be in agreement with what Āpastamba has prescribed, as $94 \times \frac{15}{14} + 7\frac{1}{2} \approx 108.2$, to which the factor is adjusted by Kātyāyana in the sūtra. Apart from ASl 6.2, the subsequent sūtras ASl 6.3–5 also involve division by 7, and not $7\frac{1}{2}$. This seems to have been an independent practice, or tradition, than the scheme presented by Baudhāyana.

This alternative version has not received due attention in the literature. Notably, in particular, in the translation of the sūtra ASl 8.6 given in Sen and Bag (1983) the authors state "... should be divided into *seven and half equal parts* and each part added to each *puruṣa* ..." (emphasis added). This is however incorrect. There is no mention of "seven and half" in the original sūtra[42]; (the translation in Kulkarni n.d. (correctly) translates as division by 7). Having missed that instance, in the commentary in Sen and Bag (1983) on the sūtra KSl 6.2 (on page 270), where they notice the difference, the authors treat it, with some apparent puzzlement, as an exceptional instance, which "does not appear to be correct" or is a simplification.[43] It may be noted that in the alternative scheme the area added at each iteration is not one *puruṣa*, but $1\frac{1}{14}$ *puruṣa*. How much enhancement is to be made is after all a matter of convention, and variant practices may not be deemed incorrect.

Before concluding this discussion, a point may be made here, based on these observations, and also supported by other instances in the Śulbasūtras that we need not go into, that the prescriptions about the dimensions, etc. did not strictly follow any sacrosanct injunctions of permanent nature but were open to adjustments by individual teachers.

5.3 Kātyāyana's Method for Putting Together Multiple Squares

We recall next a method from KSl for constructing a square with area equal to an integer multiple of a given square. Note that the issue is tractable by repeated application of the method of augmentation of squares, described in Sect. 5.1; given a number, say n, of squares of a fixed size, to combine them, rather than joining one

[42] Perhaps the error goes back to Bürk's edition of ASl, but this author is not in a position to check this at this point.

[43] They also recall an explanation from Datta (1932, pp. 166–168) which seems contrived and misses the point.

square each time, n may be expressed as a sum of squares, as $n = \sum_{j=1}^{k} n_j^2$, and squares with sides $n_1, \ldots, n_k$ may be joined successively to get the desired square.

Kātyāyana describes another method, a more direct one, which also depends on the Pythagoras principle. For later reference, I include the details of the sūtra; see also Dani (2018).

The sūtra in question, KSl 6.7, translates as the following statement.

> To produce a square putting together a number of squares of a fixed size, construct an [isosceles] triangle with one less than the number as base and one more than it as the other two sides [together] and take the altitude of the triangle for the side of the desired square.

The isosceles triangle involved would be constructed by taking a cord of length equal to the two slanting slides together, with a mark at its midpoint, tying its ends to poles at the vertices at the base, of the desired size, and stretching the cord on the ground, holding at the midpoint mark. The prescription is of course based on the fact that a slanting side together with the corresponding half the base and altitude forms a right angled triangle, to which one can apply the Pythagoras principle, together with an identity which in symbolic terms may be expressed as

$$n = \left(\frac{n+1}{2}\right)^2 - \left(\frac{n-1}{2}\right)^2,$$

where n is the number of squares to be put together. There is no evidence in the Śulbasūtras of symbolic algebraic calculations, as involved here, being carried out. The identity as above would have been recognized by observing the square tilings, and realizing the difference of the squares matched along two perpendicular sides, in terms of the rows that are left on two sides.

5.4 A Square Whose Area Is the Difference of Two Given Squares

The procedure for this is explained in BSl I.51. For this, actually a right angled triangle (half of a rectangle along the diagonal) is constructed whose hypotenuse equals the side of the larger square and one of the sides is the side of the smaller square. The specific prescription is to take a rectangle, as in the preceding construction, and identify on the newly added side the point at the desired distance; see Figure 7.

In the case of longish rectangles, when multiple squares of the size of the shorter size can be taken out, Kātyāyana suggests that a square equivalent to those may be put together with one for the remaining rectangle.[44]

[44] The sūtra described in Sect. 5.3 appears later in the work, and whether it is meant to be used here is not apparent. While evidently the sūtra is intended as simpler or more elegant than the one suggested above for the general case, the precise details are not clear, and the explanations in Kulkarni (n.d.), following (van Gelder 1963), do not seem to make it clear enough.

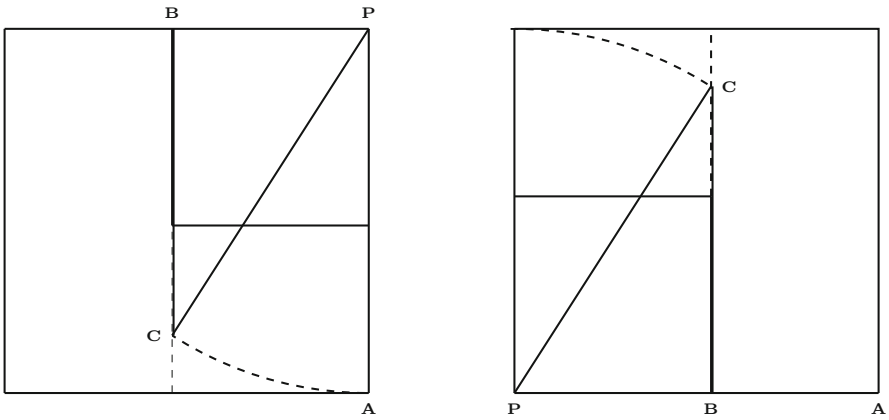

Fig. 7 The side for the difference of two squares

Unlike in the case of augmentation of squares, the result on producing a square equivalent to the difference of two given squares does not seem to have been applied directly in practice. We see, on the other hand, it being used in deriving a further consequence, a procedure for transforming a rectangle to a square, which was probably used in the constructions of some of the *citi*s (see below).

5.5 A Square with the Same Area as a Given Rectangle

Given a rectangle to be transformed into a square, it is first turned into a figure which is a difference of squares (a gnomon), by cutting of half a strip along the shorter side with width half the difference between the sides, and placed along the other side, aligned with the other shorter side (BSl I.54), as illustrated in Fig. 8. Having achieved that, Baudhāyana simply refers to the preceding construction, saying "resolution of this has been explained"; this may perhaps be the earliest case of back reference of a mathematical kind!

The process of transforming a rectangle into a square would have been needed in the construction of various *citi*s. Constructions of the *droṇaciti* (*citi* in the shape of a trough) and *parimaṇḍala kūrmaciti* (a rounded turtle shape) as described in BSl (sūtras BSl VII.2–3 and X.2–3, respectively) involve designating a certain part of the prescribed area to be turned into a circular region, and using the remaining area for other parts of the figure, a handle for the trough in the first instance and legs and head in the second; specifically, the prescribed area of $7\frac{1}{2}$ *puruṣa* is instructed to be divided into 120 square-brick-sizes (with sides 30 *aṅgulas* each), and the area of 119 and 115 of them, respectively, to be transformed into circular regions. It is not specified in the respective sūtras how this was meant to be accomplished, but in the overall context it seems reasonable to assume that first a rectangle would be constructed with the respective areas designated for the circles (say as 17×7 unit

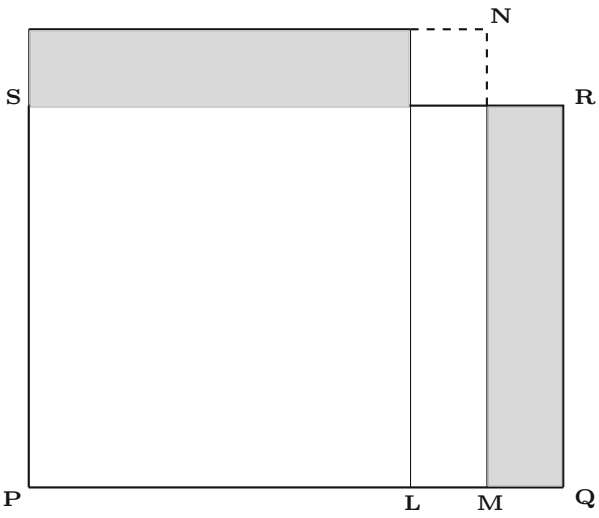

Fig. 8 Transforming a rectangle to a square

sizes in the former case and 23 × 5 unit sizes in the latter case), transfoming the rectangles into squares by the method described above, and then transforming the squares to a circles by the method which we describe in Sect. 7.2 below.

6 Miscellaneous Topics Around the Pythagoras Principle

This section is devoted to a variety of topics related to the theme of the Pythagoras principle, not covered in the earlier sections.

6.1 Square Roots

The methods described in Sects. 5.1 and 5.3 incorporate in particular means of finding square roots of integers, as geometric magnitudes. Rarely do we find numerical values associated with them; a rather unique case of $\sqrt{2}$ for which there is an impressive numerical expression, and some other plausible cases of numerical values associated with square roots, will be discussed in Sect. 8; we also point out that there are certain instances discussed in literature as computations of square roots in the Śulbasūtras are not quite so.

The major preoccupation in the Śulbasūtras relating to roots was about measuring out magnitures on ground which are specified by area, rather than their linear dimension. A simplest example of this, of determining a square whose area is two (square) units, was achieved by choosing for its side the diagonal of the unit square, viz, the *dvikaraṇī* as may be recalled. This is a special case of the Pythagoras

principle which has been specifically mentioned in BSl I.45, ASl 1.10–11, and KSl 2.12. The term *saviśeṣa* also appears in relation to $\sqrt{2}$; there seems to be a slight syntactical difference in the usage of the terms *dvikaraṇī* and *saviśeṣa*, with the former signifying a more geometrical entity and the latter a numerical one (scalable with the unit, nevertheless), but the distinction does not seem to be exclusive. The excess of *saviśeṣa* over the unit is referred to as *viśeṣa*, and the term appears in particular in ASl 2.2.

The side of a threefold square was also accorded a name, *trikaraṇī*, which is also mentioned in all Śulbasūtras (BSl I.46, ASl 2.6, and KSl 2.14). This is again constructed geometrically as the diagonal of a rectangle whose one side is the *dvikaraṇī* and the other side is one unit. Interestingly, there is also a name for the square root of $\frac{1}{3}$, *tṛtīyakaraṇī*; it was produced by dividing *trikaraṇī* into three parts, or by taking *trikaraṇī* of $\frac{1}{3}$ of the unit (BSl I.47, ASl 2.7–8, and KSl 2.16–18).

6.2 Semicircle with the Same Area as a Circle

We will be taking up aspects of mensuration of the circle in the next section. Here we only note an application of the idea of enhancement of areas as discussed in the last subsection to the circle, found in MSl 1.1.8. It may be recalled that the *dakṣiṇāgni* was semicircular; while *gārhapatya* was circular and *āhavanīya* a square, they were to have the same area. The abovementioned sūtra, which describes the constructios for the three *citi*s together, instructs the semicircular one to be obtained from the circlar one as follows: construct a square circumscribing the circle and draw a semicircle with its midpoint as the center, passing through its vertices; thus, for the new radius the area of the circle will be twice the original, so the semicircle will have the same area as the original circle, as desired.

6.3 Pythagorean Triples

We recalled earlier (in Sect. 4.1) that BSl mentions the Pythagorean triples (3, 4, 5), (12, 5, 13), (15, 8, 17), (7, 24, 25), (12, 35, 37), and (15, 36, 39) (the last entry of each triple being implicit). It is a specific list, and we do not know how it was arrived at. There is also no hint about more such triples being known to the author (such as through usage of an equivalent of "etc."). ASl does not present any list of such triples but illustrates the use in construction of the *Mahāvedi* (see Sect. 4.1), of the triples as above, other than (7, 24, 25).

The interest of the sulba geometers in the Pythagorean triples stemmed from their application in producing the perpendicular, through the *nyañchana* method; the reader is referred to Dani (2003) for a detailed discussion on this topic. Functionally, only one, the simplest one, viz, (3,4,5), would have sufficed their purpose. They also found the triple (12, 5, 13) and typically used it in the *nyañchana* procedure with appropriately changed markings. These triples are found used in all the four

Śulbasūtras. Driven by curiosity, a few more triples seem to have been found, which BSl notes as examples, following the statement of the Pythagoras principle, and ASl illustrates in terms of construction of the *Mahāvedi* in multiple ways. It is not clear how they might have arrived at them, and the small sample that is available tends to make any general hypothesis on this rather too speculative for our discussion here; see however (van der Waerden 1983) for some observations in this respect. It would have been noticed that the newer triples offer no particular advantage for usage with the *nyañchana*, and the procedure for requisite divisions, for the *nyañchana* markings, becomes more and more cumbersome as the sizes of the entries grow bigger. It is therefore unlikely that they would have had any further interest or motivation in finding more Pythagorean triples. And indeed no other triples, other than scalar multiples of the ones seen above, turn up in the Śulbasūtras explicitly.

It may be noticed however that the identity as in Sect. 5.4, noted by Kātyāyana, could be used to produce a sequence of Pythagorean triples, one for each odd square number n. This has been sometimes treated as a sequence of Pythagorean triples from KSl (cf. Datta and Singh 1962, II, pp. 204–205). It should be borne in mind however that Kātyāyana's sutra recalled in Sect. 5.4 has a different context, not involving Pythagorean triples, or solving indeterminate equations, and no connection is made in the original with the triples associated with the *nyañchana* procedure, nor is there any mention of some of the triples involved in the *nyañchana* procedure being particular cases of these. The restriction of choosing n to be the square of an odd integer, needed to get Pythagorean triples, is also not alluded to.

6.4 The *Mahāvedi* and a Thesis of Seidenberg

Let us recall that the *Mahāvedi* is in the shape of an isosceles trapezium whose altitude is 36 units, and the base and face are 30 and 24 units, respectively. The *Śatapatha Brāhmaṇa* and *Taittirıya Saṃhitā* give these dimensions explicitly, in terms of steps (strides) by the *yajamāna* as the unit; specifically, as described in Sen and Bag (1983, p. 170), following Eggeling's translation from *Śatapatha Brāhmaṇa* the description involves the following, with respect to Fig. 4: the *yajamāna* arriving at point W, the midpoint of the base, from a post to its west, taking 15 steps to his right where he drives a peg for the right hip, at the point B in the figure. Returning to W, he then takes 15 steps northward where he drives the peg for the left hip, at the point A. From W, he then strides 36 steps eastward and there drives the peg, at E, for the fore part. . . [the left and right shoulder points C and D are described similarly].

It may be noted that the triangle BWE has sizes (15, 36, 39) which is a Pythagorean triple, and that this fact is used in Āpastamba's construction of the vedi with what was called the *ekarajjuvidhi* (see Sect. 3.5). In Seidenberg (1978, p. 323), Seidenberg raises the question "did the priests at the time of *Śatapatha Brāhmaṇa* and the *Taittirıya Saṃhitā* know this Pythagorean triangle?" He goes on to note also that the figure "is loaded with" other Pythagorean triples (as have been used by Āpastamba in the other constructions), and arguing that this would be a major miracle if they were not to know the Pythagorean triples, and concludes that

"Aspect II was known at the time of *Taittirıya Saṃhitā*" which then forms a prop of his theory of a common predecessor[45] ("Aspect II" we may recall, without going into the details, concerns the Pythagorean triples).

Actually there does not seem to be much of a case in such an argument. First, though the author mentions all of Āpastamba's five Pythagorean triples (12, 16, 20), (15, 20, 25), (5, 12, 13), (8, 15, 17), and (12, 35, 37) in his reference to being "loaded with," in the last three the third point is actually manufactured, and not intrinsic to the description; Āpastamba was aware of this and makes a reference to a separate mark on the cord. The case for the "major miracle" is thus already overstated. More importantly the argument does not take into account the actual construction described in *Śatapatha Brāhmaṇa*, as recalled above. If the choice of the dimensions was motivated by knowledge of the Pythagorean triples, why would the procedure described be only in terms of taking steps left, right, or east? That would be a greater puzzle.

It seems to me that while we have here a very interesting choice of dimensions for an isosceles trapezium, it only depends on the familiarity with the triple (3, 4, 5), and the idea of scaling which was very prevalent. The trapezium is actually made up from vertices of two isosceles triangles, ABM and CDM as in the figure, one put over the other upside down. Both the triangles are scaled-up versions of an isosceles triangle with base 6 and altitude 4, and the halves of this by the altitude are (3,4,5) triangles. This seems a natural way of constructing isosceles trapezia, starting with an isosceles triangle. Scaling would be used to adjust to the desired overall shape. In this case, we see the triangles to be in the proportion 5:4, a fairly natural choice, and it yields the dimensions of the *Mahāvedi* as altitude 36 units, and the base and face 30 and 24 units. The fact that (15, 36, 39) is also a Pythagorean triple may not have been noticed until later, and even if it had been noticed, that would not have made much of a difference without being familiar with the Pythagorean principle.

This also explains why no geometry turns up in the construction described in *Śatapatha Brāhmaṇa.* While the figure was arrived at by "playing with" the (3,4,5) type triangles, the right angles themselves have gone into the background. It would then have seemed simpler, and also with a greater ritual appeal, to measure the requisite units than work through the two component triangles involved in the construction.

[45] The inference as above is used to deduce that the Indian knowledge from the Vedic period is not a derivative from the Greek tradition. In the current context however, such an argument would not be needed, as the period of the Śulbasūtras has got pushed back in the general discourse, and there is no serious contention in the field about Śulbasūtras knowledge being derived from the Greek tradition. The conclusion thus arrived at, that the Vedic knowledge of geometry is not a derivative of Greek geometry, is then used to make a case for a common predecessor. The present author has serious reservations to the theory of common predecessor as well; however, this will not be an appropriate place to go into detail about it.

7 The Circle

It may be recalled that drawing of circles was already involved in the construction of rectilinear figures; in those contexts, only certain segments were relevant, but the description is in terms of drawing circles, and the term *maṇḍala* for circle made an appearance there, right at the beginning of BSl's geometry course. The same term is found used in all the four Śulbasūtras throughout.

In the preliminary parts, the construction of a circle is described in terms of placing a pole at a point, to which a cord is to be tied, drawing the circle following a mark made on the (stretched) cord as specified in the individual contexts; the point at the pole would be the center, and the distance of the mark from it along the cord would be the radius of the circle; neither center nor the radius is referred to by any name. There was a term used commonly for the diameter, *viṣkambha*, which stands also for "width" in a wider context; in respect of the circle, the term was used as a reference measure of the size.

In the later practical contexts of construction of *citi*s however, the circles are mostly produced by transforming squares into circles (there are some notable exceptions – see below for details.). In this way, a circle would be constructed with the area desired for the context. The construction for this, which is explained in all the Śulbasūtras is described in Sect. 7.2 below. This aspect of the Śulbasūtras has been the subject of much discussion in the contemporary literature on the Śulbasūtras. It has sometimes been likened to the problem of doubling the cube, associated with the legend of the oracle of Delphi, in the Greek tradition (see Seidenberg 1975, 1978, 1981), as a motivating objective. In this context in Sect. 7.3, we shall go over the details of how the issue unfolds in the Śulbasūtras, and comment on the thesis as above, in the light of the observations.

The problem of squaring the circle, namely the converse of the process as above, of transforming a circle to a square, is also considered in Śulbasūtras. For this, Baudhāyana gives, rather than a geometric construction, an intricate numerical factor for the ratio of the side of the desired square to the diameter of the given circle. This will be discussed in Sect. 7.6.

There are two notable exceptions where circles, or rather arcs of circles, appear as part of the design of *vedi*s that are not constructed by transforming a square of the desired area into a circle. One is the *dakṣiṇāgni* mentioned earlier, which is in the shape of a semicircle (bounded by the diameter). As it is to have the same area as the *gārhapatya* which is circular, it is obtained simply by constructing a circle with twice the area as the latter (a scaled-up version in the same overall spirit as discussed in Sect. 5.2) and taking half it; the revised unit for this is produced by joining the end points of a quarter of the circle.

Another exception in this respect occurs in the construction of a *vedi* called the *Dārśapaurṇamāsika vedi*. The design involved is rather unique, in that it involves circular arc segments for its contours. It consists of first constructing an isosceles trapezium, with face, base, and altitude 48, 64, and 96 *aṅgulas,* respectively, and marking out circular arcs joining the pairs of adjacent vertices, lying within the

trapezium, the latter define the boundaries for the activities for the *yajña*. We shall discuss this *vedi* in some detail in Sect. 9.1.

7.1 Circumference of a Circle

The notion of circumference of a circle does not make any significant appearance in the Śulbasūtras, and in particular it does not feature in the geometrical expositions in BSl and ASl. There is however a passing reference to it in BSl, in the later part, in sūtras BSl I.112–113. This is in the context of describing the setting for the *Aśvamedha yajña*, which involves a row of circular pits. The pits are described to have 1 *pada* diameter (*viṣkambha*) and 3 *padas* circumference (*pariṇāha*). While that twofold part of the description is of no consequence there, and is simply made as an elaboration, it indicates that the ratio of the circumference to the diameter was taken to be 3, as was the case in many ancient cultures.[46]

There is however a sūtra in the Mānava Śulbasūtra, MSl 3.2.13, marking a departure from the belief. We recall the original sūtra here for reference to some of its parts below.

Viṣkambhaḥ pañcabhāgaṣca viṣkambhastriguṇaśca yaḥ |
sa maṇḍala parikṣepo na vālamatiricyate ||
A fifth of the diameter and three times the diameter; that is the circumference of the circle – not a hair-breadth remains.

Here *maṇḍala parikṣepa* is the term used for the circumference, it may be noted that it is different from the term *pariṇāha* that we came across in BSl, indicating that there was no uniform common term adopted for it yet. The last part *na vālamatiricyate* translates as "not a hair [breadth] remains." The ratio of the circumference to the diameter of a circle is thus assigned an upper estimate of $3\frac{1}{5}$, actually rather on the high side, and there is palpable jubilation over its not missing even a hairbreadth! The value is not seen recalled anywhere later however, whether in a practical context, or by way of dissemination.[47]

[46] In Dani (2022), I made a suggestion that this may have to do with the fact that fractions came into human thought process much later than circles – on account of wheels – and once an integer value was assigned to it, for various reasons the ratio may have come to be adhered to until much later, even after fractions became a part of the overall discourse.

[47] It may be recalled here that, on the other hand, the value $\sqrt{10}$ adopted for the same ratio by the Jaina scholars, from a somewhat later period from the same millennium BCE, had a long life of over a 1000 years and was used subsequently in theoretical and practical computations across many cultures; see Dani (2023) for details.

7.2 Construction of a Circle with a Given Area

Unlike the circumference, the area of a circle turned out to hold substantial interest for them. Indeed, there are many *citi*s, as we shall recall in some detail in the next section, involving construction of circles covering a given area. In implementing this, naturally a square would be an appropriate reference figure; we have seen earlier that conversion of rectilinear figures to a square was widely discussed. After obtaining the area in the shape of a square, it is to be converted to a circle using the procedure which we now describe; having described the procedure in his preparatory sections, Baudhāyana assumes that it will be applied accordingly wherever it is needed, and there is no specific recalling or back-reference mentioned at any later point.

In BSl, this is taken up immediately after the rectilinear geometry parts discussed in the earlier sections, in BSl I.58. Given a square, to get a circle equivalent to it Baudhāyana's prescription goes as follows: Take half the diagonal of the square and drop it from the center along the eastward direction, and draw the circle including a third portion of the part jutting out (see Fig. 9, with $\mathrm{QS} = \frac{1}{3}\mathrm{QR}$); it is implicit that the square is drawn along the cardinal directions and the half-diagonal is along the south-east or north-east directions.

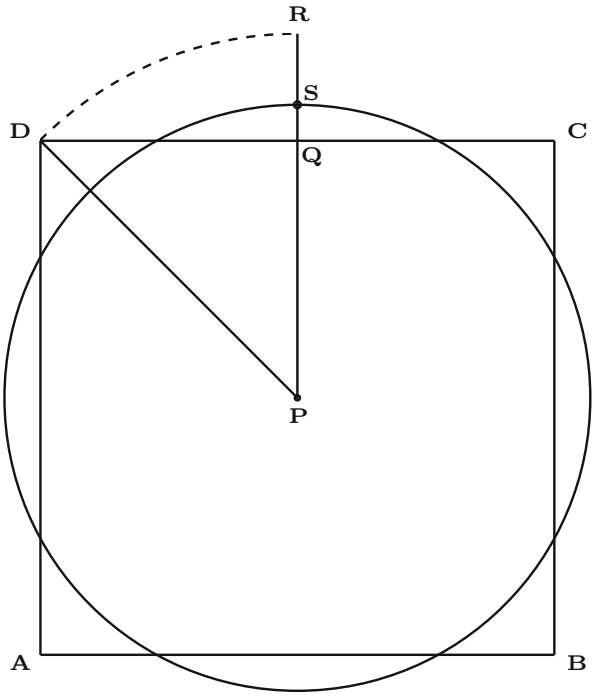

Fig. 9 Constructing a circle with the same area as a given square

For a square with side $2a$, the prescribed radius works out to be $a + \frac{1}{3} \times \left(\sqrt{2} - 1\right)a = \left(2 + \sqrt{2}\right)a/3$. For the unit square $\left(a = \frac{1}{2}\right)$, the area of this circle works out to be 1.01725…, a little more than that of the original square. If the circle is to be unit circle, then the initial square has to be correspondingly smaller and its area may be seen to be 3.0883…; the latter would thus "correspond" to the value in their context to the familiar constant π – it should be noted however they were not assigning any numerical value to the ratio involved, but only giving a construction of the desired circle in their context.

Realizing that the length of diameter of the circle would be between that of the side and the diagonal square, they would have looked for a suitable proportion of the extra length over the side to it. They could rule out half as unsuitable in this respect; one way to see this, at an intuitive or visual level, would be to see how much of the perimeter of the square lies inside. An easy calculation (with our present means) shows that for that choice over $\frac{3}{4}$th of the perimeter lies inside. This could have been easily noticed (even if not in precise terms), and considered far too much if the portions lying inside and outside are to be equal. For the next simple choice for the proportion to be $\frac{1}{3}$ however, the ratio of the segments lying inside and outside is significantly close to 1, the former being about 17% larger, but this may have seemed okay, keeping in mind that the corner points are farther from the circle than the midpoints of the sides.[48]

I may also recall here, as first pointed out in Dani (2010), that if they were to choose the proportion to be three on ten, a meaningful option in the context of their familiarity of the decimal system, they would have got much better results; however, they could not have anticipated it. Besides, although the decimal system was commonly used for integers it was seldom involved in fractions, or proportions.

Āpastamba gives the same construction for the task at hand (in ASl 3.2–3), though in somewhat different words. Interestingly it is then followed up (in ASl 3.4–5) with the comment "*sānityāmaṇḍalam | yāvaddhīyate tāvadāgantu |*." The second part means "as much is left out that much comes in." For the first part, there have been two alternative interpretations in the literature. One of the commentators Karavindasvāmī interprets the lines as "The circle is exactly as large as the square, for as much the circle falls short, so much comes in," while another commentator Kapardisvāmī breaks up *sānityā* as *sā anityā* and asserts that the circle construction is an approximate one (cf. Sen and Bag 1983, p. 161). Though linguistically both the interpretations are possible, it seems certain, as argued in Thibaut (1875, see

[48] Divakaran (2018) contains a suggestion on how the choice of $\frac{1}{3}$ as the factor may have been made. However, it seems far-fetched to believe that calculations as proposed would have been made at the time of Śulbasūtras. Second, the argument assumes implicitly that they knew that the ratio of circumference to the diameter, of a circle, and that of its area to the square of the radius to be the same, which has no justification. Besides, the argument fails to take note of the fact if the equality is assumed, and the ratio was taken to be 3, as has been recalled while discussing the details, they would not need Baudhāyana's construction as above to produce a circle with area as a given square – it would suffice to take the diameter of the circle to be $\frac{2}{\sqrt{3}}$ times the side of the given square, as seen to be implicitly involved in the Mānava Śulbasūtra (see Sect. 7.8).

pp. 252–253), that Āpastamba meant that the circle has the same size as the square – claiming no allowance as an approximation; without that, the subsequent part would be incongruous, as it does not quite make sense to say "this is an approximate construction; as much is left out so much comes in."[49]

The method has also been recalled in KSl 3.13; the sūtra seems a little less condensed than in BSl and uses some different wording, indicating an active retelling of the principle. MSl, on the other hand, has a different take on the issue. We shall defer the discussion on it to Sect. 7.4 and discuss next the application of the procedure as above in the construction of various *citi*s.

7.3 Circles Appearing in Construction of *Citi*s

It may be recalled that the three *agni*s, *āhavanīya*, *gārhapatya,* and *dakṣiṇāgni,* formed an integral part in the performance of all *kāmya yajña*s. There is detailed description of their relative locations in the overall plan, given in BSl I.63–69.

Of these, the *gārhapatya agni* could be either of square shape or circular, typically the latter (though not always, contrary to a prevalent belief in this respect), and the *dakṣiṇāgni* in the shape of a semicircle.[50] There are also other *citi*s, *rathacakraciti* (in the shape of a chariot wheel), *droṇaciti* (in the shape of a trough), and *parimaṇḍala kūrmaciti* (a round turtle shape), described in BSl, involving circles in their design; in the case of *gārhapatya,* the area is prescribed to be one (square) *vyāyāma*,[51] while in the other cases the area of the circles involved is prescribed, depending on the design so that the total area of the *citi* would agree with the prescribed area for the *yajñas* performed in similar contexts (typically $7\frac{1}{2}$ *puruṣa*). Baudhāyana describes two types for *rathacakraciti*, one corresponding to a wheel as a full flat disc, and another a wheel with spokes (connecting a nave to an outer rim), and for the latter type the construction involves three concentric circles, one corresponding to the nave of the wheel, and two others corresponding to the annular outer rim, the two parts being connected by a set of 16 spokes; the specific sizes are described in terms of distribution of the net area into the three parts (the

[49] It may also be noted here that the word "exact," especially in its formal usage, has a stronger connotation than the Sanskrit word *nitya*, as can be gauged from its alternative meaning as "regular," and Āpastamba would have more likely meant that the two areas are the same as far as normal judgment would go, and not by any intrinsic or universal standard, as may be suggested by the choice of the word "exact" in the English translations.

[50] The notion of the three *agnis* in combination appears in the Ṛgveda (5.11.2), without any names. The *Śatapatha Brāhmaṇa* includes names for two of the *agnis, gārhapatya* and *āhavanīya*, and the former is mentioned to be circular (see Datta 1932, p. 27, and Seidenberg 1978, p. 339, for related discussions). The mention of specific sizes for the *agnis* are known to appear for the first time in the Śulbasūtras; for all that one can say, the areas proposed for them *happen* to be equal, and there is no independent statement about their being required to be so; and quite possibly the choices were made only after there was better understanding of geometry, and means of achieving equality to an extent became part of it.

[51] For the square version that would be the length of the sides.

nave, rim, and spokes). The procedure for constructing this *citi* then consists of construction of three squares with a common midpoint, and transforming each of them into a circle by the procedure described in Sect. 6.2.[52]

It is generally believed that the areas of the three *agni*s *āhavanīya*, *gārhapatya,* and *dakṣiṇāgni* were stipulated to be the same, and this has been viewed in some works, especially (Seidenberg 1975, 1978, 1981), as the motivation for the invention of the procedure described in Sect. 6.2. It is true that the *citi*s are found to be constructed with equal areas (as far as the intent is concerned, though differences would arise due to inexactness of the procedure). This stands out prominently in MSl (sūtras 1.1.7 and 1.1.8) where all the three are presented together, along with prescribed constructions; Seidenberg (1978) cites the sūtra as the sole "explicit reference for the equality in the area" of the three *agni*s. There is however no explicit statement of the "stipulation" found anywhere in the Śulbasūtras. There is also no mention of anything like legend or influential statement or injunction, say attributed to the *Brāhmaṇa*s as one finds in various other contexts, that would correspond to the legend of the oracle of Delphi in the context of the problem of doubling the cube. The issue involved emerges as a practical matter and is seen to be handled as such, through routine practice, with no qualms about making approximate constructions. There is also no account, or indication, of a quest for finding a solution, or attempts to improve an ad hoc solution that was adopted, as we find in the case of the problem of doubling the cube. As seen in the other examples above, the task came down to constructing circles covering specific areas and in the case of *gārhapatya* the area having to match with *āhavanīya* is just one instance, and possibly a later one, since in BSl there is no emphasis on it. As such, the analogy drawn between the circling of a square as above with the developments around the problem of doubling the cube in the Greek context, as in Seidenberg (1975, 1978, 1981), seems misplaced.

It is also not apparent that the discovery of the method lends credence to the notion of "ritual origin," as made out in the abovementioned papers; it should be borne in mind that nowhere is there any statement in the Śulbasūtras suggesting that the method was discovered in the course of their own pursuits, and was not say part of folk knowledge from the time, arising from other pursuits; this is not to make a case for it, but to point out that it has not been ruled out; see also Joseph (2016, pp. 63–64), for analogous comments. It may also be recalled here that various similar geometrical facts were discovered by Jaina scholars of antiquity who did not have any ritual practices involving geometry; see Dani (2023), and other sources cited there.

[52] While the shapes of the bricks in the constructions of the *citis* are generally rectilinear, with the designs that are provided serving as rectilinear *approximations* to the desired figure (bird, turtle, etc.), in the instances involving circles in the design, the brick shapes are not always rectilinear and can have a rounded edge, and the design can match the desired figure exactly.

7.4 Construction of a Circle with a Given Area: The Mānava Version

The method described in Sect. 7.2 has also been described MSl. In fact, one finds it twice, once (in MSl 3.2.10)[53] in a general form (and accompanied by some emphasis with the preceding sūtra drawing special attention to it) and also in MSl 1.1.8, where it is recalled in the course of describing the construction of the *gārhapatya agni*. Still, there seems to be yet another sūtra, MSl 3.2.15, on the same issue, proposing another construction. There is no internal cross-referencing, and each appears as an independent statement. The sūtra MSl 3.2.15 reads as

caturasraṃ navadhā kuryāt dhanuḥ kotyāstridhatridha |
utsedhātpañcamaṃ lumpetpurīṣeṇeha tāvatsamaṃ ||

The first part readily translates as "divide the square into nine parts [by dividing] the transversal and vertical sides into three each." *utsedhātpañcamaṃ* means "a fifth of the jutting out part." Unfortunately the last part is problematic. Literally it just says something like "erase that much with rubble." And what is one supposed to get from that? The sequence of the sūtras around it also do not provide any clue about what is intended. The context seems to have prompted the authors of Sen and Bag (1983) to dismiss a set of sūtras including it with the comment "Possibly these are not problems of quadrature of the circle. Ordinary squares are drawn without any mathematical significance." In Kulkarni (n.d.), where the MSl part is based on van Gelder (1963), the sūtra is interpreted as describing a circle with the area of a given square, but the prescribed radius is taken, by way of interpretation of the second half of the sūtra as above, to be half the side plus $\frac{4}{5}$th of the jutting out part of the chords. The analysis following the interpretation, as described there, shows the result to be grossly erroneous; one way of highlighting how much it is in error would be to note that it corresponds to a value π which is about 2.63. It was pointed out in Dani (2010), and followed up in Dani (2022), that if one takes the circle passing through the points which are at $\frac{1}{5}$th along the chords from the corresponding sides of the square (see Fig. 10, with $\mathrm{QS} = \frac{1}{5}\mathrm{QR}$), then that indeed has area very close to the area of the square; skipping the details of the calculations, which may be found in Dani (2010), I may mention that for the unit square the area of the circle produced works out to be about

[53] In van Gelder (1963), and also in Sen and Bag (1983) and Kulkarni (n.d.) following the former, the sūtra as a whole is treated as describing the construction of a circle of equal area as a square by the same method as in Baudhāyana; it has however been noted in Hayashi (1990) that while the sūtra does contain in its second part a variant of Baudhāyana's method for circling a square, the first part is about squaring a circle; and the latter we will be discussing later. The miscomprehension involved in the earlier works seems to have been mainly due to the fact that in the original text as presented there a word, *caturasraṃ,* is missing in the previous sūtra MSl 3.2.9; the latter purports to provide an introduction to the issue being addressed, so missing the word affects comprehension of MSl 3.2.10, as has been clarified in Hayashi (1990).

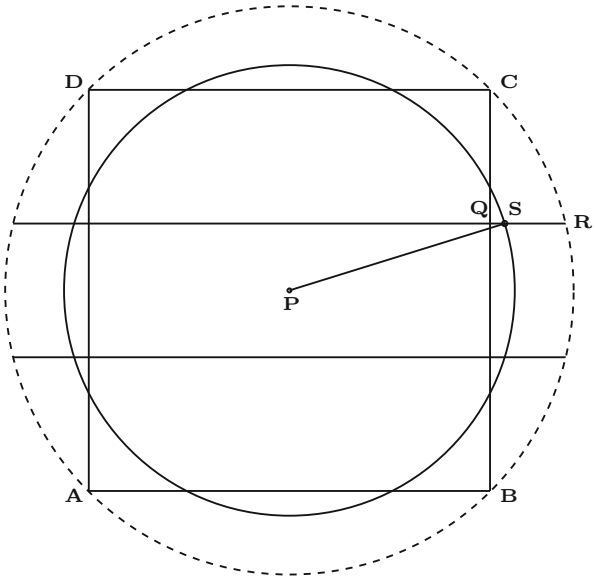

Fig. 10 Mānava's construction of a circle with the area as a given square

0.9947, involving an error of only about $\frac{1}{2}$%, considerably more accurate than Baudhāyana's prescription.

There are many pointers suggesting that this was in fact intended as a construction of the circle with the area of the given square. I have discussed in detail in Dani (2022) how the construction described here can be thought of as a refinement of Baudhāyana's construction, with the bisector replaced by the trisectors and the factor $\frac{1}{3}$ in Baudhāyana's construction replaced by $\frac{1}{5}$. That in particular motivates why the points on the jutting out parts at their $\frac{1}{5}$th from the side of the square are more appropriate, rather than from the other end at the circle, as chosen by van Gelder and followed in Kulkarni (n.d.).

There are a few disconcerting points however. First, that it never resurfaces again, either in the Śulbasūtras or in other Indian works of the period or later. Second, here the author shows no particular satisfaction over, or awareness of, the novelty and value of the construction, unlike in the case of his revision of the ratio of the circumference to the diameter of the circle (see Sect. 7.4), nor does he relate it to the other construction in any way. It should be borne in mind however that while we can now see it as a more accurate construction than the earlier one, in their time this may not have been so easily verifiable. In that sense, it was for them just another construction whose merits could not be ascertained.

I may mention finally here that there is also another interpretation of the verse, given by R.C. Gupta (1988), interpreting "utsedha" to mean "height," which in turn the author takes as the radius of the circumscribing circle. With those interpretations, the author deduces the area of the circle produced, starting with the unit square, to be

$8\pi/25$, so the procedure corresponds to a value of π as 25/8. I have however argued in detail in Dani (2022) that while it may lead to a good value, the interpretation is unsatisfactory in various ways, including especially that it does not involve the first part of the verse at all, and that interpretation of "utsedha" as radius of the circumscribing circle lacks justification in the overall context; we shall not go into further detail of this here.

7.5 Value of π?

At many places in the literature on the Śulbasūtras, one finds references like "the value of π known to the geometers of the Śulbasūtras," "Baudhāyana's value of π," etc. These can be quite misleading; Hayashi (1990, p. 77) has opted to say it seems meaningless. Such references implicitly suggest the following:

(i) That they knew the circumference of the circle is proportional to its diameter and/or the area is proportional to the square of the diameter
(ii) That they knew the ratio of the circumference to the diameter is the same as the ratio of the area to the square of radius (semidiameter)
(iii) That having determined such a number they used it to determine one from the other numerically

It is quite reasonable to assume that they know (i), in respect of both the circumference and the area, as the statements in the sūtras in respect of these are made independently of the size involved; though from a strict mathematical point of view it is a difficult issue, they would probably be convinced of its validity, in both cases, from the analogous facts about rectilinear figures. Also, they were quite used to the idea of scaling of figures, in the context of which these assertions would seem natural.

They just could not have been aware of (ii). In fact, if they were to believe that the two ratios were the same, then according to BSl I 112–113 they would consider it to be 3, and Baudhāyana would have given a solution in terms of the *trikaraṇī*, which would be exact, rather than the construction as in Sect. 7.2. Second, Mānava Śulbasūtra which takes the side of the square with the same area as the altitude of the inscribed equilateral triangle, which amounts having the (common) ratio to be 3, would not be bothered to suggest $3\frac{1}{5}$ as a bound for it as discussed in Sect. 7.1!

As to (iii), there is no evidence that the values determined for π were ever used as a numerical factor in another instance. The simple historical reality seems to be they never had an occasion to compare the two ratios, and with regard to areas they were content to start with squares and produce circles which they believed would have the same area. Their trust in that as the correct equivalent circle, and the geometric method as the unique way of addressing the task, is attested by the fact that Kātyayana describes the same method, several centuries after Baudhāyana.

7.6 Squaring the Circle

The converse problem of finding a square with the same area as a given circle is also considered, and a serious effort seems to have gone in to arriving at the resolution of it presented in BSl, as we shall see below.[54] This is especially notable, as the practical objectives, such as of arranging the areas of *āhavanīya* and *garhapatya* to be equal or fixing the size of *rathacakraciti* would be fulfilled by their construction(s) of a circle with the same area as a square (to the extent they could achieve it) discussed in Sect. 7.2. In practical terms, it was circles that needed to be constructed with a given area, which to begin with is described in square shape, as in the construction of *rathacakraciti*. On the whole also in the construction of the altars, one does not find any occasion to convert a circle into a square. Clearly therefore the task was undertaken out of curiosity. As commented in Delire (2003), it is a "manifestation of Baudhāyana's concern to complete his mathematical corpus."

Unlike the solution of the problem of finding a circle with the area of a given square, the resolution of this converse problem is not geometrical but is by describing a numerical factor as the ratio of the size of the desired square to the diameter of the given circle. One may wonder whether a geometric procedure was attempted, unsuccessfully,[55] or the process of trying to understand the numerical significance of the procedure for transforming a square to a circle led to consideration, and the resolution that is presented, of the converse problem. Given the overall context, it seems inconceivable that they could not have come up with a geometrical procedure, on a similar footing as the other way construction. As noted above, the exercise was driven by curiosity, and not a practical objective, and the curiosity could well be about better understanding of the numerical factor in the geometric construction in Sect. 7.2; once the factor is understood, in a certain way, inverting it would give a resolution of the converse problem.

[54] The problem considered here should however not be confused with its counterpart in the Greek tradition, which involved accomplishing the task only with a straight edge and compass; in the context of the Śulbasūtras, any procedure implementable by an artisan would be admissible. In this respect, discussions of the two on the same footing, as for instance in Seidenberg (1975), Sect. 4, seem quite out of place and unwarranted.

[55] It may be worthwhile to recall one of Seidenberg's theses, from (Seidenberg 1972, p. 175), in the author's own words: "This leads to our second main thesis: The first crisis occurred in mathematics because the ritualists could not reverse their (canonical) circulator of the square in a geometric way. The resulting efforts to find an arithmetic solution of the squaring of the circle gave rise to the algebraic tradition. Geometry was dislocated from its ritual base." While there is no doubt that the fact of looking for nongeometric solution is of enormous significance from an historical point of view, the characterization in this, as a crisis and its resolution, seems far-fetched. We do not really know whether geometric resolution was seriously attempted, or simply the effort to understand the surd magnitudes of a kind that were showing up for the first time led to the "algebraic" realization. As far as reading from the Śulbasūtras goes, the transition seems to have been seemless, and the matter even seems to have been forgotten quite soon, rather than leading to a new framework or insights.

The description of the factor by which to multiply the diameter of a given circle to get the side of the square with the same area, given in BSl 1.59, immediately following the construction described in Sect. 7.2 goes as follows: divide the diameter into 8 parts, further divide 1 of the parts into 29 parts and take away 28 of them, and also a sixth minus its eighth of the (remaining) part; in terms of numbers, the factor described literally is

$$1 - \frac{1}{8}\left(\frac{28}{29} + \frac{1}{29}\left(\frac{1}{6} - \frac{1}{6 \times 8}\right)\right). \tag{1}$$

This may equivalently be written as

$$\frac{7}{8} + \frac{1}{8 \times 29} - \frac{1}{8 \times 29 \times 6} + \frac{1}{8 \times 29 \times 6 \times 8}, \tag{2}$$

which is the form expressed in Thibaut (1875), and various other sources also have separated out the part $\frac{7}{8}$ from the expression above. The latter has the advantage of setting the magnitudes of the components in perspective. It would however be important to keep track of the specific wording used, especially as we do not yet know the precise significance of why the factor was described in terms of a combination of terms as above; the alternate presentations may convey the impression[56] that $\frac{7}{8}$ was first separated out (as a leading factor) and then the difference was analyzed in some way to get the remaining part of the expression. This may or may not actually be how calculations proceeded, though the choice made does seem to be borne out in some ways (see below).

We note that the fraction as in the expressions reduces on simplification to $\frac{9785}{11136}$ and for the circle with unit radius the expression yields the area 3.088..., a little more than 98.3% of the actual value. A notable point about this is that the error is of the same order as in the construction of the circle with the same area as a square, discussed in Sect. 7.2. We recall that the factor there was $\frac{2+\sqrt{2}}{3}$, and note that $\frac{2+\sqrt{2}}{3} \times \frac{9785}{11136} = 1.00000238\ldots$. The two numbers being such close reciprocals inescapably suggests that the latter was in fact computed as the reciprocal of the former, with the small difference attributable to an error introduced by the process of computation of the reciprocal. On the whole, there is a general consensus that the number would have been computed as the reciprocal of the factor $\frac{2+\sqrt{2}}{3}$ as in the convertion from a square to a circle. Beyond that, however, the formula has remained an enigma for various reasons. The key questions that remain are how was the reciprocal of $\frac{2+\sqrt{2}}{3}$ computed, and why is it presented as the combination as seen in the above expression. It has been the subject of numerous papers, but the issues associated with it still seem unresolved. We shall take up a discussion on this separately in the following subsection and continue here on other details on the issue.

[56] In fact, some of my comments in Dani (2010, on p. 29) are based on such an understanding, based on my familiarity at that time with only the alternative expressions as above.

7.7 Alternative Factor for Squaring the Circle

In BSl I.60, immediately following the sūtra with the formula as in the last subsection, Baudhāyana gives also another prescription. It is separated from the previous one by "or else" (*api vā*), and the sūtra seems to mention it to be "inexact"[57] indicating that it is proposed only as a simpler alternative. The prescription consists of dividing the diameter into 15 parts and dropping 2 of them, to get the side of the desired square; thus, the factor concerned would be $\frac{13}{15}$. This formula turns out to be very crude: For the circle of unit radius, it gives the square with side $\frac{26}{15}$, whose area would be $\left(\frac{26}{15}\right)^2 = 3.0044\ldots$, in place of the correct value 3.14159 ..., smaller by more than 4%. Even in terms of fractions with small denominators, there are better approximations possible.[58] The fraction $\frac{7}{8}$, which is recognizable as a substantial part in Baudhāyana's previous formula, would serve as a better approximate value, giving the area for the unit radius circle to be $\left(\frac{7}{4}\right)^2 = 3.0625$, than the suggested factor $\frac{13}{15}$. It is therefore not clear why Baudhāyana gave that as an alternative value, even as an approximation.

One explanation that has been put forth relies on the assumption that the area of the circle was taken to be $3r^2$, where r is the semidiameter (radius) of the circle, arrived at as the average of the areas of the inscribed and superscribed squares; see Datta (1932, p. 147), and Sen and Bag (1983, pp. 163–164). The factor for describing the side of the desired square in terms of the diameter would be $\sqrt{3}/2$, and $\frac{13}{15}$ was taken as approximation for it; see Sect. 8.5 for a discussion relating to this approximation. There is no specific evidence supporting such an explanation, but it seems plausible that the area of the unit circle was also taken to be 3, matching the ratio of circumference to diameter, especially in practical contexts.

A different explanation is found in Delire (2005), where it is argued that if we choose the approximation $\frac{7}{5}$ for $\sqrt{2}$ then the factor $\frac{1}{3}\left(2+\sqrt{2}\right)$ for obtaining the diameter of the circle from the side of the original square, as in Sect. 7.2, reduces to $1+\frac{2}{15}$, and the author comments that "they could well have considered $1-\frac{2}{15}$ as the inverse of $1+\frac{2}{15}$"; the latter part does not seem convincing, as the fraction involved is readily invertible, but perhaps may not quite be ruled out.

[57] Here again, there is an ambiguity comparable to the one seen near the end of Sect. 7.2: The clause "*eṣānityācaturasrakaraṇī,*" appearing at the end of the sūtra in this respect, can be interpreted in two ways, with *eṣānityā* split as *eṣā anityā* or *eṣā nityā*; Thibaut and those following him have adopted the former, with *anityā* interpreted as inexact, leading to what we noted above. On the other hand, the latter alternative possibility is adopted in Delire (2005, p. 68), with the word *nityā* taken to mean traditional – which is close to the currently common meaning as "perpetual." In a way, this explanation fits better with the fact that only this other factor appears in ASl and KSl (see below), as tradition is a more likely reason for adhering to it.

[58] The factor $\frac{8}{9}$ which was adopted by the ancient Egyptians gives for the unit circle the area to be 3.16049 ...; see Gillings (1972, Chapter 13).

Curiously, none of the other Śulbasūtras mention Baudhāyana's elaborate formula.[59] ASl and KSl recall only the approximate $\frac{13}{15}$ formula, right after recalling the procedure for producing a circle of equal area from a square, which they do essentially with the same wording as in BSl; it is as if the finer formula is forgotten by their time, and the approximate version follows the other way construction as a mandatory converse.

7.8 Mānava's Conversion of Circle to Square

The Mānava Śulbasūtra, which departs from BSl in many propositions, on the other hand, introduces another resolution for the converse operation: The first part of sutra MSl 3.2.10 prescribes, as explained by Hayashi in (1990) (departing from the earlier interpretations in van Gelder 1963; Kulkarni n.d.; Sen and Bag 1983), for a given circle, the altitude of the equilateral triangle with the diameter of the given circle as its base, as the side of the desired square. For a circle with unit radius, the altitude of the equilateral triangle will be $\sqrt{3}$ and hence the area of the prescribed square will be 3, in place of the desired value $\pi = 3.14159\ldots$ This is even cruder than the Baudhāyana's crude alternative value recalled by Āpastamba and Kātyāyana, as discussed earlier, as far as comparison with the true value goes. In the context of some of the interesting observations from Mānava Śulbasūtra noted earlier, this comes as an anticlimax! However, if the area of the circle was believed to be three times the square of the radius, a possibility mentioned earlier in Sect. 7.7, the construction gives exactly a circle with the desired area.

7.9 Understanding Baudhāyana's Formula

For much of the history in respect of analysis of the formula, it would be convenient to refer the reader to Kichenassamy (2006), which has been the latest notable contribution on the issue, and includes also a detailed account of the earlier explanations. Here we only summarize some of the crucial points that have emerged from the discourse.

It is well-known that Śulbasūtras contain a very good numerical approximation for $\sqrt{2}$, and we will be discussing it later in Sect. 8, given as

$$1 + \frac{1}{3} + \frac{1}{3 \times 4} - \frac{1}{3 \times 4 \times 34}. \tag{3}$$

[59] There is a suggestion in Seidenberg (1975, Sect. 14, p. 517) that the "squaring of the circle was interpolated"; presumably the reference is to the elaborate expression and not the approximate one. Its omission in the later Śulbasūtras gives some credence to the possibility. Nevertheless, the speculation does not seem worthy of serious consideration, since the issue involved is not known to have evoked an interest in the tradition at any later stage.

It should also be clear that the value would be of no consequence in their practical work; in practice, if they needed a length measuring $\sqrt{2}$ units they would naturally have used the *dvikaraṇī,* namely, the measure of the diagonal of the unit square. Evidently the value as above was determined in some theoretical context, and the context at hand presents the unique candidate in this respect. In other words, to determine the reciprocal of $\frac{2+\sqrt{2}}{3}$ they wanted to get an understanding $\sqrt{2}$ in terms of fractions.

In the expression for $\sqrt{2}$ as above, we find another number, apart from the ratio as in (1) written in a way that is quite unusual for us. This brings to mind the ancient Egyptian practice of writing each (rational) number as a sum of distinct unit fractions (viz, fractions with numerator 1). What is involved here is different however, and unfortunately we do not have a large enough sample of their writing numbers in this form, from which one could try to identify a pattern; in fact, the two fractions that we saw so far written in this manner are the only ones of the type in the entire body of Śulbasūtras; there are a few other fractions with simple descriptions.

It may be observed at this point that having determined $\sqrt{2}$ as above, if they had realized that $\frac{1}{2+\sqrt{2}} = \frac{2-\sqrt{2}}{2} = 1 - \frac{1}{2}\sqrt{2}$, the desired reciprocal could have been recognized as (approximately)

$$3 - \frac{3}{2}\left(1 + \frac{1}{3} + \frac{1}{3 \times 4} - \frac{1}{3 \times 4 \times 34}\right) = 1 - \frac{1}{8} + \frac{1}{8 \times 34}, \tag{4}$$

giving a much simpler expression for the desired ratio, so apparently that reduction of the surd was not recognized. Instead, the substitution for $\sqrt{2}$ may be considered to have been made in the denominator itself. If we substitute for $\sqrt{2}$ from (3), we get a fraction which on simplification turns out to be $\frac{1224}{1393}$. On the other hand, while the expression in (1) is close to that, its denominator turns out to be 8×1392. We may therefore further suppose after following whatever process they were adopting for the successive terms in the expansion some part was ignored, leading to the expression as above. Specifically it may be observed that $\frac{1224}{1393} = \frac{7}{8} + \frac{41}{1393}$, while the given expression as in (2) equals $\frac{7}{8} + \frac{41}{1392}$, which would support such an assumption.

A suggestion somewhat along these lines was made by Thibaut (1875), who seems to have assumed, based on workouts seen in the commentaries, that such a computation could have been made by the authors of the Śulbasūtras as well. The problem however is that such an assumption is untenable, as was pointed out by C. Müller in 1930 (cf. Kichenassamy 2006, p. 157, for details and reference), as there is no evidence to show that the authors of the Śulbasūtras had the computational skills as involved, and the explanations of the commentators, who are from more than a 1000 years later, cannot be relevant in this respect.

There have over the period been several attempts to explain the expression through various arithmetical stratagems (see Kichenassamy 2006 for details), but none of them seem, as noted in Kichenassamy (2006), to be satisfactory. A key point made in Kichenassamy (2006) is that though it is given as a numerical expression, the reasoning is likely to have involved geometric thinking, at least at a heuristic level, and especially

the author emphasizes likely use of the idea of scale, and scaling of figures depending on the context, which is very much involved in the Śulbasūtras. Kichenassamy provides an explanation based on these ideas. It is however not clear to the present author whether even the reasoning in Kichenassamy (2006) can be said to be conclusive. One substantial issue that comes to mind with regard to the reasoning is that the entire body of Śulbasūtra works, extending over centuries, is treated as a homogeneous knowledge system, and patterns in several much later calculations or applications have been brought in to explain how Baudhāyana may have reasoned. Second, on the whole it also has the feel of a "verification," with a bit of number-crunching, a criticism which has been leveled on the earlier proofs (see Kichenassamy 2006) though at a somewhat different level. Hopefully a clearer image would emerge along these lines, but we may have to wait a while for the last word to be said on the issue.

8 Square Roots in the Śulbasūtras

It was noted in Sect. 7.9, (3), that Baudhāyana presents an expression for $\sqrt{2}$, as

$$1+\frac{1}{3}+\frac{1}{3\times 4}-\frac{1}{3\times 4\times 34}$$

which is 1.4142156..., in place of 1.4142136..., accurate five decimal points (six significant decimal digits).[60] In this context, we review in this section that and other values for roots of numbers appearing in the Śulbasūtras.

8.1 $\sqrt{2}$ in Mānava Śulbasūtra

Curiously, the Mānava Śulbasūtra does not introduce the *dvikaraṇī*, and where the measure is involved in a construction, an approximation of $\sqrt{2}$ as $1+\frac{1}{3}+\frac{1}{12}$ is used in MSl 3.3.1–2, in a rather specific context. The latter value, equivalent to $\frac{17}{12}$, is evidently a cruder approximation compared to Baudhāyana's formula, which has not been mentioned. In the Mānava Śulbasūtra, $\sqrt{2}$ turns up also in another guise, and it has been quantified numerically. The context involved is to describe the size of the largest square contained in a circle (MSl 3.2.14). To quantify the side of the square in terms of the diameter of the given circle, the prescription is to divide the diameter into ten (equal) parts and take away three of them. This amounts to an approximation of $\sqrt{2}$ as $\frac{10}{7}$. Incidentally, the largest square contained in a circle is also involved in the designs for brick-tiling of some of the *citis* involving circular regions, in particular the *rathacakraciti* described in BSl V.5 and ASl 12.17; the tiling within that square is into a grid of 144 squares of uniform size, while that of outside

[60] This is comparable to the Babylonian value depicted on the cuneiform tablet YBC-7289, in sexagesimal system, which corresponds to $1+\frac{24}{60}+\frac{51}{60^2}+\frac{10}{60^3}=1.4142129\ldots$ (see Robson 2007).

segments is somewhat ad hoc and nonuniform, with 14 tiles in each of the four segments; the side of the square is not quantified, however, and is only mentioned as the largest possible square (*yāvat-sambhavet-samacaturasraṃ*-literally "as much possible square"); presumably it was meant to be determined by taking two diameters perpendicular to each other, but this is not specified.

8.2 Explanations of Baudhāyana's Formula

The elaborate formula (1) apparently had the context of the issue of transformation of a square into a circle and the other way, and it could specifically be for the purpose of computing the ratio of the side of the square to the diameter of the circle produced by the procedure as in Sect. 7.2. On the other hand, in ASl and KSl the formula is mentioned right after introducing *dvikarṇī*, apparently as something related to it; as noted earlier neither of them mentions Baudhāyana's refined formula (1) for the side of a square of area transformed from a circle.

How was Baudhāyana's formula (1) arrived at (by him or whoever may have done it prior to him)? Like the question about the expression for squaring a circle, this has also been the subject of much discussion, though it may be said that some of the explanations here seem much more plausible than was the situation with the previous question.

The approximation formula

$$\sqrt{a^2+b} \approx a + \frac{b}{2a} \tag{5}$$

for $a > 0$ and b smaller compared to a, of either sign, seems to have been known in ancient India. While there is no specific evidence in this respect, some calculations of square-roots going into several terms, especially in the Jaina literature (see Dani 2023), would be difficult to explain without recourse to such a formula. Second, the formula has a simple visual geometric explanation: When squares with area $a^2 + b$, $b > 0$, and a^2 are matched along a corner and two sides, the difference is readily seen to consist of two strips whose one side is a and the other is the excess over a that is desired, except for a small square which can be ignored; this readily illustrates that the desired excess should be $\frac{b}{2a}$; and a similar argument works for b negative. It is conceivable that (3) was derived from this approximation formula. If one is to start with simple-minded choice for a, the "first guess," say as 1 or $1\frac{1}{3}$ the formula, would have to be applied repeatedly to get (3). Actually all the known calculations, from those and even somewhat later times, seem to fit in the pattern of single application of the formula, so one may wonder if they may have applied the formula iteratedly in this instance. We note that the less accurate expression $1 + \frac{1}{3} + \frac{1}{12}$ used in MSl could be deduced in this way, choosing $a = 1 + \frac{1}{3}, b = \frac{2}{9}$. It could also be surmised that it was directly noticed that $17^2 = 289 = 2(144) + 1 = 2(12)^2 + 1$, which is quite plausible especially in the context of the square grids used in the tiling of *rathacakraciti*. If with that one chooses the approximation formula with $a = \frac{17}{12}$,

which is recognized to be close to $\sqrt{2}$, we have $b = -\frac{1}{144}$ and we get the result to be $\frac{17}{12} - \frac{1}{144} / \frac{34}{12}$ or $\frac{17}{12} - \frac{1}{12\times 34}$. This matches with the value of the expression in (3) but leaves open the question about expansion into components as appearing there. One possibility is that they understood the number as it is calculated here but expressed it in the components as a sort of natural representation that they were used to. We do not know enough about how they dealt with fractions, of which there are very few instances in the works, to be able to make a definitive judgment on this.

There have been seemingly arithmetic explanations of (3) by Thibaut (reproduced in detail in Datta 1932, pp. 189–192) and Rodet (see Rodet 1879, pp. 162–165, or Sen and Bag 1983, pp. 165–167). Thibaut's version, though somewhat belabored in its import, essentially matches with the arithmetic involved in the explanation as above, without the geometry. Rodet's explanation involves a more complicated approximation formula; there does not seem to be much justification in assuming that a formula of that kind would have been used in ancient times.[61]

8.3 Datta's Explanation

A more plausible explanation involving geometric reasoning which is consistent with the Śulbasūtras practices is due to Bibhutibhushan Datta (1932, pp. 192–194).[62] Consider two unit squares placed alongside as in Fig. 12, to be transformed into one square. We chop the second square into three equal strips vertically, and place the farthest one at the top of the first square, horizontally, matching the unit side. We now cut up the middle strip into three equal parts, each a square with side $\frac{1}{3}$, and shift the top one alongside the other strip places at the top of the first square. The figure now consists of a square with side $\frac{4}{3}$, and a strip of height $\frac{2}{3}$ and width $\frac{1}{3}$. We cut the strip vertically into four equal parts, the width of which will then be $\frac{1}{12}$. Two of these are placed horizontally at the top of the square with side $\frac{4}{3}$ formed earlier, and two on the side, vertically along the side. The figure produced so far is a difference of a square with side $1 + \frac{1}{3} + \frac{1}{3\times 4}$ and a small square of size $\frac{1}{12}$. At this stage, for futher adjustment Datta writes down a quadratic algebraic equation (together with an

[61] I may also mention here that in Dani (2010) I suggested that, keen on determining a value for $\sqrt{2}$, they may also have done it through direct measurements with cords. It was argued that such a determination would have been possible in their context since if one starts with a size of 35 feet for the side of the square and measure the diagonal in terms of pieces as suggested by the expansion (see Dani 2010 for details), then the last step would involve measuring out a piece of about 3 feet by one which is over an inch, and that this would indeed be possible. This argument has a lacuna however that it does not take into account that for a square drawn on the ground the measurements may not match closely enough with the respective mathematical values, and a small error can lead the result astray.

[62] Strictly speaking, Datta's original explanation is not entirely geometric, as he resorts, toward the end (see below), to algebraic reasoning, of a kind which actually is not evidenced anywhere in the Śulbasūtras. His basic idea however can be completed to arrive at Baudhāyana's formula, in the spirit of the Śulbasūtras constructions, as will be seen below.

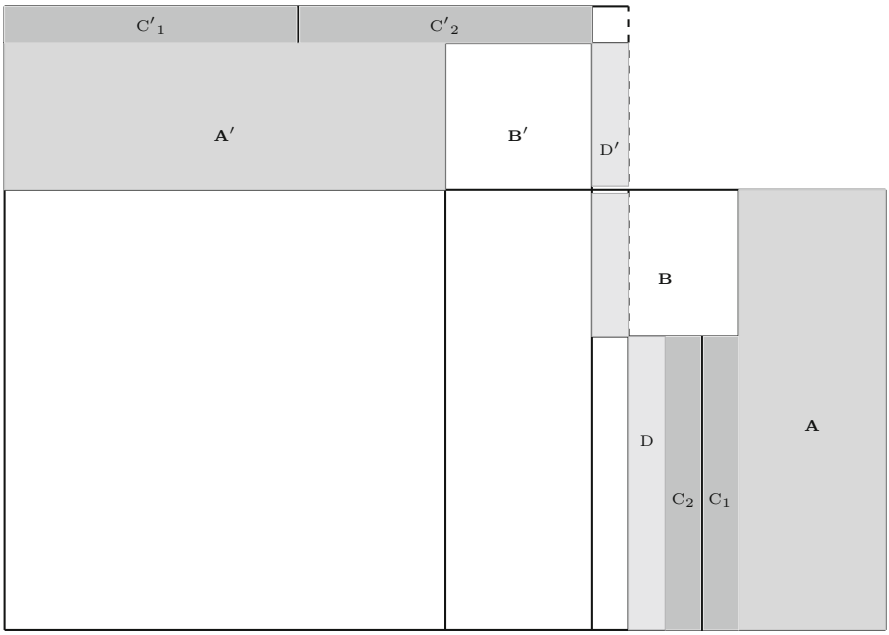

Fig. 11 Datta's construction of $\sqrt{2}$

algebraic approximation) to explain the last term. It can however be seen that we may continue along the lines of the argument as above and get the result; if strips of width $\frac{1}{12\times34}$ are cut along two perpendicular sides of the bigger square, they would make an area as much as the area of the smaller square, minus the area of a square of side $\frac{1}{12\times34}$ (on account of the overlap at the corner). Ignoring the latter tiny square, we see that the square with side $1+\frac{1}{3}+\frac{1}{3\times4}-\frac{1}{3\times4\times34}$ is (approximately equal to the original) 2 unit squares. This establishes (5) (Fig. 11).

This proof seems properly in the spirit of constructions in the Śulbasūtras and also incorporates a possible explanation of the number being expressed in the particular fashion; whether the latter is of significance, and valid, we cannot say, as it is not really understood what the pattern of numbers signifies and why it was adopted.

8.4 Irrationality of $\sqrt{2}$?

There are often claims made, imputing the knowledge of irrationality of $\sqrt{2}$ to the authors of the Śulbasūtras (see Datta 1932, p. 195; Sen and Bag 1983, p. 168). Sometimes the issue is linked, rather disingenuously, to knowing the value they assigned to be approximate. The Śulbasūtra geometers would indeed have known, at least at the time when the value was first determined, that it was approximate; arriving at such a value would have involved one or other computational process –

as the intricate value could obviously not have been the result of pure intuition – and no matter what the process was, whether one of the possibilities that we discussed or otherwise, in the course of the operation it would be recognized that the process has not come to an end, so the value is not exact. There is however no indication that it made any difference to them. Contrary to the general perception of thrust on precision or accuracy, the Śulbasūtras are seen to be open to adopting, for convenience, approximate values, even when more accurate values are available. Sometimes the word *saviśeṣa* for the adopted numerical value of $\sqrt{2}$ is brought in to argue that it was being explicitly declared as approximate (see Sen and Bag 1983, p. 168). This however involves a misinterpretation. *Viśeṣa* corresponds to extra, and in this instance the reference seems to be extra over the unit; this is suggested by the fact that description of *saviśeṣa* begins with the unit and prescribes adding parts to it (rather than by a direct representation), and this interpretation is also borne out by the use of *viśeṣa* in ASl 2.1, as has also been noted in Datta (1932, p. 197). In any case, the term carries no connotation of the difference from the implicit target being small, or eligible of being ignored, as with the word approximate.[63]

More importantly, even if one grants that they were quite conscious about the value being approximate and chose to put it on record, it still has little to do with being aware of the irrationality of $\sqrt{2}$ as a number. Asserting a number to be irrational involves that it can in no way be described as a ratio of two integers, and not just that the value one settled on, perhaps after a great deal of effort, does not quite represent it. Irrationality needs to be concluded by a proof and is not ensured by the fact that diligent efforts of even a great scholar did not produce a rational value for it. After all, rational numbers also can be approximated by other rational numbers and can arise as limits of sequences or series of rational numbers.

The Śulbasūtras were concerned with practical aspects of geometry of altar building. They are seen to have taken an enlightened view of the subject and identified various principles and constructions useful for the activity, but were nevertheless focused on practical matters. One does not find them getting involved with philosophical or arithmetical aspects of numbers, and it is wrong to indulge in wishful claims about it.

8.5 Other Square Roots

A numerical understanding of square roots, relating issues such as how they compare with other fractions, or their (approximate) value, did not hold much relevance for the Śulbasūtra geometers; the unique case of how they may have got interested in this respect in $\sqrt{2}$ we discussed above.[64] A couple of other instances have been

[63] The mention in Sen and Bag (1983, p. 169) of the use of *kiñcidviśeṣa*, by way of comparison, is not meaningful, since in the latter the part *kiñcid* makes all the difference.

[64] As pointed out in Thibaut (1875, p. 241), some commentators on the Śulbasūtras are seen to apply Baudhāyana's elaborate formula (3), for figures on the ground as well, but it is a useless exercise.

noted in this respect, in which the inference is indirect, and rather tentative; these are mentioned also in Seidenberg (1978). First, as mentioned earlier ratio $\frac{13}{15}$ proposed for the ratio of the side of a square and the diameter of a circle with the same area, as a simpler and common option, was perhaps meant to be for $\sqrt{3}/2$, based on the premise that the area of a circle is $\frac{3}{4}$th of the square of its diameter. Following the steps as in Datta's proof for the expression for $\sqrt{2}$, as described in Sect. 8.3 (excluding the last part of it involving subtraction), leads to the expression $\sqrt{3} \approx 1 + \frac{2}{3} + \frac{1}{15}$; first from the two squares to be added rectangles of width $\frac{2}{3}$ may be joined to the first square along two perpendicular sides, and a square with side $\frac{2}{3}$ may be filled in from the remaining rectangle with width $\frac{2}{3}$; thus, we get a square of side $1 + \frac{2}{3}$ and a balance rectangle of size $\frac{1}{3} \times \frac{2}{3}$, and the latter may cut up into ten strips of width $\frac{1}{15}$, and length $\frac{1}{3}$, and arranged along the edges of the square, making a square of side $1 + \frac{2}{3} + \frac{1}{15}$, except for an overlap of a square of side $\frac{1}{15}$ which is ignored; see Datta (1932, p. 194), if necessary, for details of arriving at this expression – the more refined version of the approximation obtained there is however an extrapolation which is hardly likely to have been involved in the Śulbasūtras.

Another instance relates to Baudhāyana's construction of *Droṇaciti*, shaped as a square trough with a rectangular handle, with net designated area of $7\frac{1}{2}$ (square) *puruṣa*. He chooses the square to have side length $3 - \frac{1}{3}$ *puruṣa* and the handle to have sides $\frac{2}{3}$ and $\frac{7}{12}$, with the areas of the two adding up to the designated size. It would seem that the broadly intended distribution of the areas would be 7 *puruṣa*s for the square trough and $\frac{1}{2}$ *puruṣa* for the handle. If so, $3 - \frac{1}{3}$ is meant to be an approximation for $\sqrt{7}$; of course it is in excess by $\frac{1}{9}$ *puruṣa,* and this has been adjusted in the area of the rectangle chosen. The surmise that $3 - \frac{1}{3}$ was chosen as an approximation for $\sqrt{7}$ fits with the fact that it conforms to the standard approximation formula $\sqrt{a^2 - b} \approx a - \frac{b}{2a}$ recalled in Sect. 8.2, with $a = 3$ and $b = 2$.

In Datta (1932, pp. 203–205), one finds also a reference to "a serious attempt" having been made in Baudhāyana Śulbasūtra to find an approximation to the value of $\sqrt{5}$, which has also been reproduced uncritically in Sen and Bag (1983, pp. 174–175). The discussion is based on Baudhāyana's description of three alternative ways for fixing the location of *dakṣiṇāgni* with respect to the *āhavanīya* and *gārhapatya agnis* (which are along the east-west line, with the former to the east), on the southern side from them. The locations described for the *dakṣiṇāgni* are clearly meant to be possible variants that may be adopted, conforming to an overall scheme, and not meant to describe the same spot.[65] Our author, on the other hand, treats it as if an identical spot is being described and deduces approximate values of $\sqrt{5}$, and

[65] Without going into the full details, I may mention that broadly speaking a spot is being marked on a line segment parallel to the one joining *āhavanīya* and *gārhapatya agnis* which is at a certain distance toward the south from the latter, and somewhat westward from the midpoint of the parallel segment; while in one method the point is described in terms of the level on the segment joining the *āhavanīya* and *gārhapatya agnis,* in the other two it is described in terms of the distances from the two of them.

$\sqrt{2}$; the author even alludes to it as "an attempt, though without much success, to find an approximation ..." The assumption is all the more surprising, as two of the three methods in BSl, as well as the corresponding descriptions in ASl and KSl, involve using the same pattern of construction with different numbers of parts being made, which would obviously not be intended to describe the same spot. Not surprisingly the approximations arrived at are no good, with values for $\sqrt{5}$ ranging from 2.16 to 2.4, and those for $\sqrt{2}$ varying from 1.2 to 1.44 (!). The source for the gross inaccuracy in the result lies in the author's unjustified assumption that the exact same spot was being described, and does not have to do with the capability of the sūtrakāras to determine a good approximation to $\sqrt{5}$; there is no evidence that such a problem or task occurred to them, in the first place. A purposeful "attempt" to describe $\sqrt{5}$ would surely have found a better expression than a description of the same ritual spot in multiple ways.

9 Configurations of Shapes and Numbers

There are some interesting configurations of shapes and numbers appearing in the construction of various *vedi*s and *citi*s, which it would be appropriate to recall here. On the other hand, there are several unwarranted associations and claims found in literature which ought to be clarified. This section is aimed at meeting this dual objective.

9.1 Dārśapaurṇamāsika Vedi

This is a *vedi* which as mentioned in Sect. 7 incorporates some circular arcs in the design, starting with an outline consisting of an isosceles trapezium, with face, base, and altitude 48, 64, and 96 *aṅgulas,* respectively. The arcs are drawn within the trapezium (see Fig. 12) joining the pairs of adjacent vertices. The *vedi* is described in BSl I.71–75, ASl 4.5, and MSl 1.4. It has a long tradition and is mentioned in *Taittirīya Saṃhitā* and *Taittiīya Brāhmaṇa* (see Sen and Bag 1983, p. 175).

Plotting of the arcs is described as follows: Taking a cord with double the size of the *pārśvamānī*, a mark is made at its midpoint. Tying the ends of the cord to poles at the two vertices on the southern side, the cord is stretched southward on the ground, and a pole is put at the location of the midpoint mark. Then tying both points of the cord to that pole, the southern arc of the design is drawn, by tracing the midpoint, turning the stretched cord around (note that it would be an arc passing through the two southern vertices). There is some ambiguity whether *pārśvamānī* stands for AD as in the figure or the altitude of the trapezium (more likely the former), but clearly the intended curve is the segment of the circle with that as the radius, with the point on the southern side which is equidistant from the two vertices. The northern arc is instructed to be drawn similarly, and for the arcs on the east and west the instruction proceeds analogously, with a cord of double the length of the side itself.

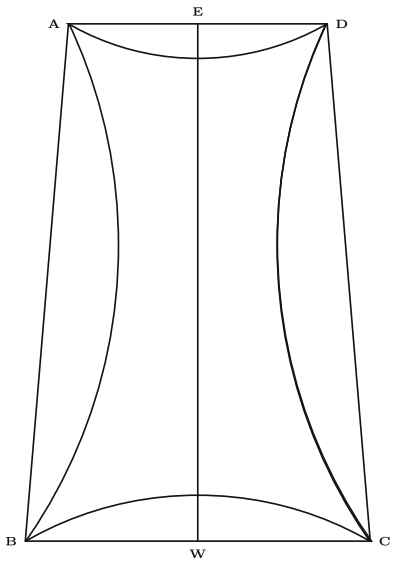

Fig. 12 *Dārśpaurṇamāsika vedi*

The arcs drawn are thus evidently a part of the design esthetics, coupled presumably with some metaphysical associations. One finds however a very fanciful interpretation of the arcs in Shylaja (2012), in terms of astronomy; it seems meaningless as there is no reference at all in the original to any external considerations, and the arcs are clearly meant to be segments of circles; while the name of the *vedi* only relates it to new moon and full moon, vague allusions are made in (Shylaja 2012) to eclipses and paths of planets, in this respect.

9.2 Tiling of *Gārhapatya*

For the *gārhapatya agni,* the layers were to be tiled with 21 bricks and for the five layers one needed two designs for the alternate layers, and they had to be such that the edges of the bricks in the successive layers do not overlap except at the boundaries of the whole figure. One such pair given is a simple one in which the square is divided into a grid of 21 congruent rectangles, with seven rows and three columns for one plan and three rows and seven columns for the other. Apart from this, there is another scheme described, consisting of division only into squares (of two different sizes); the tiling for the pair of layers is as in Fig. 13 (one presumes the arrangement was meant to be symmetrical as shown – the sūtras actually state only the number of tiles of the different sizes). For the first layer, from a square grid of four rows, the subdivision of the square formed by the middle four squares is replaced by one into a square grid with three rows, thereby enhancing the total number, by 5, to 21. For the second layer, starting with a square grid of three rows, four of the squares are subdivided into four squares each, bringing the total to 21;

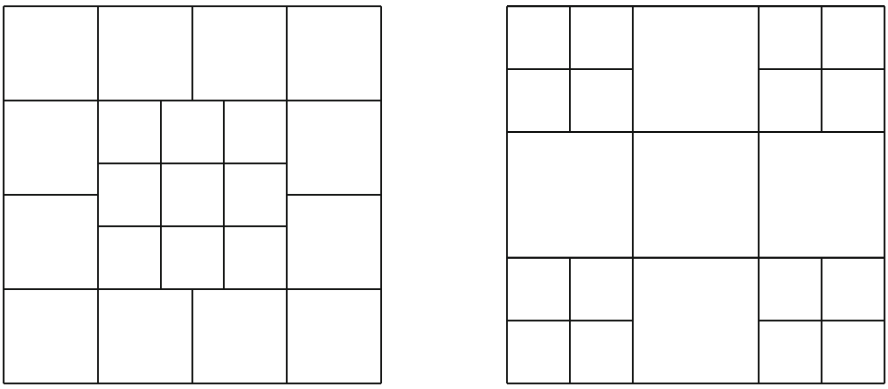

Fig. 13 Gārhapatya tiling

instead of the four corner squares as seen in the figure, choosing the four side squares would also produce a symmetrical design (there is no specification between these two possible choices) (Fig. 13).

In Datta (1932, pp. 180–182), the task of finding such patterns is projected as having been carried out via solutions of simultaneous indeterminate equations. It is quite far-fetched to suppose that Baudhāyana considered the simultaneous equations $\frac{x}{m^2} + \frac{y}{n^2} = 1$ and $x + y = 1$, as suggested in Datta (1932), and obtained solutions to the system (whether by a technique or by trial and error); there is no evidence to support such an assumption. On the other hand, interesting as the patterns produced, it can be seen that they are accessible to being carried out by intelligent boys and girls who have not yet been introduced to algebraic techniques. The geometers would in fact have been quite attuned to thinking of grids and making manipulations such as substituting a subgrid of two rows by one of three rows, etc.

Interestingly, for the circular version of *gārhapatya* a subdivision into 21 tiles is produced as follows: Starting with an inscribed square and a grid of squares in three rows, the chords are extended to the circle. This divides each of the four segments of the exterior of the inscribed square in the circle into 3 parts, thus adding 12 parts, taking the total number of parts to 21. The tiles at the boundary are of course no longer rectilinear but have rounded edges.

9.3 Tilings of *Kāmya Citis*

As noted earlier, the *kāmya citi*s consisted of five layers of brick-tilings, each layer of which had to have 200 bricks, and the edges of the bricks in the successive layers are not to overlap except at the edges of the *citi*. There is no restriction on the shapes of the bricks, and Baudhāyana uses four types of bricks. Recalling this background, Datta (1932) projects it as an issue of solving another system of simultaneous equations, which he introduces at the outset as "a much more difficult problem" (than the one involved in Sect. 9.2). Actually, while the tiling patterns introduced in

the Śulbasūtras for various shapes are esthetically appealing, and testify to noteworthy artistic skills, there is no serious mathematics involved in making the choices for the design; in particular, it does not involve solving any systems of linear equations. As has been commented in Seidenberg (1978, p. 338), one could first divide the designated area into suitably close to 200 parts, and follow it up by splitting up some of them to adjust for the deficit; similarly, if the parts go over 200 merging some of them could be considered, availing of the fact that multiple shapes were admissible for the tiles, providing flexibility in this respect. One can readily spot in the tilings where such adjustments have been made. As an example, let us consider Āpastamba's tilings for the simple design of *prauga citi* in ASl 12.7–11. It is a *citi* in the shape of an isosceles triangle (obtained by joining vertices at the base of a square to the midpoint of the opposite side). For the first layer, the scheme goes as follows. There is a primary subdivision of the triangle by dividing the three sides into 12 equal parts each, and joining the corresponding points (with the count starting from each vertex); this produces a division of the original triangle into 144 triangles. To increase the number to 200, a subdivision of a *small group of* triangles is undertaken. Some triangles are divided into four each (by joining the midpoints of its sides), while others are divided into two each (along the perpendicular bisector of the base). The former would increase the total number of parts by three with subdivision of each, while the latter will do so by one. With these provisions, one can then readily attain the target of 200 parts, as designated. As illustrated in Kulkarni (n.d.), 16 of the small triangles are divided into 4 each and 8 others into 2 each, contributing together to make up for the deficit of 56 – it could of course have been done in numerous other ways. For the second layer, a similar primary division is adopted with division of the sides into 13 parts each in place of 12, producing 169 triangles in the first instance, and dividing 7 of them into 4 each and 10 others into each 2 each making up the deficit of 31.[66] The designs described for various *citis* can be analyzed in a similar way in terms of a primary division and subdivisions for adjustments. It may also be noticed that sometimes the adjustments seem to have been done at the cost of losing bilaterial symmetry, which one may suppose they would normally have liked to maintain.

It may also be pointed out that the issue of nonoverlap of edges in successive layers would have been a routine issue in brick-laying, which is historically a much older activity, in the Indian context, if one keeps in mind the Indus valey civilization. Using lateral shifts or rotations of patterns would have been used, and one witnesses similar techniques applied in the Śulbasūtras, with some extra artistic still. There is however no serious mathematical issue at play here.

[66] One could also have first divided the triangle into 225 triangles in a similar way, merged nine groups of 4 from among them into double sized triangles, thereby reducing the number to 198, and then added 2 by splitting 2 triangles into 4, to bring the total to 200.

9.4 Configuration of *Rathacakraciti*

The *Rathacakraciti* came in two varieties, one a flat round wheel in the shape of a disc, and another one with spokes. The latter, described in BSl V.9–36, had three components, consisting of a (circular) nave, and outer annular rim and the middle part with the spokes (and the gaps between them), and the distribution of the designated total area for the *citi* ($7\frac{1}{2}$ *puruṣa*, when being performed the first time) is seen to involve an interesting play with numbers. For the purpose of the procedure of the construction, the designated area for the citi is realized as consisting of 225 square bricks of uniform size (of area $\frac{1}{30}$ *puruṣa* when the area is $7\frac{1}{2}$ *puruṣa*). Baudhāyana then adds to this the area of 64 such squares for the area of the gaps between the spokes in the middle region, thus getting 289 squares for the area of the circle corresponding to the outer edge of the felly (rim). The nave is assigned 16 of the squares, and the area of the circle corresponding to the inside edge of the felly is taken to be 144 squares. Thus, the area between the nave and the rim is 128 squares, half of which agrees with the 64 corresponding to the gaps. Now squares of area sizes 289, 144, and 16 of these squares, viz, 17, 12, and 4 times the side of the squares as above, are plotted with a common midpoint. These squares are then transformed into circles by the procedure described in Sect. 7.2, producing the concentric circles corresponding to the nave and the inner and outer edges of the felly. In the middle region, 16 spokes are plotted evenly, so that the gaps account for the area of 64, as prearranged by the above choices. Thus, the area of the *citi* works out to 225 of the squares as above, which equals the designated area for the *citi* as per the choice made. The tiling of the *citi* into 200 bricks is done independently. We shall not go into the details here, except to mention that it neatly uses splitting of 200 as $64 \times 3 + 8$; in one of the designs the 8 parts are assigned to the nave, 4 each to the 16 spokes and division of the felly into 2 rings of 64 parts.

One may spot in this procedure an interesting numerical relation $12^2 - 4^2 = 2(17^2 - 15^2)$; it may be noted that the task itself does not warrant the sizes involved to be in integers. As Seidenberg remarks, this shows noteworthy facility with numbers. It does not however indicate any systematic development of techniques with regard to indeterminate equations.

Before concluding this discussion, I would like to clarify a curious confusion found in the literature in respect of Baudhāyana's description of the procedure as above. The sūtras, after arriving at the collection of the 289 squares, BSl V.13–16 go on to say "The side of this square comprises 16 bricks. Thirty-three bricks still remain. These are to be placed on all sides round the borders (to make a square)" (cf. Prakash et al. 1968a, p. 165–166) (parenthetical explanations adjusted to the context here). In this respect, Thibaut, in his foundational work (Thibaut 1875, p. 261), comments "It is strange that we are not direted to construct the whole square at once, but are told to form at first a square out of 256 bricks and then to place the remaining 33 bricks around it." He then goes on to record a long-winded explanation of the commentator (Dvārakānātha) which he evidently finds unsatisfactory, and one would agree with him on it. Recalling Thibaut's question, in Seidenberg (1978,

p. 333) the author offers an explanation, which however seems to bring in irrelevant aspects and ultimately hardly connects meaningfully with the original text and Thibaut's query. In the translation in Sen and Bag (1983, p. 94), the authors parenthetically add "so as to obtain a square of side containing 17 bricks," throwing no light on why it was not taken up directly. The translations in Prakash et al. (1968a) and Kulkarni (n.d.) seem to be of no help on the issue either.

A simple explanation is as follows. Baudhāyana wanted to begin with a square whose size is made of an even number of the small squares, so that he can readily make sense of the *middle square* consisting of 16 of the original squares, for the nave (and also similarly a square of width 12 squares for the inner circle of the felly); it would not make sense to take middle 16 squares from a square-grid of 17 rows. Keeping that objective, Baudhāyana further wanted the remaining 33 squares to be placed around the 16×16 square without disturbing the centrality of the square for the nave; the commentator's interpretation to place them "on the north side and east side of the square," as included parenthetically in Prakash et al. (1968a) and other similar words in Sen and Bag (1983), is plain wrong. The commentators (ancient as well as modern) seem to have missed the point that Baudhāyana's instruction, in BSl 5.16, as "*tābhirantansarvataḥ paricinuyāt*" (These are to be placed on all sides round the borders) does not correspond to transporting the squares individually, but incorporating their area, in the same spirit as transformation of figures that we discussed in earlier sections. Thus, a natural choice for following the instruction would be to divide each square into two rectangular halves and to arrange the 66 rectangles along the border of the 16×16 square, turning it into a 17×17 square; see Fig. 14 (the figure in Sen and Bag

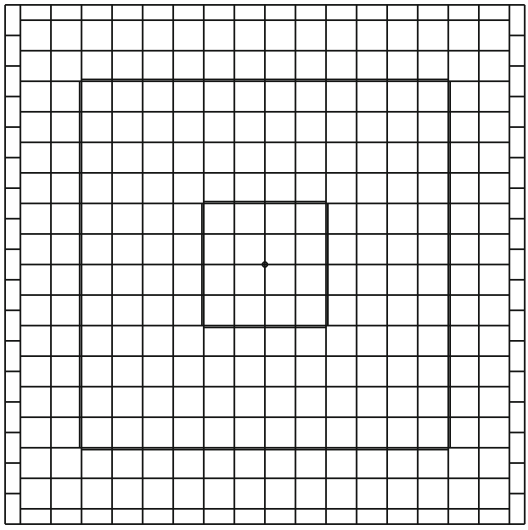

Fig. 14 Preparing for *Rathacakraciti*

1983, on p. 217, is misleading and does not correspond to Baudhāyana's instruction, though it presents a plan that Baudhāyana could have adopted, by constructing a 17×17 square straightaway, and describing the squares for the nave and the inner edge of the felly differently, to render them central).

10 In Place of Conclusion

The Śulbasūtras provide us a unique window to the mathematics in India in the millennium BCE; while there are indeed other mathematical developments traceable from that period, as also some of the earlier periods such as from the Indus valley civilization, they are based on sources that are either indirect or relatively scanty in comparison. The long time frame, extending over at least half a millennium if not much more, which they represent as a historical period with a relatively constant cultural milieu, brings an additional attraction, motivating their study.

In this review, I have highlighted various significant mathematical ideas evidenced in the Śulbasūtras, together with an overall profile of the mathematical edifice that got built up following the pursuit inspired by the projects for erecting elaborate and intricate altars and fireplaces for sacrificial worship. In doing so, I have endeavored to maintain a high degree of veracity and discussed the contours of various exaggerated assertions that have been in vogue and also tried to clarify some of the misunderstandings. Without any claims about the narrative being error-free, the author hopes that it will provide a clearer picture of the mathematical contents and their significance in respect of the historical development of mathematics.

The inquiry into the mathematics in the Śulbasūtras raises a variety of questions, or what we may even call puzzles. Some of these pertain to their mathematics, which we have noted in the course of this review. There are deeper puzzles from the point of view of history of mathematics. A principal one that comes to mind is why do the works seem so stagnant, or even declining in standard, with Baudhāyana's oldest Śulba standing out as the beacon for such a long tradition. While there are a few flourishes seen in the later Śulba works, that we have noted, a good deal of mathematically interesting parts are seen to be forgotten or ignored in the later woks. It may also be recalled, as noted in Datta et al. (1980, p. 124), geometry did not make much progress in the post-Vedic period in India, until much later, following the impact of Greek mathematics around the turn of the millennium. One may also wonder in this context about the mode of transmission, geographically across the country and from generation to generation, and how it may have brought about the change in content. Answers to these questions may hold the key to what lessons may be drawn from the study, for our times. It is hoped that this detailed review of the works will contribute in making progress toward understanding these issues.

Appendix

Concordance of sūtras between Śulbasūtras

Topic	Section	BSl	MSl	ASl	KSl
Constr. of perpendicular by "compass" method	3.1	I.22–28	–	–	–
Nyañchana method with (3, 4, 5)	3.2	I.30–35	1.3.6	4.11	1.17
Nyañchana method with (5, 12, 13)	3.2	I.42–44	1.1.11–12	1.3–6 1.7	1.12 1.14
Constr. of perpendicular by "arrow" method	3.3	I.36–40	–	1.13–18	–
Nyañchana method with other triples	3.5	–	–	5.13–17	–
Constr. of rhombus	3.6	I.57	3.6.4	12.12–15	4.6
Transf. of square to an isosceles trapezium	3.8.1	I.55	–	–	–
Transf. of square to a rectangle (special)	3.8.4	I.52	–	–	3.4
Transf. of square to a rectangle (general)	3.8.5	I.53	–	3.1	–
Pythagorean principle	4	I.48	3.1.10	1.8	2.11
Combining two squares	5.1	I.50	3.3.6	2.10–13	2.22
Enhancement of figures by scaling	5.2	II.1–5	–	8.16	5.x, 6.2–5
Combining multiple squares	5.3	–	–	–	6.7
Difference of two squares	5.4	I.51	–	2.14–17	3.1
Constr. of a square equivalent to a rectangle	5.5	I.54		2.21–23	3.2–3
Pythagorean triples	6.3	I.49	–	5.3–17	–
Circumference of a circle	7.1	I.112–113	3.2.13	–	–
Constr. of a circle equivalent to a square	7.2 7.4	1.58	1.1.8 3.2.15	3.2–5	3.13
Squaring the circle (refined)	7.6	1.59	–	–	–
Squaring the circle (approx.)	7.7	1.60	3.2.13	3.6–8	3.14
Evaluation of $\sqrt{2}$	8	1.61	3.3–1.2	1.10	2.13

Julian or Gregorian calendar date. Another rather infamous perpetual calendar has been used for nearly four centuries among Javanese people in Indonesia. This Javanese calendar combines the *Saka* Hindu, lunar Islamic, and western Gregorian calendars. In addition to the regular 7-day, lunar month, and lunar year cycles, it also contains 5-day *pasaran*, 35-day *wetonan*, 210-day *pawukon*, octo-year *windu*, and 120-year *kurup* cycles. The Javanese calendar is used for cultural and spiritual purposes, including a decision to tie the knot among couples. In this chapter, we will explore the relationship between mathematics and the culture of Javanese people and how they use their calendar and the arithmetic aspect of it in their daily lives. We also propose an unprecedented congruence formula to compute the *pasaran* day. We hope that this excursion provides an insightful idea that can be adopted for teaching and learning of congruence in number theory.

1 Introduction

Arithmetic and number theory find applications in various cultures throughout the world. In addition to solving everyday problems using elementary arithmetic operations, our ancient ancestors also developed and invented perpetual calendars without any aid of modern electronic calculators and the computer. A perpetual calendar is a system dealing with periods of time that occur repeatedly. It is organized into days, weeks, months, and years. A date of a calendar structure refers to a particular day within that system. A calendar is used for various civil, administrative, commercial, social, and religious purposes.

The English word "calendar" is derived from the Latin word which refers to the first day of the month in the Roman calendar. It is related to the verb *calare* ("to announce solemnly, to call out"), which refers to the "calling" of the new moon when it was visible for the first time (Brown 1993). Another source mentions that the modern English "calendar" comes from the Middle English *calender*, which was adopted from the Old French *calendier*. It originated from the Latin word *calendarium*, which meant a "debt book, account book, register." In Ancient Rome, interests were tracked in such books, accounts were settled, and debts were collected on the first day (*calends*) of each month (Stakhov 2009).

Generally, the calculation of and periods in the calendrical system are synchronized with the cycle of the Sun or Moon. Hence, the names solar, lunar, and lunisolar calendars, where the latter combined both the Moon phase and tropical (solar) year. Our current Gregorian and the previously Julian calendars are solar-based calendars, as well as the ancient Egyptian calendar. An example of the lunar calendar is the Islamic calendar. Prominent examples of the lunisolar calendar are the Hebrew,

Chinese, Hindu, and Buddhist calendars (Richards 1998; Reingold and Dershowitz 2018).

Studying calendar systems from any culture cannot be separated from attempting to gain insight and understanding not only in the arithmetic behind them but also in the interconnectivity with mathematics, the history of mathematics, astronomy, mathematics education, and sociocultural aspects. Hence, the study of perpetual calendars is encompassed by the fields of ethnomathematics and ethnoastronomy, the research areas where diverse cultural groups embrace, practice, and develop mathematics and astronomy in their daily lives.

Figure 1 summarizes a theoretical framework used for the discussion on the Javanese calendar considered in this chapter. Although the title of this chapter contains the term "ethnoarithmetic," indeed that covering a topic on the Javanese calendar embodies other aspects beyond the cultural and mathematical, in this case, arithmetical aspect per se. As we observe at the third level of the Venn diagram presented in Fig. 1, an excursion into the Javanese calendar intersects and includes four distinct but related disciplines: mathematics, education, culture, and astronomy.

Fundamental work in the area of ethnomathematics has been documented by Ascher (2002). The author elaborated on several mathematical ideas and their cultural embedding of people in traditional or small-scale cultures, with some emphasis on time structure and the logic of divination. In particular, the book also covered an explanation of the Balinese calendar. For discussion of the Balinese

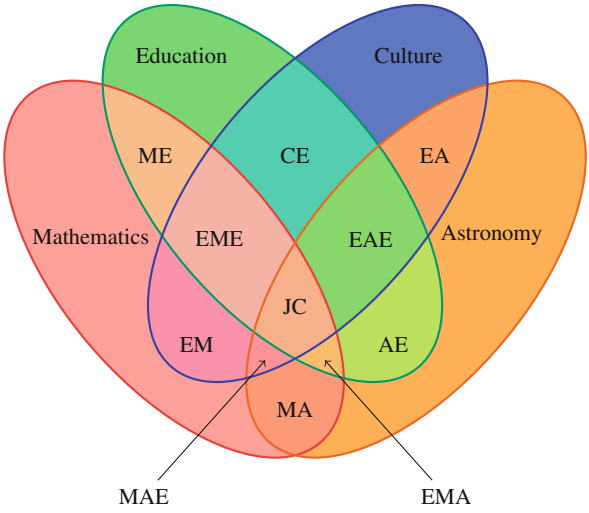

Fig. 1 A theoretical framework for an ethnoarithmetic study of the Javanese calendar. At the first level of the intersection, ME denotes mathematics education, EM denotes ethnomathematics, MA denotes mathematics astronomy, AE denotes astronomy education, EA denotes ethnoastronomy, and CE denotes cultural education. At the second level of the intersection, EME denotes ethnomathematics education, MAE denotes mathematics astronomy education, EMA denotes ethnomathematics astronomy, and EAE denotes ethnoastronomy education. The third level of the intersection is the heart of discussion; we have JC as the Javanese calendar

calendrical system and its multiple cycles, consult Vickers (1990); Darling (2004); Proudfoot (2007); Ginaya (2018); and Gislén and Eade (2019c).

To the best of our knowledge, the only monograph that discusses an intersection of three components of the theoretical framework is a volume edited by Rosa et al. (2017). The book covers diverse approaches and perspectives from ethnomathematics to mathematics education, particularly in several non-Western cultures. Since these topics stimulate debates not only on the nature of mathematical knowledge and the knowledge of a specific cultural group but also on the pedagogy of mathematics classroom, the field of ethnomathematics certainly offers a possibility for improving mathematics education across cultures.

A collection of essays dealing with the mathematical knowledge and beliefs of cultures outside the Western world is compiled by Selin and D'Ambrosio (2000). The essays address the connections between mathematics and culture, relate mathematical practices in various cultures, and discuss how mathematical knowledge is transferred from East to West. A coverage of calendars in various cultures is also briefly touched.

Since many calendrical systems are invented based on the movement of celestial bodies, particularly the Sun and Moon, we cannot dismantle the role of astronomy in the study of calendars, including the Javanese one. Various civilizations incorporate the cyclical movements of both the Sun and Moon into their calendrical systems (Ruggles 2015). Some examples of this calendrical-astronomical relationship can be observed among others in the Jewish (Cohn 2007), Indian (Dershowitz and Reingold 2009), Chinese (Martzloff 2000, 2016), mainland Southeast Asian (Eade 1995), and Islamic calendars (Proudfoot 2006).

An explanation of the mathematical and astronomical details of how many calendars function has been covered extensively by Reingold and Dershowitz (2018). A related series with non-Western ethnomathematics is a book on non-Western ethnoastronomy that has been edited by Selin and Sun (2000). In particular, the book also dedicated one chapter on an astronomical feature of the Javanese calendar, where a season keeper (*pranotomongso* or *pranata mangsa*) guides agricultural activities among rural peasants in Java (Daldjoeni 1984; Ammarell 1988; Hidayat 2000). The readers might be interested to compare this with the cultural production of Indonesian skylore across three ethnic groups: Banjar Muslim, Meratus Dayak, and Javanese peoples (Ammarell and Tsing 2015).

Integrating the Javanese calendar into elementary school education as an ethnomathematics study has been attempted by Utami et al. (2020). Another attempt is to embed some topics related to calendrical systems into the first-year seminar on the mathematics of the pre-Columbian Americas (Catepillán 2016). A study from Taipei, Taiwan, on the movements of the Moon at the primary level, introduced pupils to both the Gregorian and Chinese calendars in the context of physical classroom environments (Hubber and Ramseger 2017).

Although we propose an intersection of only four disciplines in our theoretical framework, the list is by no means exhaustive. Another possibility is to include psychology or the interaction between mathematics and psychology. For instance, a theoretical foundation on the calendrical system and the psychology of time has been

modeled by Rudolph (2006). In particular, the author proposed that Balinese (also equally applied to Javanese) time might be neither "circular" nor "linear," but *profinite*. Since the Javanese calendrical systems involve 5-day *pasaran*, 7-day *saptawara/dinapitu*, and 30 *wuku* cycles, it could be modeled by the group of *profinite integers* $\widehat{\mathbb{Z}}$. This group bundles together all different sets of the ring of p-adic integers $\mathbb{Z}_p$ and various finite sets $\mathbb{Z}/(p)$ of integers modulo p, where p denotes prime integers (Milne 2020).

A discussion on calendar timekeeping scheme in Southeast Asia is covered by Gislén (2018). An overview of the calendars in Southeast Asia is given by Gislén and Eade (2019a). In their subsequent papers, they and Lân also discussed calendars from Burma, Thailand, Laos, and Cambodia (Gislé and Eade 2019b), Vietnam (Lân 2019), and Malaysia and Indonesia (Gislén and Eade 2019c), eclipse calculation (Gislén and Eade 2019d), and chronicle inscriptions (Gislén and Eade 2019e). See also Eade (1995), Ôhashi (2009), and (Golzio 2012) for basic facts and further explanations of the calendrical systems in India and (Mainland) Southeast Asia.

This chapter is organized as follows. After this introduction, the following section briefly covers the calendars from ancient and contemporary times, which includes the pre-Gregorian and Gregorian calendars. After that, a discussion on the Javanese calendar in the context of ethnoarithmetic will be dedicated exclusively in one section. The final section presents discussion and epilogue.

2 Ancient and Modern Calendars

This section briefly covers several calendars in the pre-Gregorian era and Zeller's congruence algorithm for the Gregorian calendar.

2.1 Pre-Gregorian Calendars

Before the Gregorian calendar that we are using today was adopted, numerous calendars have been used in various parts of the world. The Egyptian calendar was among the first solar calendars with its history dated back to the fourth millennium BCE.

A Mesoamerican civilization of the Maya peoples also developed a calendar system where the year was divided into 18 months of 20 days (Ascher 2002; Stakhov 2009). The Mayan calendar system contains three separate calendars, and although they are not related mathematically, all of them are linked in a single calendar system. The first one is called the "long count," used by the Mayans to measure date chronology for history recording. The second one is the *Haab* calendar, a nonchronological civil calendar. The third one is the Mayan religious calendar, also nonchronological, called the *Tzolkin* (Ascher 2002; Cohn 2007).

Related to the Maya civilization is the Inca Empire, where the latter also developed its calendar system, which was based on several different astronomical cycles,

including the solar year, synodic and sidereal lunar cycles, and local zenith period (Urton and Llanos 2010). A variety of mathematical developments among the native Americans from the prehistoric to present has been compiled by Closs (1996). In particular, one chapter of the book discusses the calendrical system of the Nuu-chah-nulth (formerly referred to as the Nootka), one of the Indigenous peoples of the Pacific Northwest Coast in Canada (Folan 1986).

Some calendars are based on lunisolar, and one of them is the Jewish calendar. Also called the Hebrew calendar, it is still used until today, mainly for Jewish religious observance. Although the Jewish calendar was developed in its current format during the Talmud period in the fifth century CE by Rabbi Hillel II, the up-to-date counting has accumulated more than 5000 years (Ascher 2002; Cohn 2007). For our information, AM 5781 began at sunset on Friday, 18 September 2020, and will end at sunset on Monday, 6 September 2021 CE. Here, AM means *Anno Mundi*, the Latin phrase for "in the year of the world."

Although the traditional Chinese calendar is also a lunisolar type, the most fundamental component is the sexagenary cycle, i.e., a cycle of 60 terms marked by coordination between 12 celestial stems and 10 terrestrial branches, which is also known as the "Stems-and-Branches" or *gānzhī* (干支) (Martzloff 2000). A discussion on the mathematical aspect of the Chinese calendar has been covered extensively by Aslaksen (2001, 2002, 2006). A historical aspect of the Chinese calendar is discussed by Sun (2015). Astronomical aspects and the mathematical structures underlying the calculation techniques of the Chinese calendar are highlighted by Martzloff (2016).

The *Hijri*, or Islamic calendar, is a lunar calendar consisting of 12 lunar (synodic) months in a year of 354 or 355 days. It is still widely used in predominantly Muslim countries alongside the Gregorian calendar, primarily for religious purposes. The current counting started from 622 CE, commemorating the emigration of Prophet Muhammad and his companions from Mecca to Medina (*hijra*) (Hassan 2017). In the Gregorian calendar reckoning, the current Islamic year is 1422 AH, which approximately runs from 20 August 2020 until 9 August 2021. AH means *Anno Hegirae*, the Latin phrase for "in the year of the Hijra." In particular, the history of Muslim calendars in Southeast Asia in the historical and cultural context has been successfully traced by Proudfoot (2006).

2.2 Gregorian Calendar

The language of congruences is a basic building block in arithmetic and number theory. It allows us to operate with divisibility relationships in a similar way as we deal with equalities. Congruences have many applications, and one of them is to determine the day of the week for any date for a given perpetual calendar. In particular, the procedure for finding the day of the week for a given date in the Gregorian calendar has been discussed by Carroll (1887); Conway (1973); Burton (2011); and Rosen (2011). See also Gardner (1996) and Cohen (2000).

The Gregorian calendar was promulgated by Pope Gregory XIII and is a replacement of the Julian calendar, proposed by Julius Caesar in 46 BC. Starting from 1582, the Catholic states were among the first countries to adopt the Gregorian calendar by skipping 10 days in October: Thursday, 4 October 1582, was followed by Friday, 15 October 1582. Greece and Turkey are among the last countries that adopted the Gregorian calendar when they changed on 1 March 1923 and 1 January 1926, respectively.

Let W denote the day of the week from Saturday = 0 to Friday = 6, k denote the day of the month, m denote month, and N denote year. For the month, the convention is March = 3, April = 4,. . ., but January = 13, and February = 14. For the year, N is the current year unless the month is January or February, for which N is the previous year. The relationship between year and century is given by $N = 100\ C + Y$, where C denotes zero-based century and Y denotes a two-digit year. Note that the purpose of adopting this expression is not to confuse C with the standard century number, which is $C + 1$ for the first 99 years. The formula for finding the day of the week W of day k of month m of year N is given by Zeller's congruence algorithm (Zeller 1882, 1883, 1885, 1887):

$$W \equiv \left(k + \left\lfloor \frac{13(m+1)}{5} \right\rfloor + Y + \left\lfloor \frac{Y}{4} \right\rfloor + \left\lfloor \frac{C}{4} \right\rfloor - 2C\right) (\text{mod } 7). \tag{1}$$

Here, $\lfloor x \rfloor$ denotes the floor function or greatest integer function and mod is the modulo operation or remainder after division.

As an example, we are interested in finding the days of the week when a Javanese heroine and educator Raden Adjeng Kartini was born and passed away. She was born in Jepara, a town on the north coast of Java, located around 80 km to the northeast of Semarang, the present capital of Central Java province in Indonesia. Kartini was a pioneer for girls' education and women's emancipation rights in Indonesia, at the time when Indonesia was still a part of the Dutch East Indies colonial empire. She could be correlated with her European counterparts, including an English advocate of women's right Mary Wollstonecraft (27 April 1759 – 10 September 1797) or a Finnish social activist Minna Canth (19 March 1844 – 12 May 1897) (cf. Kartini 1911, 1920; Wollstonecraft 1792; Canth 1885).

Kartini was born on 21 April 1879, so we have $k = 21$, $m = 4$, $N = 1879$, $C = 18$, and $Y = 79$. She passed away on 17 September 1904, at the age of 25, and we identify that $k = 17$, $m = 9$, $N = 1904$, $C = 19$, and $Y = 4$. Using Zeller's congruence formula (1), the days when Kartini was born W_b and passed away W_d can be calculated as follows, respectively:

$$W_b \equiv \left(21 + \left[\frac{13(5)}{5}\right] + 79 + \left[\frac{79}{4}\right] + \left[\frac{18}{4}\right] - 36\right) (\text{mod } 7)$$

$$\equiv (21 + 13 + 79 + 19 + 4 - 36) (\text{mod } 7) \equiv 100 (\text{mod } 7) \equiv 2 (\text{mod } 7)$$

$$W_d \equiv \left(17 + \left[\frac{13(10)}{5}\right] + 4 + \left\lfloor\frac{4}{4}\right\rfloor + \left\lfloor\frac{19}{4}\right\rfloor - 38\right) \pmod 7$$
$$\equiv (17 + 26 + 4 + 1 + 4 - 38) \pmod 7 \equiv 14 \pmod 7 \equiv 0 \pmod 7.$$

Hence, Kartini was born on Monday, 21 April 1879 and passed away on Saturday, 17 September 1904. She was buried at Bulu Village, Rembang, Central Java, around 100 km east of Jepara.

3 Javanese Calendar

This section features the main characteristics of the Javanese calendar. We start with the geographical location of the island of Java, the Javanese people, and a brief historical background of the calendar. After providing a detailed discussion, we close the section by computer implementation of the Javanese calendar.

3.1 Where Is Java?

Java is an island in Indonesia, not a programming language, although the latter was renamed after some Javanese coffee by its founders. It is located in the southern hemisphere, around 800 km from the Equator. It extends from latitude 6° to 8° south, and longitude 105° to 114° east. With an area of 150,000 square kilometers, it is about 1000 km long from west to east and around 200 km wide from north to south. The island lies between Sumatra to the west and Bali to the east. It is bordered by the Java Sea on the north and the Indian Ocean on the south (see Fig. 2). It is the world's 13th largest island (Cribb 2000).

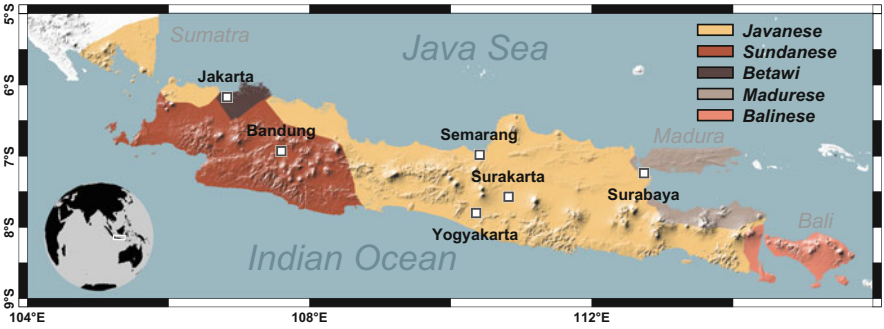

Fig. 2 The situation of the Java island, main cities, and present spoken languages: Javanese (Central and East Java, and a small enclave in North-West Java), Sundanese (West Java), Betawi (in and around Jakarta metropolitan area), Madurese (Madura Island and a part of North-Eastern Java), and Balinese (Bali Island and a small part of Eastern Java). Basemap uses ETOPO5 and SRTM3 topographic data and shaded relief mapping code (Beauducel 2020a). ETOPO5 is a 5 arc-minute resolution relief model for the Earth's surface that integrates land topography and ocean bathymetry dataset. SRTM3, the Shuttle Radar Topography Mission, is a 3 arc-second resolution digital topographic database of land elevation limited to latitudes from 60° south to 60° north

3.2 Who Are Javanese People?

The Javanese people are a native ethnic group to the island of Java. They form the largest ethnic group in Indonesia, with more than 95 million people living in Indonesia and approximately 5 million people living abroad. Although they predominantly reside in the central and eastern parts of the island, they are also scattered in various parts of the country (Taylor 2003; Ananta et al. 2015). See Fig. 2. Javanese people have their own language which is distinct from Indonesian. The Javanese language is a member of the Austronesian family of languages written in Javanese *hanacaraka* or *dentawyanjana*. Thanks to its long history and legacy of Hinduism and Buddhism in Java, the language adopted a large number of Sanskrit words (Marr and Milner 1986; Errington 1998).

3.3 A Background of the Javanese Calendar

Javanese people use the Javanese calendar simultaneously with two other perpetual calendars, the Gregorian and Islamic calendars. The former is the official calendar of the Republic of Indonesia, and the latter is used mainly for religious purposes. Prior to the adoption of the Javanese calendar in 1633 CE, Javanese people used a calendrical system based on the lunisolar Hindu *Saka* calendar (Ricklefs 1993).

The Javanese calendar was inaugurated by Sultan Agung Adi Prabu Hanyakrakusuma (1593–1645 CE), or simply Sultan Agung, the third Sultan of Mataram who ruled Central Java from 1613 CE to 1645 CE. Although the counting of the year follows the *Saka* calendar, the Javanese calendar employs a similar lunar year as the Islamic *Hijri* calendar instead of the solar year system like the former (Gislén and Eade 2019a). The Javanese calendar is sometimes referred to as AJ (*Anno Javanico*), the Latin phrase for Javanese Year. Since 2008, the difference between the Gregorian and Javanese calendars is about 67 years, where the current year 2020 CE corresponds to 1953 AJ (Oey 2001; Raffles 1817).

3.4 Some Characteristics of the Javanese Calendar

Different from many other calendars that employ a 7-day week cycle, the Javanese calendar adopts a 5-day week cycle, known as *pancawara*. Amalgamating with the 7-day week cycle of the Gregorian and Islamic calendars, namely the *saptawara* cycle, one obtains the 35-day cycle, known as *wetonan* (Darling 2004). This foundation cycle interferes with additional cycles:

- A 210-day cycle of 30 weeks, named as the *pawukon*.
- A more complex combination of the lunar month *wulan*, which has 29 or 30 days, the lunar year *taun*, which is 12 lunar months, *windu*, which is 8 lunar years, and finally *kurup* of 15 *windu* or 120 lunar years minus 1 day, which matches exactly the Islamic calendar cycle (Proudfoot 2007).

Table 1 Main cycles of the Javanese calendar

Cycle name	Length	Unit	Comment
Pancawara	5	Day	Javanese week 5 *pasaran* names (see Table 2)
Wuku	7	Day	Gregorian/Islamic week 7 *dinapitu* names (see Table 3) 30 *wuku* names
Wetonan	35	Day	35-day names as *Dinapitu* and *Pasaran*
Wulan	29 or 30	Day	Day number in a *wulan* is *dina* 12 *wulan* names (see Table 5)
Pawukon	30	*Wuku*	30 weeks $\equiv$ 210 days
Taun	12	*Wulan*	354 or 355 days *Taun* number starts on 1555 AJ 8 *taun* names (see Table 6)
Windu	8 4	*Taun* *Windu*	96 *wulan* $\equiv$ 81 *Wetonan* $\equiv$ 2,835 days 32 *taun*, 4 *windu* names
Lambang	2	*Windu*	16 *taun*, 2 *lambang* names
Kurup	15	*Windu*	120 *Taun* -1 day $\equiv$ 42,524 days 4 *kurup* names until today (see Table 8)

There are also additional cycles, but they are no longer used in the Javanese tradition. To be exhaustive, we list them here (Richmond 1956; Zerubavel 1989):

- A 6-day cycle called the *Paringkelan*: "Tungle," "Aryang," "Wurukung," "Paningron," "Uwas," and "Mawulu."
- An 8-day cycle called the *Padewan*: "Sri," "Indra," "Guru," "Yama," "Rudra," "Brama," "Kala," and "Uma."
- A 9-day cycle called the *Padangon*: "Dangu," "Jagur," "Gigis," "Kerangan," "Nohan," "Wogan," "Tulus," "Wurung," and "Dadi."

The list of main cycles and characteristics is summarized in Table 1 and is detailed in the following subsubsections. Figure 3 shows an original table of the main cycles' names written in the Javanese script *hanacaraka*.

3.4.1 *Pancawara* and *Pasaran*

The Javanese 5-day cycle is named *pancawara* and made of 5 days known as *pasaran*: "Lêgi," "Pahing" (or "Paing"), "Pon," "Wage," and "Kliwon." The word comes from "pasar" which means market. Historically, the market was held and operated on a 5-day cycle based on a *pasaran* day, e.g., "Pasar Kliwon" or "Pasar Lêgi." Until today, most of the markets in Java still have a *pasaran* name like the Kliwon Market in Kudus, Central Java, although they usually operate every day (Oey 2001).

Each *pasaran* is associated with some symbols, in particular, the five classical elements of Aristotle, colors, cardinal directions (note that the Javanese culture has

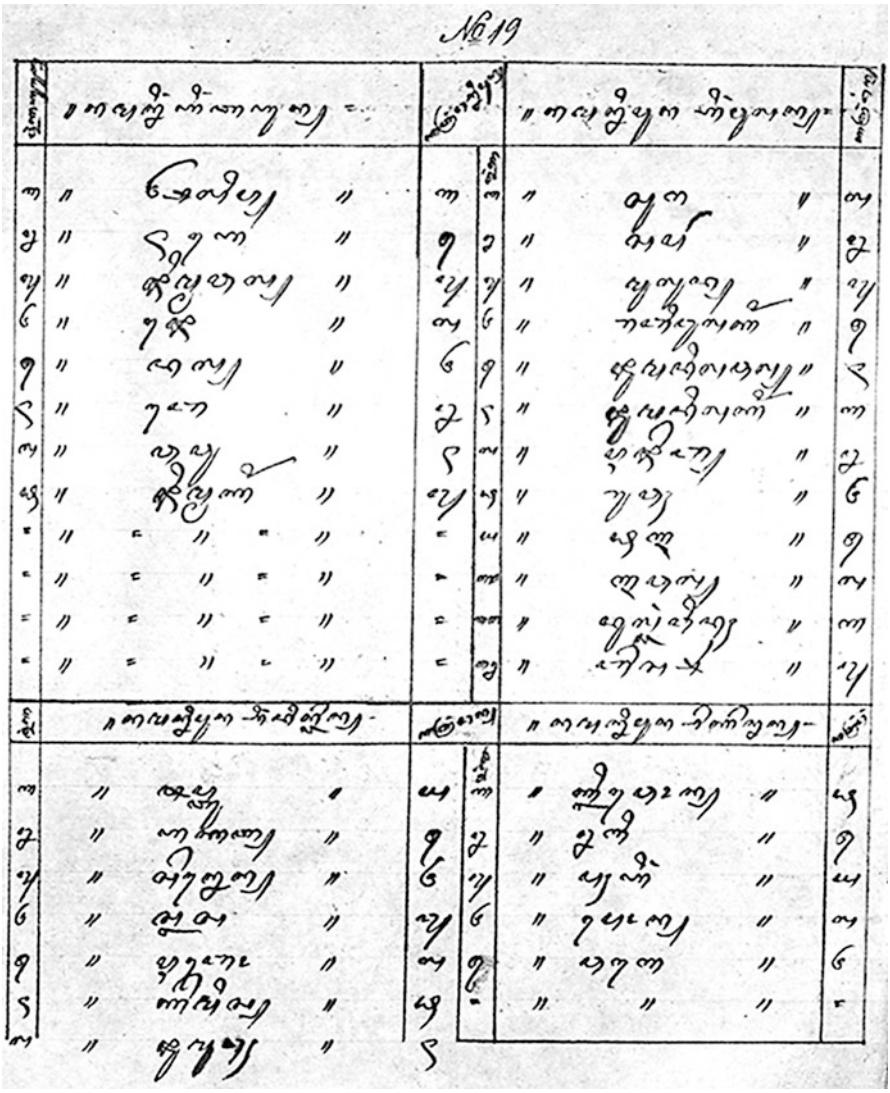

Fig. 3 Table list of 8 *taun*, 12 *wulan*, 7 *dinapitu*, and 5 *pasaran* names in Javanese Sanskrit, after Warsapradongga (1892)

five of them including a center), and human posture (Pigeaud 1977) (cf. Brinton 1893). See Table 2.

The computation of the *pasaran* day from the Gregorian or Islamic calendar date can be performed using a similar strategy as Zeller's congruence algorithm. Indeed, the formula is based on the observation that the day of the week progresses predictably based upon each subpart of the date, i.e., day, month, and year. In this

Table 2 Names of the five *pasaran* days in the Javanese week and commonly associated symbols

Ngoko	Krama	Meaning	Element	Color	Direction	Posture
Pon	Petak	–	Water	Yellow	West	Sleep
Wage	Cemeng	Dark	Earth	Black	North	Sit down
Kliwon	Asih	Affection	Spirit	Mixed color	Focus/center	Stand up
Lêgi	Manis	Sweet	Air	White	East	Turn back
Pahing	Pahit	Bitter	Fire	Red	South	To face

case, we will consider the 5-day Javanese week *pasaran*. Each term within the formula is used to calculate the offset needed to obtain the correct day.

Let P denote the *pasaran* day, in the order of Pon $=0$, Wage $=1$, Kliwon $=2$, Lêgi $=3$, and Pahing $=4$. We now propose the following *pasaran* day congruence formula:

$$P \equiv \left(k + \left\lfloor \frac{3(m+1)}{5} \right\rfloor + \left\lfloor \frac{Y}{4} \right\rfloor + 4C - 4\left\lfloor \frac{C}{4} \right\rfloor \right) \pmod 5. \tag{2}$$

where k, m, C, and Y denote the same variables as the ones defined for Zeller's congruence formula (see expression (1) in the previous section). Each term in (2) can be analyzed as follows:

- The variable k represents the progression of the day of the week based on the day of the month since each successive day results in an additional offset of one.
- The term $+\left\lfloor \frac{3(m+1)}{5} \right\rfloor$ adjusts for the variation in the days of the month. Indeed, starting from March to February, the days in a month are {31, 30, 31, 30, 31, 31, 30, 31, 30, 31, 31, 28/29}. The last element, February's 28/29 days, is not a problem since the formula had rolled it to the end. The number of days for the 11 first elements of this sequence modulo 5 (still starting with March) would be {1, 0, 1, 0, 1, 1, 0, 1, 0, 1, 1} which basically alternates the subsequence {1, 0, 1, 0, 1} every 5 months and gives the number of days that should be added to the next month. The fraction $\frac{3}{5} \equiv 0.6$ applied to $m+1$ and the floor function have that effect and will add the proper amount of days.
- Since there are 365 days in a nonleap year, and $365 \pmod 5 \equiv 0 \pmod 5$, there is no need to add an offset for the normal year.
- For the leap years, $366 \pmod 5 \equiv 1 \pmod 5$, so 1 day must be added to the offset value by the term $+\lfloor \frac{Y}{4} \rfloor$.
- There are 36,524 days in a normal century and 36,525 days in each century divisible by 400; the term $4C$ adds $36{,}524 \pmod 5 \equiv 4 \pmod 5$, 4 days for any century, and $-4\lfloor \frac{C}{4} \rfloor$ removes these 4 days for a century divisible by 400.
- The overall function, (mod 5), normalizes the result to reside in the range from 0 to 4, which yields the index of the correct day for the date being analyzed.

For example, to find the *pasaran* of the very first day in the Javanese calendar (1 Sura 1555 AJ Alip) which corresponds to 8 July 1633 CE, we have $k = 8$, $m = 7$, $C = 16$, and $Y = 33$. Using (2), we obtain $P \equiv 8 + 4 + 8 + 64 - 16 \equiv 68 \pmod 5 \equiv 3 \pmod 5$. Hence, 8 July 1633 CE was a "Lêgi." From the previously considered example, the *pasaran* days when Kartini was born P_b and passed away P_d can be calculated as follows:

$$P_b \equiv (21 + 3 + 19 + 72 - 16) \pmod 5 \equiv 99 \pmod 5 \equiv 4 \pmod 5$$

$$P_d \equiv (17 + 6 + 1 + 76 - 16) \pmod 5 \equiv 84 \pmod 5 \equiv 4 \pmod 5.$$

Hence, both 21 April 1879 and 17 September 1904 fall on a "Pahing."

3.4.2 *Dinapitu*, *Wuku*, and *Pawukon*

Dinapitu literally means "day 7" in Javanese and corresponds to the day names in the Gregorian/Islamic calendar week with exact equivalence, i.e., from Monday to Sunday: "Sênèn," "Selasa" (or "Slasa"), "Rêbo," "Kêmis," "Jemuwah" (or "Jumungah"), "Sêtu," and "Ngahad" (or "Ahad"). In recent literature, we often find the name of the days in the Indonesian language (from Monday to Sunday: "Senin," "Selasa," "Rabu," "Kamis," "Jumat," "Sabtu," and "Minggu"). They are also associated with particular symbolic meanings. See Table 3. The names of the days of the week are similar in both languages as they are absorbed from Arabic except for Sunday in Indonesian which was assimilated from the Portuguese "Domingo."

The 7-day cycle is called *saptawara* or *padinan,* and a week is named a *wuku*. The period of 30 *wuku* makes the *pawukon* cycle, i.e., 210 days (Proudfoot 2007). There are 30 different names of *wuku* (Soebardi 1965; Headley 2004) (see Table 4). Figure 4 shows an example of the Javanese calendar with *padinan*, *pasaran*, *wuku*, and *paringkelan* information, among others.

3.4.3 *Wetonan*

The *wetonan* cycle combines the 5-day *pancawara* cycle with the 7-day *wuku* week cycle. Each *wetonan* cycle lasts for $7 \times 5 = 35$ days, with 35 distinct combinations of the couple "*dinapitu pasaran*" which is called the *weton*. Figure 5 displays the 35-day *wetonan* cycle of the dual *dinapitu pasaran*. The 7-day *wuku* cycle is arranged clockwise from Monday to Sunday and the 5-day *pasaran* day progresses

Table 3 List of names of the 7 days in a *wuku* Gregorian week (cf. Rizzo 2020)

Dinapitu	Padinan	Week day	Symbol
Ngahad	Dite	Sunday	Silent
Sênèn	Soma	Monday	Forward
Selasa	Anggara	Tuesday	Backward
Rêbo	Buda	Wednesday	Turn left
Kêmis	Respati	Thursday	Turn right
Jemuwah	Sukra	Friday	Up
Sêtu	Tumpak	Saturday	Down

Table 4 List of names of the 30 different *wuku* in a *pawukon*

1	Sinta	7	Warigalit	13	Langkir	19	Tambir	25	Bala
2	Landep	8	Warigagung	14	Mandasiya	20	Medangkungan	26	Wugu
3	Wukir	9	Julungwangi	15	Julungpujut	21	Maktal	27	Wayang
4	Kurantil	10	Sungsang	16	Pahang	22	Wuye	28	Kulawu
5	Tolu	11	Galungan	17	Kuruwelut	23	Manahil	29	Dukut
6	Gumbreg	12	Kuningan	18	Marakeh	24	Prangbakat	30	Watugunung

from the center of the disk outwardly from Lêgi to Kliwon. It shows a spiral pattern that repeats seven times and sweeping five sectors each, indicated by solid black, solid blue, dashed-black, dashed-blue, dashed-dotted black, dashed-dotted blue, and dotted black spirals, respectively.

Although the *weton* can be calculated independently using either Eq. (1) or (2), it is also possible to propose a single congruence formula:

$$\begin{aligned} w &= k + \left\lfloor \frac{153(m+1)}{5} \right\rfloor + 15Y + \left\lfloor \frac{Y}{4} \right\rfloor + 19C + \left\lfloor \frac{C}{4} \right\rfloor + 5 \\ W &\equiv w \pmod 7 \\ P &\equiv w \pmod 5 \end{aligned} \tag{3}$$

where k, m, C, and Y are the same variables as defined for previous congruence formulas, w is a 35-day offset congruence, and W or P corresponds to the index of *dinapitu* or *pasaran* day, respectively. Each term of the congruence can be analyzed as follows:

- The variable k represents the progression of the day of the week based on the day of the month, since each successive day results in an additional offset of one.
- The operation $+\left\lfloor \frac{153(m+1)}{5} \right\rfloor$ adds the proper amount of days for each month, considering January and February as the 13th and 14th months of the previous year, respectively.
- The operation $+15Y$ adds an offset of $365 \pmod{35} \equiv 15 \pmod{35}$ days for the common, nonleap years.
- The operation $+\left\lfloor \frac{Y}{4} \right\rfloor$ adds 1 more day for the leap years since $366 \pmod{35} \equiv 16 \pmod{35}$.
- The operation $+19C$ adds $36{,}524 \pmod{35} \equiv 19 \pmod{35}$, 19 days for any regular century (a century with nonleap year).
- The operation $+\left\lfloor \frac{C}{4} \right\rfloor$ adds 1 more day for a century leap year that is divisible by 400 since $36{,}525 \pmod{35} \equiv 20 \pmod{35}$.
- The operation +5 adjusts the final offset to fit the indexes defined for *dinapitu* W and *pasaran* P after (mod 7) and (mod 5), respectively.

Let us take the same example of 8 July 1633 CE with $k = 8$, $m = 7$, $C = 16$, and $Y = 33$. Using (3), we have $w \equiv 8 + 244 + 8 + 304 + 4 + 5 \equiv 573$, $W \equiv 573 \pmod 7 \equiv 6 \pmod 7$, and $P \equiv 573 \pmod 5 \equiv 3 \pmod 5$. Hence, the 8 July 1633 CE was a

Fig. 4 An example of the Javanese calendar for December 2020 CE issued by the Kraton palace in Yogyakarta. It contains information on *Jimakir taun*, *Bakdamulud* and *Jumadilawal wulans*, *pasaran* day, *padinan* weekday, *wuku*, and *paringkelan,* among others. Each column in the wuku row lists *wuye*, *manahil*, *prangbakat*, *bala*, and *wugu*, respectively. Each column in the *paringkelan* row lists *paningron*, *uwas*, *mawulu*, *tungle*, and *aryang*, respectively. The information on *pranatamangsa* reads as "*kanem* (the sixth), 43 *dinten* (days), 9 November–21 December 2020." The text that follows *candranipun* (interpretation) says "*rasa mulya kasucian; wit woh–wohan sami mawoh, kathah bun upas mejahi taneman; peksi kuntul sami neba, nyebar winih yen lintang luku sampun katingal hing wetan*." It can be translated as follows "a noble sense of holiness; fruit trees–the same fruit grows, a lot of poisonous dew drops kills plants; heron birds are identical, spread the seed if the plowing star has been observed in the east."

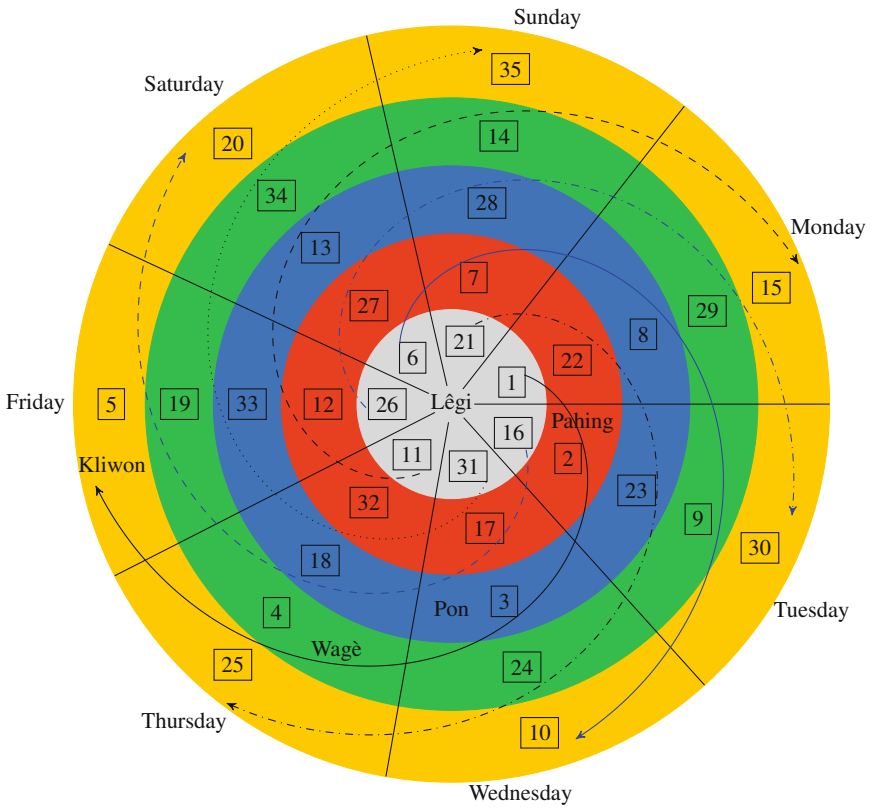

Fig. 5 A 35-day cycle of *wetonan* in the Javanese calendar. The regular Gregorian 7-day cycle is arranged clockwise from Monday to Sunday. The 5-day *pasaran* cycle is arranged from inside to outside. The white disk, red, blue, green, and yellow rings correspond to "Lêgi," "Pahing," "Pon," "Wagè," and "Kliwon," respectively

"Jemuwah Lêgi." Notice that we are able to replace both the congruence formulas (1) and (2) using our original single congruence relationship (3). Obtaining both *dinapitu* and *pasaran* days using a tabular method has been attempted by Arciniega (2020), and a *Java* application based on the Indian calendar for calculating the Javanese calendar has been developed by Gislén and Eade (2019e).

The *wetonan* cycle is especially important for divinatory systems, celebrations, and rites of passage as birth or death. Commemorations and events are held on days considered to be auspicious. In particular, the *weton* of birth is considered playing an important role in any individual personality, in a similar way as a zodiac sign does in Western astrology. The two *weton* days of future spouses are supposed to determine their background nature compatibility and are used to compute the best date of marriage using a strict arithmetic formula (Utami et al. 2019). It also figures in the timing of many ceremonies of *slametan* ritual meal and many other traditional divinatory systems (Utami et al. 2020). The eve of "Jemuwah Kliwon" is considered

particularly popular and auspicious for magical and spiritual matters (Darling 2004; Arciniega 2020).

The anniversary of Javanese birthday occurs every 35 days, so about a thousand times in a century (exactly 1043 times). For a newborn baby, the first occurrence of *weton*, i.e., aged 35 days, is named "selapanan" where the parents will cut hairs and nails of their child for the first time. For adults, the *weton* of birth is considered as an eminent day, not festive but expressing humility and blissfulness. For example, a person may fast (sometimes also the day before and the day after), stop his commercial activity, avoid taking any major decision, or simply be more generous to surrounding people through philanthropic actions such as share a blessed meal or some "jajan pasar" (early morning fresh sweet snacks from the market).

The *weton* for the birth and death of Sultan Agung is "Jemuwah Lêgi," which is also the first day of the Javanese calendar he created. This *weton* is therefore one of the recurrent noble days (see sub-subsection *Dina Mulya*) and considered as an important night for pilgrimage. Indeed, the *weton* of every King's birth is a special day; the present Sultan Hamengkubuwana X was born on 2 April 1946 CE, a "Selasa Wage." This *weton* has been chosen for his ascension to the throne, on 7 March 1989 CE. Every "Selasa Wage," the animated touristic center of Yogyakarta, Jalan Malioboro, is closed to motor vehicles, and the covered sidewalks "kaki lima," where commercial activity usually abound, are entirely cleaned.

As another especially prominent example, the present palace of Kraton Yogyakarta has been inhabited by Sultan Hamengkubuwana I and his regal suite on the "13 Sura 1682 AJ" (7 October 1756 CE), a "Kemis Pahing." In 2015, the Governor decided that every "Kemis Pahing," schoolchildren, public servants, and in particular those working in territorial services of Yogyakarta, must wear the traditional costume all day long, as a reminder of their regional culture. Merchants from traditional markets are encouraged to do the same.

3.4.4 *Wulan*

The lunar month is named a *wulan* and lasts for 29 or 30 days. There are 12 different names: "Sura," "Sapar," "Mulud," "Bakdamulud," "Jumadilawal," "Jumadilakir," "Rejeb," "Ruwah," "Puasa," "Sawal," "Dulkangidah" (or "Sela"), and "Besar." The length of each *wulan* is attributed as follows (see Table 5 and the next sub-subsections):

- "Sura," "Rejeb," "Puasa," and "Dulkangidah" are always 30 days.
- "Bakdamulud," "Jumadilakir," "Ruwah," and "Sawal" are always 29 days.
- "Sapar," "Mulud," "Jumadilawal," and "Besar" have lengths depending on the *taun* and *kurup*.

3.4.5 *Taun*

A *taun* is a cycle on 12 *wulan* and corresponds to the Javanese lunar year. There are eight different *taun* names: "Alip," "Ehé," "Jimawal," "Jé," "Dal," "Bé," "Wawu," and "Jimakir," formed by different *wulan* length sequences (see Table 5). For seven of the *taun*, the sequence alternates monotonically between 30- and 29-day lengths.

For the final *wulan* "Besar," it can be either 29 or 30 days, depending not only on the *taun* but also on the *kurup*, the 120 lunar year cycle, which has different day length sequences for the fifth *taun* "Dal." As a result, the total day length of a *taun* varies from 354 (short or normal year, named "Taun Wastu") to 355 (long or leap year, named "Taun Wuntu"), as described in Table 6:

- "Alip," "Jimawal," and "Bé" are always normal years, with a *wulan* "Besar" of 29 days.
- "Jimawal" and "Wawu" are always leap years, with a *wulan* "Besar" of 30 days.
- "Jé" and "Dal" are normal or leap depending on the *kurup.*
- "Jimakir" is a leap year for the 14 first *windu* but becomes a normal year for the final *windu* of a *kurup* cycle.

Each *taun* is assigned by a monotonic increasing number, based on the Indian calendar *Saka*. The reason was Sultan Agung decided to continue the counting from the Shalivahana era, which was 1555 at the time when inaugurating the Javanese calendar (cf. Nuraeni and Azizah 2017). Thus, the Javanese calendar began on "1 Sura Alip 1555 AJ," which corresponds to 8 July 1633 CE.

3.4.6 *Windu* and *Lambang*

Eight *taun* make a *windu* (Proudfoot 2006). Despite the variability of each *taun* length, the total length of a normal *windu* is constant since it always contains both five short and three long *taun*, which is a total of 2,835 days (about 7 years 9 months in the Gregorian/Islamic calendar). This corresponds to exactly 81 *wetonan*. This means that each "New Windu" day, dated as "1 Sura Alip," falls on the same *weton*.

Table 5 List of names of the 12 *wulan* Javanese lunar months and the associated number of days, depending on the *taun* and *kurup* (see Table 6)

		Wulan length (days)				
		Taun 1–4, 6–8	Taun 5			
No	Wulan Name	All Kurup	Kurup 1	Kurup 2	Kurup 3	Kurup 4
1	Sura	30	30	30	30	30
2	Sapar	29	29	30	30	29
3	Mulud	30	30	29	29	30
4	Bakdamulud	29	29	29	29	29
5	Jumadilawal	30	30	30	29	30
6	Jumadilakir	29	29	29	29	29
7	Rejeb	30	30	30	30	30
8	Ruwah	29	29	29	29	29
9	Pasa	30	30	30	30	30
10	Sawal	29	29	29	29	29
11	Dulkangidah	30	30	30	30	30
12	Besar	29/30	30	30	30	29
	Total (days)	254/355	355	355	354	354

Table 6 List of names of the 8 *taun* Javanese lunar years forming a *windu*, and the associated number of days, an alternate between 354 (short or normal year) and 355 (long or leap year, gray-shaded cells) days, depending on the *kurup*

No	Name	Krama	Meaning	Taun Length (days)			
				Kurup 1	Kurup 2	Kurup 3	Kurup 4
1	Alip	Purwana	intention	354	354	354	354
2	Ehé	Karyana	action	355	355	355	355
3	Jimawal	Anama	work	354	354	354	354
4	Jé	Lalana	destiny	354	354	355	355
5	Dal	Ngawanga	life	355	355	354	354
6	Bé	Pawaka	back and forth	354	354	354	354
7	Wawu	Wasana	orientation	354	354	354	354
8	Jimakir	Swasana	empty	355	355	355	355

Table 7 List of names of the four *windu* and two *lambang*

Windu name	Lambang name
Adi	Langkir
Kuntara	Kulawu
Sêngara	Langkir
Sancaya	Kulawu

There is an exception to that rule: The final *windu* of a *kurup* cycle (see the next sub-subsection) is always shortened by 1 day, with a 29 days *wulan* "Besar" during the final *taun* "Jimakir." This induces a shift in the *wetonan* cycle at each *kurup*.

Furthermore, there are four different names of *windu*: "Adi," "Kuntara," "Sengara," and "Sancaya" that compose a 32-*taun* cycle. Another cycle of 16 *taun* is combined using two different names of *windu*, called *lambang*: "Kulawu" and "Langkir." These two cycles are summarized in Table 7.

3.4.7 *Kurup*

The longest cycle in the Javanese calendar is called a *kurup*, formed by 15 *windu*, which is equivalent to 120 *taun* or 1440 *wulan* (Gislén and Eade 2019c). But the very last *wulan* of the cycle, i.e., the twelfth *wulan* "Besar" of the eighth *taun* "Jimakir" of the fifteenth *windu*, has only 29 days, so that the total length of a *kurup* is $2{,}835 \times 15 - 1 = 42{,}524$ days (about 116 years and 6 months in the Gregorian/Islamic calendar) (Rosalina 2013). The period has the same number of days as in 120 lunar years of the Tabular Islamic calendar, a rule-based variation of the Islamic *Hijri* calendar. Although the number of years and months are identical, the months are determined by arithmetical rules instead of observation or astronomical calculations.

Moreover, each *kurup* determines the following, as given in Tables 5 and 6:

- Which of the *taun* "Jé" or "Dal" has a long *wulan* "Besar."
- The sequence of *wulan* lengths in the *taun* "Dal."

Hence, the full date sequences in the calendar vary between *kurup*.

As the *weton* of the first day of a *kurup* repeats at each first day of the *windu*, a *kurup* is named using the corresponding *weton* falling on "1 Sura Alip." Table 8 lists the first five *kurup*.

Meanwhile, the Sultanate of Mataram was divided under the Treaty of Giyanti between the Dutch and Prince Mangkubumi in 1755 CE. The agreement divided ostensible territorial control over Central Java between Yogyakarta and Surakarta Sultanates. The former was ruled by Prince Mangkubumi, also known as Raden Mas Sujana or Hamengkubuwono I (1717–1792 CE), and the latter was administrated by Sinuhun Paliyan Negari, who was known as Pakubuwana III (1732–1788 CE) (Ricklefs 1974; Soekmono 1981; Frederick and Worden 1993; Brown 2004).

During the second *kurup* (1749–1821 CE), some experts realized that the Javanese calendar was still 1 day behind compared to the Islamic *Hijri* calendar. Hence, the King of Surakarta, Susuhunan Pakubuwana V (1784–1823 CE), decided to end the *Kurup* "Amiswon" in the year 1748 AJ, even though it had only been running for nine *windu* and two *taun*. So, the *taun* "Ehé" 1748 AJ, which was supposed to be a leap year, was made only 354 days, and the third *kurup* "Aboge" started on the *taun* "Jimawal" 1749 AJ. But some noticed that it would be more appropriate if the incrementation of *kurup* should have been carried out 2 lunar years before, namely on the *taun* "Alip" 1747 AJ. As a consequence of this delay, the third *kurup* "Aboge" is only 118 *taun* long. However, the Sultanate of Yogyakarta did not make a similar decision and pursued the second *kurup* normally, so that the calendar in the two concurrent regions was different during 46 years (see Table 9). On *taun* "Jimakir" 1794 AJ, the Sultan of Yogyakarta, Hamengkubuwana VI (1821–1877 CE), finally agreed and decided that the third *kurup* "Aboge" will also end with *taun* "Jimakir" 1866 AJ, reconciling the two calendars.

Table 8 List of names of the five first *kurup* Javanese 120 lunar year cycles, their short names (a contraction of the *weton* at each new *windu*, i.e., on "1 Sura Alip"), the first and last *taun*, the total amount of *taun*, and the starting dates in the Gregorian calendar

No	Kurup name	Short name	First Taun (AJ)	Last Taun (AJ)	Taun	Start date (CE)
1	Jamingiyah	A'ahgi	Alip 1555	Jimakir 1674	120	8 July 1633
2	Kamsiyah	Amiswon	Alip 1675	Ehé 1748	74	11 December 1749
3	Arbangiyah	Aboge	Jimawal 1749	Jimakir 1866	118	28 September 1821
4	Salasiyah	Asapon	Alip 1867	Jimakir 1986	120	24 March 1936
5	Isneniyah	Anenhing	Alip 1987	Jimakir 2106	120	26 August 2052

Table 9 List of dates of the second and third *kurup* in the Sultanate of Yogyakarta

No	*Kurup name*	*Short name*	*First Taun (AJ)*	*Last Taun (AJ)*	*Taun*	*Start date (CE)*
2	Kamsiyah	Amiswon	Alip 1675	Jimakir 1794	120	11 December 1749
3	Arbangiyah	Aboge	Alip 1795	Jimakir 1866	72	16 May 1866

The fourth and present *kurup* "Asapon" is planned to last a normal length of 120 lunar years and will end on "29 Besar Jimakir 1986 AJ," which is 25 August 2052 CE. The following day will start the fifth *kurup* "Anenhing" ("Alip Senen Pahing") on "1 Sura 1987 AJ Alip," but the sequence of leap years has not yet been decided, so it is formally impossible to calculate the exact *dina*, *wulan*, and *taun* for such a distant future date. Nevertheless, there is no obstacle with other strictly monotonic cycles such as *weton*, *wuku*, and *windu*.

3.4.8 *Dina Mulya*

Dina mulya are the noble days in the Javanese calendar. Except for the "Siji Sura" which is the new lunar year and falls on the first day of the first *wulan* every *taun*, others are associated with a specific *weton* and specific *taun* or *wuku* (see Table 10).

3.5 Computer Implementation of the Javanese Calendar

The computation of the full Javanese calendar has been implemented using *GNU Octave*, a Matlab®-compatible scientific language with a single function "weton.m" (Beauducel 2020c). When using a computer, however, the determination of the weekday or *pasaran* day from a date in the Gregorian calendar does not require the congruence formula (3). In fact, most computer languages are able to calculate the exact number of days that last from any reference date, correctly taking into account leap years. In the case of the Javanese calendar, the linear timeline will be the number of days counted from 8 July 1633 CE, which falls on "Jemuwah Lêgi 1 Sura Alip 1555 AJ Jamingiyah," the first day of the first *kurup*. Using that facility, calculation of the 7-day week cycle can be made by a simple modulo 7, the *pasaran*

Table 10 List of the noble days *dina mulya*

Dina Mulya	Weton	Wuku	Dina	Wulan	Taun	Occurrences
Siji Sura	–	–	1	Sura	–	1 every 354/355 days
						(new lunar year)
Aboge	Rêbo Wage	–	–	–	Alip	10 during the *Taun*
						Every 7/8 years
Daltugi	Sêtu Lêgi	–	–	–	Dal	10 during the *Taun*
						Every 7/8 years
Kuningan	Sêtu Kliwon	Kuningan	–	–	–	Every 210 days
Hanggara Asih	Selasa Kliwon	Dukut	–	–	–	Every 210 days
Dina Mulya	Jemuwah Kliwon	Watugunung	–	–	–	Every 210 days
Dina Purnama	Jemuwah Lêgi	–	–	–	–	Every 35 days

cycle by a modulo 5, the *wetonan* cycle by a modulo 35, and the *pawukon* cycle by a modulo 210 functions. Moreover, since any modern digital calendar is able to set a periodic event, a specific *weton* date repeated every 35 days will smoothly give the corresponding *wetonan* cycle over the whole calendar.

On the other hand, the computation of *dina*, *wulan*, *taun*, *windu*, and *kurup* is more complicated since the exact sequences vary throughout history following human decisions, making these cycles neither exactly cyclic nor monotonic. Hence, the proposed computing strategy is to construct, for each *kurup*, a *windu* table as a 8×12 matrix of rows *taun* versus columns *wulan*, containing the day length of that specific *wulan*. This matrix is repeated 15 times to form a complete *kurup*, or less for the second and third *kurup*. Then, all the matrices are concatenated. The cumulative sum of this table elements, in the row order, gives the total number of days that last from the origin at the beginning of each lunar month, and can be compared to the linear timeline described above. Thus, a simple "table lookup" function will give the corresponding *kurup*, *windu*, *taun*, and *wulan* indexes, and the *dina* will be given by the remainder.

We have discussed earlier that the Javanese months *wulan* adopt the lunar month, and this is closely related but does not necessarily correspond exactly with both the Islamic *Hijri* and Tabular Islamic calendars. For the former, the length of the months, whether 29 or 30 days, depends on the moon's visibility or weather conditions. The latter, however, adopted a convention of 30-day months for odd-numbered months (including the 12th month in a leap year) and 29-day months for even-numbered ones. On the other hand, the number of days in a Javanese *wulan* depends on a complex combination of *taun* and *kurup*, as we observed in Table 5. As a consequence, discrepancies are inevitable between the Javanese and Islamic calendars. The two calendars correspond exactly only during the first *kurup*, i.e., the first 120 lunar year cycles. Table 11 displays the corresponding Gregorian dates of the Javanese and (Tabular) Islamic New Year, 1 Sura and 1 Muharram, respectively, for the past half century. While more than 85% of the dates match, we observe that, in general, a 1- or 2-day gap may occur between the two calendars.

The Gregorian dates in Table 11 can be obtained using the function "weton.m" by typing in

```
>> weton('all',' 1 Sura')
>> weton(datenum(1633,7,8):now,' 1 Sura')
```

The two syntaxes are strictly equivalent. The output spits out 400 items from 1555 AJ to 1954 AJ. Note that the space before "1" is important, else, 11 and 21 Sura will be spitted out as well. Additionally, it is also essential to introduce the time window from 8 July 1633 CE onward as the dates without this will be considered invalid in the Javanese calendar. Here are other examples (recall Kartini's birthdate):

```
>> weton(1:now,'28 Bakdamulud 1808')
Error using weton (line 247)
Some dates are invalid (before 08-Jul-1633)

>> weton('all','28 Bakdamulud 1808')
```

Table 11 Examples of the Javanese and (Tabular) Islamic New Year for the past 52 years and their corresponding Gregorian dates. The bracketed (6) December 2010 was the observed date

Javanese year	Gregorian date (CE)	Islamic year	Gregorian date (CE)
1900 AJ	30 March 1968	1388 AH	31 March 1968
1906 AJ	24 January 1974	1394 AH	25 January 1974
1914 AJ	29 October 1981	1402 AH	30 October 1981
1922 AJ	3 August 1989	1410 AH	4 August 1989
1927 AJ	11 June 1994	1415 AH	10 June 1994
1930 AJ	8 May 1997	1418 AH	9 May 1997
1935 AJ	16 March 2002	1423 AH	15 March 2002
1944 AJ	8 December 2010	1432 AH	(6) 7/8 December 2010
1951 AJ	23 September 2017	1439 AH	21/22 September 2017
1954 AJ	20 August 2020	1442 AH	19/20 August 2020

```
Senen Pahing Langkir 28 Bakdamulud 1808 AJ
Be Adi Langkir Arbangiyah (Aboge), 21 April 1879 CE

>> weton(1879,4,21)
Senen Pahing Langkir 28 Bakdamulud 1808 AJ
Be Adi Langkir Arbangiyah (Aboge), 21 April 1879 CE
>>
```

Observe that the last two distinct inputs produce identical outputs. In the Islamic *Hijri* calendar, 21 April 1879 CE corresponds to 28 Rabi'ath-Thani 1296 AH. More details of the Islamic calendar and its relationship with the Gregorian calendar are beyond the scope of this chapter. Interested readers may consult Proudfoot (2006); Cohn (2007); Reingold and Dershowitz (2018), and the references therein.

4 Discussion and Epilogue

4.1 Javanese View of Time

Different from other calendars where the calculation is often based mainly on the movement of celestial bodies, such as the Sun, the Moon, and the stars, the elements of the Javanese calendar are composed of several cycles, including the solar-based Gregorian and lunar-based Islamic calendars. The Javanese people have a different perspective on time, for which some of these cycles are not all related to the movement of the celestial bodies or seasonal changes, such as the 5-day cycle *pasaran*, 35-day cycle *wetonan*, and 210-day cycle *pawukon*. This could be compared with the 260-day cycle *Tzolkin* in the Maya calendar (Jenkins 1994; Rice 2007; Cohn 2007; Ascher 2002). On the other hand, *dina*, *wulan*, *taun*, *windu*, and *kurup* correspond to the familiar cycles we encounter in other ancient and modern calendars, i.e., daily (lunar), monthly, yearly, 8-yearly, and 120-yearly cycles, respectively.

Thanks to its geographical location, where the island of Java is only less than 1000 km from the Equator, the change of seasons should be interpreted differently from the one in the subtropical regions. The climate tends to be relatively even year-round. There is only a slight variation between daylight hours, sunrise, and sunset throughout the year. For example, the longest and shortest daylights during the southern hemisphere summer (December) and winter (June) solstices in Yogyakarta (7.78° S, 110.37° E) are 12 hours and 38 minutes and 11 hours and 43 minutes, respectively (Beauducel 2020b). Although one could hardly notice this 1-hour difference over the 6-month period, Javanese residents do notice the difference between the time of sunlight and sunset. The morning civil twilight, when the geometric center of the Sun is 6° below the horizon, begins at 05:30 when the Sun reaches the Tropic of Cancer in June, but this morning twilight can be observed before 05:00 when the Sun touches the Tropic of Capricorn in December.

There are neither significant events during these both solstices nor during both equinoxes among the Javanese community. For the people who live in subtropical regions, these astronomical events can be considerably important and mark some significant events, both chronologically as well as culturally. For example, the traditional East Asian lunisolar calendars divide a year into 24 solar terms *jiéqì* (節氣). Traditionally, they celebrate the *Dōngzhì* (冬至) festival during the winter (December) solstice on one of the days between 21 and 23 December, where people make and eat the soup ball *tāngyuán* (湯圓), made from glutinous rice flour and served in a hot broth or syrup.

Nonetheless, we would not interpret that the changes of season in Java are completely absent. The following subsection briefly discusses another "calendrical" system uniquely designed for the Javanese climate.

4.2 *Pranatamangsa* Revisited

Pranatamangsa means "the regulation or arrangement of the season." It is a "calendrical" system used not only for agricultural activities among rural peasants in Java with two millennia of history but also for fish catching and capturing among Javanese fishermen. Thanks to the classical and regular seasonal rhythms, the farmers and fishermen were able to conduct and organize their activities productively using this "season keeper" (Daldjoeni 1984; Hidayat 2000).

The *pranatamangsa* calendar is arranged to fit with the solar calendar of 365- or 366-day annual period, but the length of each period (*mangsa*) is unequal, which ranges from 23 to 43 days. The number of days exhibits a symmetric pattern between the first and second semesters. Coincidentally, the 1st, 2nd, and 6th *mangsa*, and hence the 12th, 11th, and 7th *mangsa*, have prime numbers 41, 23, and 43, respectively as their lengths of days. The cycle starts at the beginning of the dry season on 23 June, around the winter solstice in the southern hemisphere (Van Den Bosch 1980; Daldjoeni 1984). Table 12 lists the names of *mangsa*, each of its period in *pranatamangsa*, and the four main seasons.

Table 12 *Pranatamangsa* at a glance

No.	Starting day	Name of *mangsa*	Length (days)	Season
1	23 June	Kaso	41	*Kemarau* or *Ketiga* (Dry season)
2	3 August	Karo	23	
3	26 August	Katelu	24	
4	19 September	Kapat	25	*Labuh* (Transition; beginning of rainy season)
5	14 October	Kalima	27	
6	11 November	Kanem	43	
7	23 December	Kapitu	43	*Penghujan* or *Rendheng* (Wet season)
8	4/5 February	Kawolu	26/27	
9	2 March	Kasanga	25	
10	27 March	Kasadasa	24	*Maréng* (Transition; ending of rainy season)
11	20 April	Désta	23	
12	13 May	Saddha	41	

When the length of the 8-month *Kawolu* is 26 days, the year is a common year or *wuntu*. When a year becomes a leap year or *wastu*, *Kawolu* will have 27 days. According to the most popular climate classification system, the Köppen-Geiger scheme, the island of Java features both tropical rainforest and monsoon climates, i.e., Af and Am, respectively (Beck et al. 2018, 2020). Thus, dry and wet seasons occur intermittently throughout the year. However, as we observed in Table 12, there are two seasons of *Labuh* and *Maréng* that serve as a transition from one distinct season to another (cf. Kristoko et al. 2012; Zaki et al. 2020).

There are several of future implications of the *pranatamangsa* system. First, due to climate change and global warming, seasonal rhythms tend to be irregular than what they used to be in the past. Second, with the advent of technology, the historically twice harvest-time annually may be extended to more than two times. Third, with the regional and global industrialization, many farmers abandoned or sold out their lands, worked in factories, and relocated to urban areas.

The topic of *pranatamangsa*, these aforementioned implications, and other possible ramifications are separate topics in themselves. An in-depth discussion is beyond the scope of this chapter and should be covered elsewhere. We wrap up this section and chapter with the following conclusion.

4.3 Conclusion

In this chapter, we have discussed the cultural, historical, and arithmetic aspects of the Javanese calendar. Along with the internationally acknowledged Gregorian and the majority-embraced religiously Islamic *Hijri* calendars, the Javanese calendar has its unique place in the hearts of many Javanese people in Indonesia as well as Javanese diaspora overseas. Although many Javanese people have adopted modern

lifestyle, the Javanese calendar is still utilized in various daily affairs, including to choose the best possible time for arranging a wedding day.

While determining the day of the week for any given date can be computed using Zeller's congruence algorithm of modulo 7, the *pasaran* day of the Javanese calendar can be calculated using a new congruence formula of modulo 5. Additionally, we have also proposed a unique and combined congruence formula for calculating both the day of the week and *pasaran* day for any given date in the Gregorian calendar. Furthermore, using a computer program *GNU Octave* "weton.m" (Beauducel 2020c), all the cycles of the Javanese calendar, i.e., *wetonan*, *wuku*, *wulan*, *windu*, *lambang*, and *kurup* can also be determined straightforwardly.

Dedication NK would like to dedicate this chapter to his late father Zakaria Karjanto (Khouw Kim Soey, 許金瑞) who introduced and taught him the alphabet, numbers, and the calendar in his early childhood. Karjanto senior was born in Tasikmalaya, West Java, Japanese-occupied Dutch East Indies on 1 January 1944 (Saturday Pahing) and died in Bandung, West Java, Indonesia on 18 April 2021 (Sunday Wage).

Acknowledgment The authors would like to thank Matthew Arciniega (Vortx, Inc., Ashland, Oregon, United States of America) for sharing the contents of his old website and Roberto Rizzo (University of Milano–Bicocca, Italy) for pointing to the article written by Proudfoot (2007). FB warmly thanks Alix Aimée Triyanti for her cultural influence and inspiration, and all his Javanese friends for their enthusiastic support.

Abstract

Mathematicians used to be highly invested in the study of the history of their own field, but their voice in historiographical discussions has diminished in influence in the past century. One prominent narrative paints this as a justified fall from grace: mathematicians wedded to present mathematical values looked at the past with prejudiced eyes, whereas a new generation of historians were better able to appreciate the past proper, in its own terms. But the best internalist mathematical historiography of old needed no such external corrective. It was already committed to avoiding presentism and anachronism, for reasons that were not in opposition to mathematical values but rather derived directly from a positive vision of the role that history could play in the mathematical community. In this vision, a historical understanding of how a field developed is a proxy for first-hand research experience in that field. It follows that it is essential for historical accounts to thoroughly convey the scope and limitations of alternative conceptions and approaches, including dead-end developments, since this is precisely what sets the critical knowledge gained by first-hand research experience apart from the doctrinal knowledge gained merely from a textbook. Hence, from this point of view, presentist historiography is not the natural outlook of the mathematician, but rather a direct antithesis of the mathematician's most fundamental

reason for studying history. To study past mathematics precisely as it appeared to active researchers at the time is not foreign to the mathematician, but a direct corollary of the mathematician's core conviction that only those with first-hand research experience in a field of mathematics truly understand it. A sophisticated internalist historiography derived from these ideals was articulated to a greater extent in the past than is commonly recognized today. By going back to its roots, the mathematician's historiography could revive some of the virtues that have been neglected in recent years.

Historiography · Internalism · Presentism · History of the history of mathematics

1 History of the Relation Between History and Mathematics

The "right" way to study history depends on what one wants historical inquiry to achieve. Historiographic practices – such as using modern mathematical concepts when analyzing past thought – are not inherently good or bad, but can only be judged relative to the intended goals of historical scholarship. To be able to say *how* we should do history, we must therefore first understand *why* we do history at all. So to understand the mathematician's relation to history, we must first ask ourselves: What purposes does history serve to the mathematical community? To answer this question, it will be instructive to look at some snapshots of how the relationship between mathematics and history has evolved over time.

In a way, mathematics can be regarded as inherently ahistorical. "Mathematics is . . . under the spell of the belief in its objective nature. . . . Motives [for undertaking particular investigations] are often more hidden than revealed" since "it is not the style of mathematics to speak about subjective things." But experience shows that the Platonic dream of achieving disembodied perfection is alas "a chimera." By contrast, Aristotle "laid out with the greatest care how thinkers before him thought about all the matters he was dealing with, and with this kind of comparative study saw how he might make a better start towards obtaining general norms." In mathematics, as much as in any other field, this suggests the value of "didactical diagnosis and therapy, on the basis of historical analyses, where these analyses serve only to turn one's attention in the right direction." History "can steer one's attention to differences and conceptual distinctions which would never come to mind by way of direct, abstract considerations." (Toeplitz 1926/2015, 308–309).

The "Platonic" perspective is thus absolutist. It aims for a state of finality and timeless perfection. History is antithetical to its purposes: it aims precisely to transcend that element of human fallibility with which past thought is contaminated. The "Aristotelian" perspective, by contrast, does not aspire to deny or erase the situatedness of knowledge. Instead, it sees past and present thought as inherently intertwined. This conflict remains at the heart of history of mathematics. Mathematicians dream of "the perfect embodiment of immutable laws," while historians are

all but defined by a "moral commitment to recording and remembering the earthly, perishable detail"; truly, "our muses … haunt us with their divergent demands" when we try to do justice to both of these perspectives (Guicciardini 2018, 148–150).

Aristotle's disciple Eudemus wrote a history of geometry – the first known treatise on the history of mathematics. The work itself is no longer extant but its overall outlook can be surmised from surviving fragments and references. Eudemus seems to have envisioned his history of geometry being used as a starting point for methodological reflection, similar to how Aristotle engaged with the views of earlier philosophers to articulate his own systems. In part, Eudemus seems to have aspired to present a kind of historical raw data to serve as the basis for such reflection, but he was evidently not shy to add interpretative analysis as well. Thus, his approach is in part comparative rather than purely chronological; he passes judgement on past mathematics, and crafts a narrative of cognitive evolution toward higher states of knowledge, culminating in the mathematics of his own time (Zhmud 2017).

The Aristotelian perspective, then, emphasizes history but treats it instrumentally. History is not expounded for its own sake, but as part of an articulation and analysis of present thought in the field. Mathematical authors of all ages have found it useful to deploy history in such a role. Lagrange and Bourbaki, for instance, incorporated extensive historical notes in treatises where they advanced systematizations of previous knowledge and reconceptualizations of mathematical fields.

This way of utilizing history to inform a systemic survey of a body of knowledge was perhaps especially natural in classical antiquity, when mathematics and philosophy advanced rapidly and were fundamentally transformed. Authors further removed from creative frontiers may take a more antiquarian approach to historical material. One may think, for instance, of how Eutocius, in the sixth century, meticulously catalogued a dozen different cube duplications by various past mathematicians (Netz 2004, 273–306) while showing few, if any, aspirations beyond simply amassing the material.

In the seventeenth century – another vastly creative and transformative era – it was again à la mode to situate research contributions in a potted historical narrative. Major works such as Descartes's *Géométrie* (1637), Wallis's *Algebra* (1685), and Newton's *Principia* (1687) all open by immediately characterizing their projects relative to a particular interpretation of what "the ancients" had done in the subject.

The seventeenth century had no time to produce any full-scale histories of mathematics. The eighteenth century took up this task with enthusiasm, producing several sprawling histories packed with information. After the creative explosions of the seventeenth century, the direction of mathematical research was now on a relatively stable and monotonous trajectory. Once again history was no longer needed to help envision major reconceptualizations of the field, but more to keep track of a growing body of accumulated work. This also fit with the fashion of the day in the sciences and intellectual work generally, which embraced massive encyclopedic surveys, cabinets of curiosity overloaded with assorted knick-knacks, and Baconian accumulation of empirical raw data (Goldstein 2008). Indeed, Montucla's *Histoire des Mathématiques* (1758) repeatedly references Francis Bacon in its preface.

As biology focused on gathering any and all specimens and sorting them into descriptive taxonomies, so history of mathematics was likewise preoccupied with assembling masses of material (Bullynck 2016, 10). "Lacroix's history of eighteenth-century analysis can be seen as the culmination of the eighteenth-century tradition of narrative mathematics. Coverage, rather than coherence, was his major goal." (Richards 2006, 707). Similarly, "Kaestner's four-volume *Geschichte der Mathematik* (1796–1800) is essentially a description of the author's large mathematical library, so that a malicious reviewer could dispatch Kaestner with the words that he seems to have written his work on the book ladder." (Stäckel 1900, 252). Historical works of this time largely assume that direct acquaintance with primary sources is a feasible next step following a standard education from current textbooks (Dauben and Scriba 2002, 88), so that the task of the historian is to survey and summarize rather than to interpret or explain.

As the quantity of mathematical publications grew rapidly, history answered "a need amongst mathematicians for information about who produced which piece of mathematical knowledge when"; in particular, "it would be one task of the historian of mathematics to attribute mathematical credit to the right person." (Schneider 1992, 620–621). "The preoccupation at this early stage in the history of the history of mathematics was an almost exclusive interest in 'priorities' – in mathematical 'firsts'." (Dauben 1999, 4).

Such "firsts"-oriented historiographies effectively assume that the development of mathematics is cumulative rather than conceptually transformative. Only then is a one-to-one matching of each tenet of present mathematics with some past work possible. Because of the conceptual stability of eighteenth-century mathematics, this view was sustainable for a while. But in the nineteenth century, it was quickly becoming obvious that mathematics was no longer progressing purely by adding knowledge, but by systematically reorganizing entire theories in ways that made much earlier work obsolete. Thus, the enterprise of encyclopedic "firsts"-oriented history lost its purpose. "In the current state of analysis we may regard these discussions [of past mathematics] as useless, for they concern forgotten methods, which have given way to others more simple and more general," Lagrange observed in 1806. Lacroix made a similar point in his *Essais sur l'enseignement* (1805): "to educate students in the ways of [historical] authors, even the most celebrated of them, must cease because since they wrote, the science has made progress which has completely changed the connections of the propositions and often their language." (Richards 2006, 709–710).

In response, the nineteenth century saw a revival of fortunes of the Platonic ideal of mathematics as historically disembodied perfect reason. Mathematical exposition should follow "purely rational principles," Lacroix observed as a contrast to his rejection of the utility of historical perspectives. Cauchy, setting the tone for decades to come,

> reconceptualized and restructured mathematics to be rigorous rather than narrative. . . . Cauchy's definitional precision effectively separated mathematics from the rest of human

> thought. . . . Cauchy clearly recognized this. The separation of mathematical argument from human reason was essential to his rigorous program. (Richards 2006, 700, 712)

This vision of mathematical rigor left little or no place for the relevance of history to mathematical understanding.

The end of the nineteenth century saw of resurgence of interest in the history of mathematics. The new generation noted how they had to break free from the anti-history sentiments widespread in the mathematical community:

> When I began to study mathematical and historical research about 30 years ago, most of the mathematicians I came into contact with thought that thorough research in this field was a waste of time, so that such work should not be considered meritorious but rather reprehensible. Now, however, such a view may be regarded as a curiosity, and most of my colleagues in the field agree that that the history of mathematics is not only relevant in itself, but also has great educational value for the study of mathematics, and that the understanding of it can often be useful even for the advancement of science. (Eneström 1900, 4)

This increased status of history can be attributed to internal mathematical developments (Stäckel 1900, 251): foundational mathematical research in the late nineteenth century undermined the simplistic notion of an absolute (and ahistorical) standard of rigor and truth, thereby reversing the rationale for anti-historicism of rigorization movements such as that of Cauchy.

History also gained new appeal as mathematics fragmented into more specialized subfields. Specialized research mathematics can often only be understood by one's closest colleagues. History, by contrast, provides a rich store of mathematical material that is accessible and interesting to all mathematicians. Therefore "one of the advantages in the study of the history of mathematics is to bring colleagues together" (Struik 1980, 24) around shared experiences and interests. Thus it became a selling point of the field that "only historical thinking can form a counterweight against the much-lamented specialisation" that was becoming more and more marked in contemporary research (Neugebauer 1927, 44).

Increased specialization also meant that that mathematicians more frequently found themselves teaching or engaging with mathematical theories with which they had little direct experience in their own research and personal mathematical practice. In such cases, there would often be an abundance of solid sources for picking up the necessary technical content, but these could often not convey the same sense of the lay of the land that an insider with hands-on experience in the field would have. History can be a substitute for this kind of first-hand experience. Retracing the thought of the pioneers of the field is a digest surrogate for personal experience. Without this perspective of what a field looks like to the active researcher, it is easy to misjudge the purpose and importance of ideas and the connections between them. "The historical investigation of the development of a science is most needful, lest the principles treasured up in it become a system of half-understood prescripts, or worse, a system of prejudices." (Mach 1883/1919, 255).

It was commonplace to argue that students of mathematics "must naturally follow the same course of development on a smaller scale, that the science itself has taken

on a larger" (Klein 1896, 248). In other words, mathematics education should follow the biological principle that key stages in the evolutionary history of a species are often recapitulated in the fetal development of each individual organism (Cajori 1896, v; Poincaré 1899, 159; Klein 1932, 268). Another sign of the unity of research and educational work envisioned at the time is that, in the nineteenth century, "in a remarkable number of cases research work in mathematics [was] stimulated by a perceived educational need: the new theory appeared more in textbooks and lecture notes than in ordinary papers" (Grattan-Guinness 1990, 155). Lectures by, for instance, Monge, Cauchy, and Weierstrass spun off entire research programs. History and teaching had a natural place in mathematics: the educator, the historian, and the research strategist shared a common goal in understanding the gist of existing work in a field, the scope and limitations of its methods, and the connections and motivations of its key ideas.

The early twentieth century was a golden age – "the most distinguished period" (Grattan-Guinness 1990, 150) – for the status of history in the mathematical community. At its peak as a world-leading research center, the Mathematical Institute at Göttingen offered a rich range of advanced courses on history of mathematics taught by leading mathematicians (Toeplitz 1926/2015, 303; Tobies 2019, 412–413). In Frankfurt, top mathematicians and students came together for in-depth seminars on a range of specialized topics in history of mathematics every semester from 1922 to 1935 (Siegel and Lenzen 1979, 224–226). Affordable editions of important primary sources in the history of mathematics aimed at the learned public sold well, as a historical perspective on mathematics was seen as befitting "every educated reader" (Dauben and Scriba 2002, 127, 130–131). History was pursued as "an honorable thing to do," and not for dogmatic ideological reasons such as an "attempt to legitimize the new mathematics by identifying it with the core element of the tradition" (Gray 2008, 372).

In this context, a new generation of mathematical historians emerged. But it was a rude awakening for the mathematical community to realize the ramifications of its neglect of history in the preceding decades. When mathematicians had turned their back on the history of mathematics in the nineteenth century, philosophers and cultural theorists had picked up the slack. The old eighteenth-century encyclopedic histories of mathematics, "understood only by professional mathematicians" (Dauben and Scriba 2002, 13), did not meet the needs of the nineteenth century. Mathematicians had abandoned history just as the transformative developments of the early nineteenth century created a need for higher-order narratives offering prominent interpretative syntheses (Bullynck 2016). Authors from humanistic fields had been happy to fill this void with works that integrated history with grand epistemological or sociocultural theories. But excessive enthusiasm for such macro perspectives had led to factual errors as well as neglect and ignorance of sources (Brentjes 2016, 50; Høyrup 2016, 65; Dauben and Scriba 2002, 19).

The new generation of mathematical historians were keen to position themselves in opposition to the excesses of the humanistic histories of the nineteenth century. An instinctive aversion to any attempts at grander "synthesis" was a natural part of this reaction (Neugebauer 1951/1969, viii; Rowe 2016, 139), as was a greatly increased

emphasis on primary mathematical sources (Dauben and Scriba 2002, 135). Propagation of errors and lack of scholarly rigor was also seen as a major threat to the status of historical scholarship (Eneström 1912/13). The fear was often expressed that mathematicians in particular might see history as an unserious field.

> If mathematicians who are not historians see that even highly praised mathematical-historical works contain a large number of unreliable data and uncritical statements, they easily get the impression that the history of mathematics does not yet exist as a real science, and that no special knowledge or training is needed to write a mathematical-historical work. If they then have any reason to want historical articles on certain mathematical subjects, it may easily happen that they turn to persons for this purpose who lack certain very important prerequisites for truly scientific research in the field of mathematics and history. (Eneström 1908/09, 9)

Moritz Cantor's multivolume *Geschichte der Mathematik* (1877–1901) became a focal point for these concerns, and stood as a symbol for the style of history that had resulted when mathematicians neglected the field (Lützen and Purkert 1994, 1–7).

> Its total lack of mathematic competence as well as its moralizing and anecdotal attitude seriously discredited the history of mathematics in the eyes of mathematicians, for whom, after all, the history of mathematics has to be written. . . . Had [Cantor] studied the texts themselves, he would have avoided countless misinterpretations and inaccuracies which have become commonplace. (Neubegauer 1956)

Attacks on Cantor's history such as this were reiterated again and again in the early twentieth century, as the new generation of mathematical historians saw this as a crucial contrast defining their distinctive historiography.

The efforts to rehabilitate history of mathematics in the eyes of mathematicians and revive its status as an integral part of mathematics itself in the early twentieth century were successful. But this was soon disrupted by war and fascism. When the continental model of university and PhD education was exported to other parts of the world, great emphasis was placed on the importance of leading students to the frontiers of original research (Turner 2020, 58). This had indeed been one element that set the PhD system and academic culture at the world-leading continental universities apart from the wider geographic range of academic institutions that now quickly rose to greater research prominence. However, broader intellectual elements of the tradition were largely discarded in this process. The outlook that sophisticated historical and philosophical awareness is essential even for a well-rounded understanding of mathematics itself had won considerable traction at leading continental institutions, but emerging academic institutions building up their rapidly expanding research infrastructure did not continue this trend.

Hence a new generation of more narrowly trained research specialist mathematicians emerged. Insofar as they addressed history, they did so with less humility, less historical and philosophical awareness, and greater overconfidence in the superiority of their own style of mathematics. In this way, they exposed themselves to critiques from historians. It became easy for historians coming from humanities disciplines to

dismiss mathematicians dabbling in history as naively writing "without consideration of basic questions of historiography" (Grattan-Guinness 1990, 157). A standard narrative emerged, alleging that the second half of the twentieth century brought "a new and more sophisticated historiography," whereas older work on the history of mathematics was commonly marked by rampant presentism and simple-minded priority questions. In older work, allegedly,

> the effect was to "explain" the subject in anachronistic concepts and terminology, to select topics for study only insofar as they had a connection to more recent developments, and to praise or damn these efforts on the basis of whether they anticipated (took a step toward) the current state of mathematical knowledge.

In the "new historiography," by contrast,

> the focus is on understanding the thought of the period, independent of whether it is right or wrong by today's account. The historiography is more philosophically sensitive in its understanding of the nature of mathematical truth and rigor, and it recognizes that these concepts have not remained invariant over time. (Kitcher and Aspray 1988, 24–25)

This narrative was very agreeable to a new generation of historians of science who "wanted independence from the sciences" and sought "to supply their own agenda for their discipline rather than accepting that of the scientist" (Lightman 2016, 2). In this way, they could characterize their own historiography as an objective improvement of standards, and the historical outlook of mathematicians as inherently naive. This basic framing remains fundamental in historiographical discussions to this day (even though, to be sure, actual professional affiliations are more fluid and complex than a neat terminological division into "mathematicians" and "historians" might suggest; Goldstein 1995, 7).

Historical circumstances facilitated over-universalization of this narrative. The single-minded focus on specialized research in the twentieth-century growth spurt of academic institutes of mathematics, often in places that had little tradition of intellectual history, produced a neglect of historical appreciation among mathematicians. What could better be regarded as a legitimate critique of this contingent circumstance has instead all too often been perceived as proof of an intrinsic fault inherent in any internalist-mathematical approach to history.

In the early twentieth century, history was a notable presence in elite mathematical culture. Leading mathematical historians were deeply anchored in this culture rather than coming from separate academic departments. This state of affairs was driven by a deeply felt conviction in the mathematical community of the rich and multifaceted ways in which history can be of integral value to the mathematical enterprise. This era set out the beginnings of what may be called a critical internalist historiography of mathematics.

History was not as central to subsequent mathematical generations. Having lost touch with the intellectual roots that informed the turn-of-the-century vision of history and its purpose within mathematics, many mathematicians reverted back to

the more simplistic views of history that had been commonplace in earlier centuries. This may be called a presentist internalist historiography of mathematics.

Critical internalism emphasized the parallels between historical understanding and creative mathematical research. The same skill of grasping the forces that have shaped a field is equally essential in historical scholarship and in the context of formulating an informed and forward-looking mathematical research program of one's own. To learn a new field is to reenact the course of its evolution in one's own mind; to digest the argument of a past work of mathematics is to feel precisely that tension between research goals and the tools available that the working mathematician of that time struggled with: this is an analog in the domain of historical scholarship of the view that the research-active mathematician of today has an authoritative claim to understanding of their field qualitatively different from any dilettante outsider account, no matter how descriptively and factually accurate. In this way, history is key to develop understanding of new fields, and to form critical judgements about it based on independent thought.

Presentist internalism, on the other hand, does not accord history any such parity of authority with present research. Critical and presentist internalisms are both committed to the ideal of active research experience as the sine qua non of mathematical understanding. But critical internalism interprets this ideal inclusively, and sees history as a way to effectively, in distilled form, obtain more of that precious form of understanding than we could have time for through conventional personal research. Presentist internalism demotes history from this perch. By conceiving the ideal of the primacy of active research understanding narrowly, to include current mathematical research only, it cuts off the critical internalist rationale for seeing history as an integral part of mathematical thought itself.

It is unfortunate that these two very different approaches are so often conflated. Much historiographical discussion in the second half of the twentieth century was framed in terms of a fundamental dichotomy between internalist-mathematical approaches on the one hand and properly historical approaches on the other. Critiques of the internalist-mathematical approach have naturally focused on the faults of presentist internalist historiography, under the mistaken impression or insinuation that this undermines internalist approaches altogether. The above contextualization suggests instead that, rather than attributing historiographic naiveté to inherent characteristics of the mathematical psyche, a better way to understand the mathematician's relation to history is in terms of the purposes history can serve to the mathematical community (Barany 2020, 1077).

2 The Role of Present Mathematics in Historiography

The mathematician's way of doing history is often portrayed as historiographically flawed in that it distorts past thought through the use of anachronistic perspectives and presentist interpretative biases. Indeed, it is often suggested that it was not until historians took over the field from mathematicians in the latter half of the twentieth

century that this rampant problem was recognized and cured (Unguru 1975; Rowe 1996, 10).

However, this diagnosis applies only to presentist internalism. Far from being inherent in any internalist approach, anachronism and presentism were strongly condemned by the critical internalists, long before they became a fault line of twentieth-century historiographic debates. Nesselmann, who studied mathematics under Jacobi before turning to history, put it clearly long ago:

> Nothing is more usual and natural when reading ancient works than our substituting the standpoint of the ancient authors with our own, … [so that] it is one of the most difficult tasks of the historian to understand and convey the conceptual background not only of each author, but also of each period of time in its individual character, and at the same time to keep the modern viewpoint in mind, without lifting the ancient author from his peculiar sphere of thinking into our present one. (Nesselmann 1842, 37–38; Smadja 2015, 229)

The same point was repeated over and over again in the critical internalist context.

> There is nothing more common and natural, especially when reading older works, than to substitute one's own point of view for that of the author, and to take for granted that the knowledge and insights we are familiar with are also taken for granted by that author, and to 'read into' him things he never thought of. It is therefore absolutely necessary to distinguish clearly the conclusions drawn from the words of an author from his own expressions. (Stäckel 1900, 255)

This strong rejection of anachronism and presentism was no mere lip service, but a fundamental recognition that these historiographic vices were in direct conflict with several of the core purposes the critical internalists intended history to serve in the broader landscape of mathematical thought.

The critical internalist ideal was that of "truly historical thinking united with personal research activity [in mathematics]." "Somewhat like history of philosophy," the history of mathematics must combine the genuinely historical with the "spirit" of research in the field itself. If it does, "even the purely professional mathematician would stand to gain from engagement with it"; if not, it will be relegated to "an entirely meaningless separate existence." (Neugebauer 1927, 39, 44). It is precisely because critical internalist history of mathematics intends to make a genuine contribution in the domain of actual mathematical thought that it must not be subservient to modern mathematics. For if historical scholarship merely passively mirrors the values of modern mathematics, it would be redundant to mathematicians and hence doomed to a "meaningless separate existence" in their eyes. Genuinely historical scholarship, on the other hand, could make relevant contributions to the mathematician by putting existing conceptions in an unexpected light, and to uncover and clarify illuminating connections between them, which is exactly what new research mathematics does.

The value of history for obtaining a form of understanding somewhat analogous to that gained through active research became all the more relevant as specialization increased. The more mathematics grew, the more mathematicians found themselves

having to engage with areas of mathematics in which they had no personal research experience. This drove home to them the insight that "it is impossible to grasp even *one* mathematical concept without having assimilated all the concepts which led up to its creation, and their connections" (Klein 1928, 1). To address this, one of the goals of historical scholarship was to recreate a distilled equivalent of first-hand research experience at a certain time and with certain tools.

> [History requires] acquainting oneself so well with the notions and procedures in use at that time that one is able to judge what could be achieved within the area known at the time and under the given conditions, and moreover by examining what these tools have in fact been used for. A thorough understanding will not be obtained until one finds a complete connection between the usability of the tools at their disposal and the range of the results they gained with them. (Zeuthen 1903, 555; Lützen and Purkert 1994, 16)

This describes not only sound historical methodology but also, and equally, the mindset of a mathematician immersing themselves in a foreign research field, or conscientiously preparing to teach a course in an area outside their expertise.

It is evident already from these considerations that an approach to history that is only interested in identifying precursors of one's preexisting notions is profoundly antithetical to critical internalist historiography – indeed, it immediately voids the core motivations for studying history at all. This applies to many other critiques of presentist internalist historiography as well.

It is common to contrast the mathematician's selective interest only in work that turned out to be important in hindsight with the historian's equal attention to dead ends and ideas that did not go anywhere (Grabiner 1975, 439–440; Grattan-Guinness 2011, 4). Again, nothing could be further from the goals of critical internalist historiography. The core aim of history to provide a critical perspective and sense of research-problem dynamic for parts of mathematics outside one's direct expertise depends very essentially on an understanding of the limitations of alternative approaches.

> Not only a knowledge of the ideas that have been accepted and cultivated by subsequent teachers is necessary for the historical understanding of a science, but also that the rejected and transient thoughts of the inquirers, nay even apparently erroneous notions, may be very important and very instructive. (Mach 1883/1919, 254–255)
>
> The historical study of the sciences must not only be concerned with tracing the progress of the human mind in the knowledge of truth, but also with recalling its errors; it is precisely the healthy appreciation of these errors which alone can make the true importance of the sciences clear. (Tannery 1930, 3)

In this respect, it is precisely the study of approaches that do *not* map neatly onto modern ones that is mathematically enlightening, and hence the particular interest of mathematicians who want history to be relevant to their concerns.

> It is certainly of interest to know when an idea or method that is part of present mathematics reached a form in which we immediately recognise it, or when a technique whose utility we now know was first used. But it is of greater interest to pay attention to those ideas and

> methods that diverge from present ones. … The modern method will generally have far more extensive uses, and it will be stated in rules that can be applied purely mechanically; but precisely because the related older methods were not so designed, but rather had to be adapted to each case, they could led to a deeper penetration and a more versatile investigation than the corresponding modern treatment. The mere fact that the less developed form required a greater effort of thought led to observations that would easily escape one who now reach the same main result with railroad speed. (Zeuthen 1903, 554–555)

The critical internalist approach sees the study of the history of mathematics as in many ways analogous to original mathematical research. "Whoever wants to find something new must often free themselves from finished rules, and this can be learnt from those who have not yet organised their procedures into finished rules." (Zeuthen 1903, 554–555). Just as mathematical innovation often consists in getting a firm grasp of ideas that are "in the air," so also historical understanding depends on that same talent to perceive the essence in a bustling body of burgeoning work (Weil 1978, 438). On a more big-picture scale, forming a clear overview of the development of ideas in a field up to a certain point is a task common to both the historian and the mathematician setting out an original research program, suggesting that mathematicians (especially research strategists) and historians of mathematics share skillsets and interests (Weil 1978, 436–437). These analogies work only if past mathematics is understood in its own terms, including its challenges and limitations as they appeared at the time. Only then is historical research analogous to mathematics research. All of these analogies break down completely if past mathematics is merely mined for precursors of modern ideas or is presumptuously judged by their degree of agreement with modern theories. This again shows why such presentist perspectives are anathema to critical internalism.

Supporting these goals often involves interpreting and clarifying past mathematics in modernized form. The historian's "most important function as far as the study of mathematics itself is concerned" is that of "studying and analyzing the works of the great mathematicians throughout history in order to make those works accessible to modern readers and researchers" (Edwards 2020, 66). Mathematics should be useful "above all to the mathematicians who are its most reliable consumers and the creators of its raw material" (May 1975, 450). Of course, "when a professional mathematician wants to cultivate the history of his science, he must, obviously, first of all submit to the rules that apply to everyone who wants to know the historical truth." But the goals of the historian and the mathematician are not incompatible. On the contrary, the mathematician can "contribute something of his own" to historical analysis by bringing current mathematical tools to bear on illuminating past thought.

> In very different expressions one can recognize the same truths. … In this way, the mathematically educated cultivator of the history of mathematics has the opportunity to interpret texts which otherwise seem to be incomprehensible, or which have been misunderstood, to find connections among historical statements which otherwise may seem to be concerned with different things, to detect the preparation of a discovery which otherwise seems to have been due to the unique gift of prophecy of one single ingenious man, and above all to find and understand the coherence in the research and knowledge of a given period and thereby its connection to the points of view of the earlier and later periods from or

> to which impulses are given. Not only will historical knowledge thereby increase and be consolidated but one will gain exactly that type of knowledge of old mathematics that will give the greatest benefit for mathematicians and pedagogues. (Zeuthen 1917, 201–202; Lützen and Purkert 1994, 17)

Such analyses must of course be careful to avoid the traps of anachronism. But the mere potential fallibility of the mathematician's method of analysis is no reason to abandon it; other historical methods have equal pitfalls of their own.

> It is not uncommon for past mathematicians to present their work in a way that differs substantially from that of modern science, and this can lead one to pay too little attention to the real train of thought when studying a text, so that one reads the modern view into the presentation. . . . By going back to the sources [and remaining close to the original form of expression], a mathematical-historical author will of course be able to avoid certain mistakes [of anachronism], but it is very possible that he will be guilty of other and perhaps even greater mistakes [such as deficiencies of mathematical understanding]. (Eneström 1911/12, 6–8)

The only foolproof way to avoid misrepresentation is to reproduce the original expressions verbatim, without commentary or analysis, but this would serve only to make the historian superfluous and capitulate on a major goal of historical scholarship.

Critical internalism has sound tools to avoid the dangers of anachronism. The structural relations between ideas, rather than their superficial surface form, is the truest indicator of their nature and essence.

> The value of a method used in the past does not depend on the greater or lesser superficial resemblance to those whose utility we now know, but on what they could be – and actually were – used for in their own time. Likewise, reaching a particular result has significance in and of itself; but the discovery of such a result may be more or less coincidental, and the value one should attribute to that discovery at a given time depends on whether the significance of the result, and its uses, were understood at the time. The correct assessment of the various mathematical advances of the past can therefore only be obtained by studying the mathematics of these times as a whole, that is to say by immersing oneself in the then customary ideas and methods. (Zeuthen 1903, 555)

The viability of interpretative hypotheses and the faithfulness of modernizing paraphrases should be judged at this deeper level of conceptual analysis rather than by excessive attention to surface form.

This point is much misunderstood. Instead of judging fidelity to historical thought in these sophisticated terms, historians often fall back on adherence to old notation and language as a proxy for non-anachronism – a conceptually simplistic and impoverished notion of historical fidelity (Blåsjö and Hogendijk 2018) that conflates critical with presentist internalism. Thus, historians congratulate themselves that "only comparatively recently has the practice of translating [historical] works into modern notation become unacceptable," praising the "new and sophisticated literature" that accords with these "historically sensitive" standards (Bertoloni Meli 2006, 9; Blåsjö 2014, 114). It is even claimed that analyzing past thought in modern

mathematical terms "implies ... a strong affirmation of the superiority of modern ideas over those of the past" (Rowe 1996, 10). But this is exactly contrary to the goals of critical internalism, to which providing a critical perspective on current mathematics is one of the main purposes of historical scholarship in the first place. Critical internalists were always very clear about this:

> The goal of my mathematical historiography ... requires ... a study that does not assume that our time has become wiser than [past mathematicians] were, but that seeks to learn something from them, and particularly to grasp that [aspect] of their way of thinking which may have been lost during the later generalising development. (Zeuthen 1903, 555–556)

Modern historians have been equally critical of the "Aristotelian" mode of engaging with history that uses an analysis of past thought as a basis for formulating new and forward-looking ideas. Cherry-picking historical evidence for self-serving ends is not history but "history-satire" (Grattan-Guinness 1973, 449), or "ransacking history" (Dauben 1994, 7). History proper asks "what happened in the past?" whereas these presentist narratives instead ask "how did we get here?" This is not "history" but "heritage": a self-centered delineation of a "royal road to me" (Grattan-Guinness 2004, 164–165).

But this modern dichotomy is too uncharitable a view of the Aristotelian mode of engagement with history. The point of the Aristotelian approach is not to use the present to judge the past, or to use the past to flatter the present. Rather, it is to use the past to conceive and understand the present. The question "how did we get here?" presupposes that the "here" is already fixed before historical inquiry begins, rather than being shaped through historical investigation. The defining characteristic of Aristotelian accounts of history is perhaps not presentism but historicism: instead of condemning such histories as abusing and distorting the past for instrumental ends, we should perhaps praise them for making history an integral part of any creative and critical thought.

The confluence of historical analysis and current thought can be seen as a source of strength and purpose rather than as a threat to historical purity and autonomy. "The historical notes in Bourbaki's *Eléments* were intended to show the antecedents of his ideas – an important goal, since a reorganization of established theories should be a natural outcome of previous mathematical development and not a rootless caprice." (May 1975, 449). Lagrange did the same "in many of his publications," basing his own systematization of the field and forward-looking research strategy on "excellent examples of serious historical research" (Dauben and Scriba 2002, 72). Indeed, it is natural for the interests of the mathematician and the historian to be united in such enterprises, since an incorrect understanding of past work will lead to a wrong-headed synthesis and hence a research program that fails to learn from the work that has already been done.

Instead of the dichotomy between "good" history pursued with a supposedly pure mind, and "bad" history contaminated by the author's own ideas, we should perhaps question the assumption that historical inquiry could and should be cleanly detached

from other dimensions of human thought, as such a critique presupposes. Indeed, one could argue that this assumption is a demonstrable logical impossibility.

> The idea of forgetting the later past of an historical episode, often put forward as desirable historiography, is impossible to achieve, since the historian has to know which notions *are* later, and this requires the historical task already to have been accomplished. . . . We have some historical text before us; say Euclid's *Elements*. How can we read it in a historical spirit? A popular answer, put forward for all kinds of history, goes as follows. When reading Euclid's work, forget all theories in the field involved that have been developed since; step into his shoes . . . and read his work with his eyes. Unfortunately, . . . this method suffers from a difficulty; namely, it is completely useless. For in order to ignore all knowledge produced since Euclid one needs to know what that knowledge is in the first place. But in order to know that we must be able distinguish it from the knowledge produced before and during Euclid's time. But in order to know that we need to know the history of Euclid's work – before studying the history of Euclid's work! (Grattan-Guinness 2004, 169, 179)

Altogether, the war on anachronism in modern historiography has sometimes been more bark than bite. It is a powerful image that translating past mathematics into modern notation and terminology is an act of unsympathetic erasure and dogmatic self-centeredness. As history of mathematics moved outside mathematics departments, this evocative motif was a neat rallying call for the self-identity of the new generation. Still, it may be fair to say that the number of actual scalps won by this method has been a bit underwhelming compared to the passion with which it has been advocated. Concrete attempts to prove its superiority over the critical internalism of old in specific cases have perhaps on the whole been less resounding than the rhetoric surrounding them (Blåsjö 2016). But if smoking-gun evidence for the culpability of old internalism is in limited supply here, then modern historiographers have had a second major prong of attack, to which we now turn.

3 Reconstruction as Historical Method

Mathematicians can be impatient readers of history. When they approach a text, they tend to ask themselves "what's really going on here?" (Rowe 1996, 9). They may prioritize "a sort of rationally reconstructed or 'distilled' history," dismissing minor aberrations with the cavalier attitude that "actual history is frequently a caricature of its rational reconstructions" (Lakatos 1976, 5, 21; Lakatos 1970).

Modern historians take a diametrically opposite view. Trying to explain why mathematical ideas developed as they did is seen as inherently dubious.

> The student of history should not ask such childish queries. His purpose cannot be to give a completely logical account of the past, for such account is obviously out of the question. It is only here and there that a few logical knots can be tied, for the rest, we must be satisfied with a faithful description of the possibilities which materialized. . . . The capriciousness of mathematical development cannot be emphasized too much. (Sarton 1957, 18)

In keeping with this conviction,

> whereas the history of science previously stressed a big picture focusing on the theoretical progress made by great scientific heroes . . ., the field is now dominated by scholars offering rich, thickly descriptive, local studies. (Lightman 2016, 1)

The mathematician is most interested in higher-order connections between ideas, while the historian finds authenticity precisely in local and idiosyncratic particulars. One may use a biological metaphor to illustrate these contrasting approaches.

> [Historical sources can be likened to] the fossils that tell us about life on earth in distant epochs, and just as the palaeontologist dares to reconstruct the fauna and flora of that time on the basis of these remains, one could demand that the historian of mathematics should try to establish the connection of mathematical ideas on the basis of the facts established by exact research and thus to bring that mathematical thought back to life. (Stäckel 1900, 260)

But there are two levels to this enterprise: the global and the local. One concerns an "evolutionary" view of history – trying to relate a given historical occurrence to its precursors and antecedents – while the other is "phenomenological" – striving for the most direct, raw experience of a historical moment in and of itself (Dijksterhuis 1953).

Both are essential for critical internalist history. The phenomenological perspective corresponds to the goal of recreating an authentic picture of the genuine research experience as it appeared to mathematicians of the past.

> The historian must re-enact the past in his own mind. . . . He must see what the [underlying] problem was, of which his author is here stating his solution. He must think that problem out for himself, see what possible solutions of it might be offered, and see why this particular [author] chose that solution instead of another. (Collingwood 1993, 282–283)

The mathematician's tendency to draw parallels to known modern problem contexts in order to create "useful pasts" (Goldstein 2010) can more charitably be seen as a way of getting at this form of authenticity rather than as a dogmatic translation into a preconceived framework.

The evolutionary perspective is equally needed, since traditional internalism intends history of mathematics to serve a supporting function to mathematical research and understanding. Purposes such as drawing up and critically assessing research programs and educational curricula demand a big-picture view of overarching developments – a need that history is well suited to address. Thus, to the internalist, "truly, the main purpose of the history of the development of mathematics is to provide information about the connection between mathematical ideas." (Eneström 1910/11, 6)

Based on confidence in a fundamental unity of mathematical through across all ages and cultures, mathematicians tend to be optimistic about the possibility of successful reconstructions on both of these levels.

> The paleontologist undertakes to reconstruct the whole organism from scarce remains, assuming that the laws of biology observed in beings living at present have always held. Who would deny that this assumption has proved to be true, that, even if some errors were made, the results of this research are more than an uncontrollable game of the imagination? It seems to be precisely because of the unity of the human spirit that the laws of productive mathematical creation which are currently in force remain applicable to earlier times. (Stäckel 1900, 262)

Today's historians have much less confidence in this assumption of unity of past and present thought, and the ability of a modern mathematician to intuitively empathize with historical thought in a way reliable enough for historical reconstruction. It is felt that the old attempts based on these hubristic assumptions underestimated their own subjectivity, and overidealized and over-linearized the irregular and contingent nature of historical development (Saito 1998, 134; Sidoli 2014, 35). To avoid these dangers, today it is almost axiomatic – "a kind of null-hypothesis" – "that there is a discontinuity between mathematical thought of the past and that of the present" (Fried 2018, 16). In terms of the biological metaphor, this corresponds to restricting of paleontology to the descriptive, factual level, and treating with great suspicion the possibility of genuinely grasping the lived experience of other organisms, as well as viewing the overall path of evolution as governed more by chance circumstance than explicable rational principles.

These problems were well known to the old generation of critical internalists.

> Doesn't one leave the field of science with the demand that the historian should not only represent the content but also the connections of mathematical ideas? Are not the historical facts then replaced by arbitrary and imaginative structures, so that such reconstructions have only subjective value? Certainly, no one will deny that taking this path brings with it great dangers, and it has rightly been warned that philosophical constructions of history made without sufficient expertise have never truly advanced our understanding. Nevertheless, I am convinced that this demand is not only justified, but that it can also be carried out. . . . Far from speaking out in favour of unbridled subjectivism, I consider it the right, the duty of the historian to go beyond the 'bare facts', and I am convinced that it is possible to fulfil this demand without having to give up the achievements of the critical school. . . . If such conjectures, which of course must always be called conjectures, explain all the facts of a complex of phenomena in a simple way, then one will be able to regard them, just as in the natural sciences, as a stage in the journey from error to truth. (Stäckel 1900, 261–263)

The divergent intuitions of the mathematician and the historian cast the viability of the method of hypotheses in the history of mathematics in very different lights. Historians, inclined to assume major discontinuities between past and present, give great credibility to documents of the time and little to later interpretations. Mathematicians, by contrast, place great faith in the brotherhood of their kind, and feel that the work of a mathematician is better understood by a mathematician of another age than by an outsider who happened to be closer merely in time and space. Already in the days of Zeuthen and Cantor, this conflict was articulated and debated at some length (Lützen and Purkert 1994, 28–33). Similarly, historians are predisposed to seeing idiosyncrasies and the particular, whereas mathematicians have a sense that their field develops almost quasi-deterministically, which implies good prospects for empathetic

understanding and reconstruction (Paumier and Aubin 2016, 209; Bourbaki 1994, 173). "Beethoven and Shakespeare did unique work, and we would not have *Fidelio* or *King Lear* if they have not lived. However, symmetric functions would have been discovered by others if Newton had not lived." (Askey 1988, 202).

Comparing the merits of these incommensurable outlooks objectively is all but impossible, and so is tallying their track records of actual outcomes. One could argue that internalism enjoyed some remarkable predictive successes: the discoveries of Archimedes's lost work *The Method* and the decoding of Babylonian mathematics, for example, can be regarded as spectacular vindications of hypotheses that had been previously stipulated on purely internalist grounds (Lützen and Purkert 1994, 25; Rowe 1996, 7). On many smaller points as well the critical internalists found that "whether I have been on the right track with [my historical interpretations], my work itself has often given me an opportunity to test" (Zeuthen 1903, 556), seeing themselves vindicated by the results. The necessity of using mathematical understanding to go beyond explicit sources can also be argued from the nature of present mathematics. "For example, Weierstrass's new foundation of the theory of functions was largely spread orally by his students. If a future historian of the nineteenth century would neglect this source of transmission, he would come to completely wrong conclusions." (Stäckel 1900, 261).

But the method of hypotheses has also had its failures. The early twentieth-century generation is often faulted for being too much under the spell of the mathematics of its own time rather than that of the historical era they were supposed to be studying (Høyrup 2016, 71; Chemla 2012, 21–26; Gray 2008, 373). A notorious example is the alleged crisis in early Greek mathematics resulting from the discovery of incommensurability, or the irrationality of $\sqrt{2}$ – a prominent topic of speculation to the critical internalists generation. Today's historians are inclined to view this as dubious history contaminated by the concerns of the mathematical community at the time – a mere projection of the *Grundlagenstreit* with Hilbert and Brouwer as the main antagonists (Knorr 2001; Saito 1998, 133).

Indeed, it is probably indisputable in retrospect that the old internalists sometimes let an inflated sense of the mathematical preoccupations of their own time go to their heads and cloud their judgement on historical matters in some cases. But one may note that the critical internalist historiographical program contains within it the tools to cure this problem. Namely, in its oft-repeated principle that history should be a vehicle for a critical perspective on current mathematical practice.

In addition to anachronistic biases, subjectivity is another charge against the method of reconstruction: "the number of plausible, reconstructed histories is often equal to the number of scholars working along such lines" (Sidoli 2014, 35). This severely undermines the allegedly semi-deterministic and unified character of mathematical development that was invoked to justify the reconstructivist enterprise in the first place. But in this case too, a corrective principle can be derived from within sophisticate internalism itself. The critical internalists were under no delusion that their reconstructions were anything but fallible, but they were confident that lively clashes of bold and clear ideas would be a self-correcting and fruitful enterprise. Daring hypotheses are valuable "if only to provoke further study." "It is the fate of all

scholarship to be valid only for a few generations; . . . let us stir up as many ideas as we can. Our grandchildren will benefit from this." (Tannery 1889, 496; Pineau 2010, 377). Many modern historians are more likely to greet the proliferation of hypotheses with exasperation than combative enthusiasm. Internalist studies that would be useful in the sense intended by Tannery, assuming an ambient culture of debate, are bound to look reckless in the risk-averse climate of today's historiography. What is constructive in one context is folly in the other. A multitude of competing alternative reconstructions is consistent with a standard conception of scientific progress, and is not in itself proof of a pathological level of subjectivity in the field. Theoretical quantum mechanics was not abandoned in the early twentieth century just because empirical findings were subject to several viable but incompatible interpretations.

In sum, relatively free-wheeling reconstruction as a historical method is naturally associated with the goals and convictions of the mathematician. Although out of fashion historiographically, this may not be a straightforward case of good riddance. Reconstructions may have a checkered track record in some respects, but the core convictions that motivated this enterprise also entail self-correcting mechanisms for overcoming precisely the weaknesses nowadays commonly associated with such approaches.

4 Conclusion

Mathematicians lost the historiography wars of the twentieth century and they have only themselves to blame. Due to an increasingly exclusive focus on specialized research productivity, mathematicians lost touch with the ideals that had led to history being accorded a central place in mathematics around the beginning of the century. The critical internalist historiography articulated by that generation gave way to a more simplistic internalism. Historians with a vested interest in wresting the field from the mathematicians pounced on this weakness and portrayed it as irrevocable. Having weakened their commitment to the intellectual unity of mathematical research, education, and historical inquiry, mathematicians were left without the tools to defend themselves. The mathematicians lost the historiography wars not for the fallibility of their approach to history, but for neglect of the ideals on which this approach was founded. The historiography of mathematics may yet have much to gain by reviving these ideals.

Abstract

The interface of the "scientific tradition" of mathematics with the traditions of American elementary education has grown in the past 200 years with state curriculum standards currently a highpoint of interactions. Episodes from the history of measure number provide a perspective suggesting current standards regarding the teaching of common fraction in American schools might be a bit wrongheaded and in need of reconsideration. Deeply rooted traditions are stubborn things, but the historical perspective provides clues for new directions.

1 Introduction

The philosopher, Philip Kitcher (1984), presents a theory of mathematical knowledge residing in and warranted by evolving mathematical practices that are primordially rooted in human interactions with the world. Kitcher's historical examples are drawn almost entirely from what Høyrup (1989) refers to as the "scientific tradition" of mathematical knowledge. This tradition is *theoretical* in contrast to the practical art of subscientific mathematical knowledge, employed in the trades, commerce, and elementary schooling well into the early modern world. While Høyrup explains the extinction of the subscientific mathematical tradition in Early Modern Europe of the late sixteenth century, DNA from that tradition is richly present in elementary mathematics education today in the USA, with its rather unique semiautonomy and guild-like practices of local control that stem from its germination in American soil in the early seventeenth century. In fact, this Americanized variant might respond to Høyrup, like Mark Twain, "The report of my death was an exaggeration" (New York Journal, June 2, 1897). Just as Kitcher's theory must not ignore the "irrational" transitions or retrograde motions Høyrup (1989, 76) describes in the subscientific tradition, epicycles should also be noticed within the American tradition. This chapter shines a light on one of these epicycles relating to practices now driven by debatable curriculum standards.

The interface of the mathematical science tradition with the mathematical practices of elementary education in the USA has radically changed in the last 200 years. One of the key developments is the relatively recent emergence of standards for school mathematics. The "standards movement" in the USA surged between 1980 and 2010, with state and national insistence on assessment-driven accountability in the outcomes of elementary mathematics schooling. Its most recent high point has been the *Common Core State Standards for Mathematics* (CCSSM). To borrow Høyrup's terminology once again, such standards and their attendant frameworks and assessments are "index fossils" marking the boundary of a critical transition in the evolution of mathematical practice at the elementary level, a transition surely to be measured by many decades *yet to come* and not just a few years.

The history of mathematics makes thoroughly clear how much we do not know and is riddled with undocumented gaps. Even so, it does offer contrasts with the present, and this chapter examines historical contrasts to the fraction schemas being taught and notoriously not well learned in USA schools in recent decades, if they ever were. Its brief survey of historical practices raises questions about the current attempts to demand of elementary school children, through what are effectively national standards, fluency and proficiency in common fraction representations, interpretations, notations, operations, and standardized algorithms. The CCSSM

stipulations for common fractions have been embedded, virtually word-for-word, in the standards of 44 states and imitated in the rest for over a decade (NGA Center and CCSSO 2010). From the perspective of history, this might be a bit wrongheaded and worthy of reconsideration. The chapter closes with suggestions for future standards and practices regarding common fractions.

When using examples from ancient history, it is sometimes challenging to find consistent meaning in the words used by translators of ancient texts. This is not a criticism but an insinuation of the nature of a discipline. To paraphrase Wittgenstein, it is possible that the nuanced denotations of ancient symbols and written terms, passing through generations and cultures from the Bronze Age to us, like many strands twisted and braided into a rope, convey no thread of *meaning* running the full length (Wittgenstein 1958, 32). Therefore, like a statistician sampling a diverse population, this chapter attempts to connect the present to the past by interweaving multiple strands of meaning from the mathematical stories of three ancient cities with a sufficiently diverse collection of threads running through current elementary mathematics practice and its recent history. With these disclaimers and foreshadowing, please hang on to the gnarled rope that is woven, and welcome to Thebes.

2 Thebes

Imagine Thebes, the exotically picturesque capital of ancient Egypt in 1550 BC. There worked Ahmosé, the scribe who created the Rhind Mathematical Papyrus, a reproduction of a mathematical text from the time of Egypt's Middle Kingdom. This ancient scribe wrote in hieratic script, a cursive related to hieroglyphics almost as a symbol-by symbol shorthand. Ahmosé's hieroglyphic for $249\frac{2}{7}$ would faintly resemble the script in Fig. 1.

Wide spaces are used to separate the hieroglyphic into *five* symbols, each symbol a unique arrangement like the dots on a dice. They are, from right to left: 200, 40, 9, $\frac{1}{4}$, and $\frac{1}{28}$. A special mark, ⌓, was used above 4 and 28 to distinguish them as sub-multiples of the unit, i.e., $\frac{1}{4}$ and $\frac{1}{28}$. Ahmosé's hieratic script for this number would contain five corresponding symbols in the same order.

There are several important things to note about Ahmosé's fractions:

1. The five symbols forming the word $249\frac{2}{7}$ belonged to a larger palette containing 38 grouping symbols representing integer numerical sizes 1, 2, 3, …, 9, 10, 20, 30, …, 90, 100, 200, 300, …, 900, 1000, 2000, …, 9000, 10,000, and

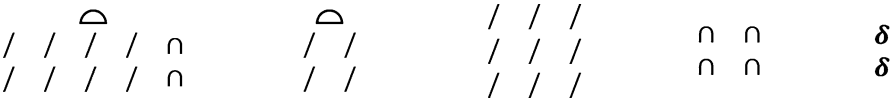

Fig. 1 Hieroglyphic for $249\frac{2}{7}$ read from right to left

100,000. The other grouping symbols on Ahmosé's numeral palette were $\frac{2}{3}$, and those some would call unit fractions, like $\frac{1}{4}$ or $\frac{1}{28}$, generated from their corresponding reciprocals with the use of the special sign.

2. The Egyptian $\frac{1}{7}$ is not the same as the unit fraction $\frac{1}{7}$, which is one of seven "equal quantities" or "aliquot parts" that compose a whole. Ahmosé seems to have thought of $\frac{1}{7}$ as a *grouping size* in the sense that a whole, as a measured quantity, has only *one* size that is its seventh *partsize*, while each of the seven equal aliquot quantities composing the whole shares that size. Thus, the partsize insinuates a ratio of an aliquot quantity to the whole quantity. Grouping sizes are not counted in Ahmosé's notation for sizing a quantity in terms of a single unit, though counting of unit quantities was certainly involved in the process of measuring and assigning grouping sizes. In contrast, the decimal 35.6, a multiplicative notation connoting $3 \times 10 + 5 \times 1 + 6 \times 0.1$, is a counting of grouping sizes: *3 tens 5 ones 6 tenths.* Indeed, what appears to be an exception, $\frac{2}{3}$, was very useful in Ahmosé's tools and methods, particularly in his doubling table and his methods for multiplication and division. Instead of being used as a count, it seems to be a special symbol for $\frac{1}{2}\ \frac{1}{6}$, perhaps preserving an earlier usage such as the size of *the-unit-less-its-third*.

   Unlike Ahmosé's fractions, a *common fraction*, as a measure number, is a count of a unit fraction. As a quantity, the common fraction $\frac{1}{7}$ can be considered a subunit, counted like a unit (hence the name *unit fraction*), and expressed as such in language and notation as, for example, *two-sevenths* or $\frac{2}{7}$. Thus, the word *partsize* is coined for this chapter to convey the Wittgenstein-like warning that Ancient Egyptian interpretations of fraction words and symbols are not common usages today.

3. A measurement in Ancient Egypt was done in the way typical of most ancient cultures: as a *simple measurement* using a count of a single unit or as a *compound measurement* using a decreasing sequence of counted amounts in a decreasing sequence of units and subunits, e.g., *4 cubits 6 hands 1 finger*. For computation purposes, given the algorithms of Egyptian practice, the latter measurement would be sized as a *single measure number in a single unit*: $4\frac{1}{2}\ \frac{1}{4}\ \frac{1}{7}$ cubit. In general, for Ahmosé to state the size of a quantity in terms of a single unit quantity meant to express the size as *a strictly decreasing sequence of the grouping sizes* from his numeral palette (Allen 2014, 123). Therefore, Ahmosé would not simply write $\frac{2}{7}$ or $2(\frac{1}{7})$ or $\frac{1}{7}\ \frac{1}{7}$, not even in his scratch work, to size the quantity we would represent as $\frac{2}{7}$. He would no more do this than one would use the numeral 32,020 to represent 340 just because $20 + 20 = 40$. In a very consistent practice, Ahmosé sized two of the seventh parts of a unit as $\frac{1}{4}\ \frac{1}{28}$. It was his way of sizing the ratio of a quantity to a single unit quantity.

The contours of Ahmosé's quantitative reasoning seem to move fluently from sizes expressed by his numerals to quantities having those sizes. In this regard, he was fully capable of reasoning with quantities in ways analogous to reasoning with

common fractions. For instance, when no measurement unit was given in a problem about an unknown quantity, he would identify the quantity with its size number. He could easily conceive of "5 hands, each the 7^{th} partsize of a cubit," a quantity he would size as $\frac{2}{3}\ \frac{1}{21}$ or as $\frac{1}{2}\ \frac{1}{7}\ \frac{1}{14}$ and would consider equivalent to the seventh aliquot part of a length that measured 5 cubits. (With common fractions, this corresponds to the insight that $\frac{5}{7} = 5 \div 7$, a theorem relating two separately defined numbers.) When performing arithmetic operations, Ahmosé could consider these five quantities as a "*heap*" of sevenths, an unsized quantity yet to be rendered as a single measure number of cubits. In fact, during a computation involving multiple heaps, Ahmosé sometimes jotted down lists of partsizes in no particular order and repeating a partsize several times.

Ahmosé would often reify partsizes into easy-to-work-with quantities by stipulating they referred to a quantity measured by a select number of units. For example, he could render $4\frac{2}{3}\ \frac{1}{5} + 1\frac{1}{2}\ \frac{1}{5}\ \frac{1}{15}$ as $5 + \frac{2}{3} + \frac{1}{5} + \frac{1}{2} + \frac{1}{5} + \frac{1}{15}$ and stipulate these sizes referred to wholes that each measured 30 units of the same kind. Thus, ignoring for the moment the 5 wholes, the fraction part of the sum amounted to putting together 20 + 6 + 15 + 6 + 2 into an unsized heap of 49 quantities each of the 30th partsize of one of the wholes. When sizing these 49 quantities by a single measure number, one of his many approaches would likely be to sort them into a heap of 30 quantities, which would be one whole, and then make heaps of size 15, 3, and 1, a *decreasing sequence* of quantities that were aliquot parts of 30. Accordingly, the size of all 49 quantities put together is $1\frac{1}{2}\ \frac{1}{10}\ \frac{1}{30}$, thereby giving $6\frac{1}{2}\ \frac{1}{10}\ \frac{1}{30}$ as his final sum. Ahmosé knew the sorting was not unique and tended not to use 1 as a "heap" size. So, instead of 15, 3, and 1, he could have created heaps of size 15, 2½, and 1½, thereby rendering the combined fractional quantities as $1\frac{1}{2}\ \frac{1}{12}\ \frac{1}{20}$ of the whole, which also might be preferred because of the larger partsizes.

Ahmosé's conceptions of fractions and sizing probably evolved from peculiarities of an oral tradition of measurement, perhaps the all-important system of grain measures. Grain measures were based on *hekat* units (≈ 5 quarts), and the naming sequence for most other grain units was developed by repeated halving and doubling of the *hekat* (Chace 1986, 18). Such a binary system would lend itself to reducing a measurement in multiple units (e.g.,1 gallon 2 quarts 3 cups), to a decreasing sequence of partsizes in one unit ($1\frac{1}{2}\ \frac{1}{8}\ \frac{1}{16}$ gallon). With relatively efficient computational algorithms, such a binary scale might have been the impetus for the evolution of the Egyptian system of measure numbers.

Unless disrupted by outside cultural influences, any oral tradition would develop computational algorithms symbiotically with its measurement systems. An arithmetic of halving and doubling seems "peculiarly" compatible (Chace 1986, 31) with the binary-scale system of grain-measure units. By the time of Ahmosé, Egyptians multiplied numbers using a doubling strategy, sometimes interleafed with multiplications by ten. If we think of multiplication originating as a scaling operation in the context of measurements, converting a grain measure from a larger unit to a smaller unit would involve a doubling strategy with the occasional multiplication by 10. (Ten entered with the *ro*, which was $\frac{1}{320}$ *hekat.*) Chace (1986, 31) suggests this

connection to grain measure as a possible source of the Egyptian multiplication technique.

To multiply 21 × 24, Ahmosé built the table shown in Fig. 2, with marks by the addends of 21:

Since $21 = 1 + 4 + 16$, Ahmosé knew $21 \times 24 = (1 + 4 + 16) \times 24 = 24 + 96 + 384 = 504$.

With fractions, such a multiplication technique demanded a way to double the partsizes on Ahmosé's numeral palette. Thus, the Rhind Papyrus opens by constructing a large table giving the double of $1/n$ for all odd integers n from 3 to 101. Ahmosé knew the table's values were the same as those when 2 is divided by n, i.e., the number that is multiplied by n to give 2. For example, the double of $\frac{1}{97}$ is given as $\frac{1}{56}\ \frac{1}{679}\ \frac{1}{776}$. Several methods were probably employed in computing the table. The simplest pattern seems to be the use of $\frac{2}{3}$, i.e., $\frac{1}{2}\ \frac{1}{6}$, as the template for entries of the form $\frac{2}{3n}$, which are all rendered in the form $\frac{1}{2n}\ \frac{1}{6n}$. The even values of n, such as 26, were not included in the table. Ahmosé knew that $2 \times 13 = 26$, and hence the *double of* $\frac{1}{26}$ is $\frac{1}{13}$. Indeed, he found quite useful and frequently invoked this *inverting rule*: $m \times p = n$ implies $m \times \frac{1}{n} = \frac{1}{p}$. Not surprisingly, Ahmosé's doubling table was a crucial tool in his computational algorithms.

These preliminaries help us understand Problem 33 in the Rhind Papyrus: *A quantity* [sometimes translated as *"heap"*], *its* $\frac{2}{3}$, *its* $\frac{1}{2}$, *and its* $\frac{1}{7}$, *to go in together, become 37. What is the quantity?* Today, $X + \frac{2}{3}X + \frac{1}{2}X + \frac{1}{7}X = 37$ and, consequently, $2\frac{13}{42}X = 37$ come to mind. Hence, $X = 37 \div 2\frac{13}{42} = 16\frac{2}{97}$. For Ahmosé, however, the problem required finding a number that multiplied $1\frac{2}{3}\ \frac{1}{2}\ \frac{1}{7}$ to get 37. He seemed satisfied to use $1\frac{2}{3}\ \frac{1}{2}\ \frac{1}{7}$ instead of reducing it to $2\frac{1}{6}\ \frac{1}{7}$ since it satisfied his sizing criteria and it conveniently expressed the problem. Doubling $1\frac{2}{3}\ \frac{1}{2}\ \frac{1}{7}$ four times, he gets $16 \times 1\frac{2}{3}\ \frac{1}{2}\ \frac{1}{7} = 36\ \frac{2}{3}\ \frac{1}{4}\ \frac{1}{28}$, which he found to be $\frac{1}{21}$ less than 37, possibly by using an abacus, and stipulating the fractions were partsizes of 84. But $\frac{1}{21}$ is the double of $\frac{1}{42}$, and he notes $1\frac{2}{3}\ \frac{1}{2}\ \frac{1}{7} \times 42 = 97$. Therefore, adapting his inverting rule, $1\frac{2}{3}\ \frac{1}{2}\ \frac{1}{7}$ times the double of $\frac{1}{97}$ is the double of $\frac{1}{42}$, or $\frac{1}{21}$. So, combining his products, $1\frac{2}{3}\ \frac{1}{2}\ \frac{1}{7} \times \left(16 + \textit{double of}\ \frac{1}{97}\right) = \left(36\ \frac{2}{3}\ \frac{1}{4}\ \frac{1}{28}\right) + \left(\frac{1}{21}\right) = 37$. Finally, getting the double of $\frac{1}{97}$ from his table, Ahmosé's answer is $16\frac{1}{56}\ \frac{1}{679}\ \frac{1}{776}$, agreeing with our $16\frac{2}{97}$.

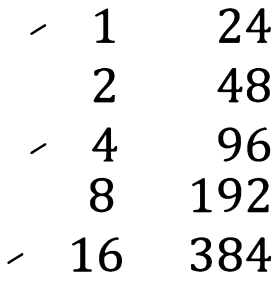

Fig. 2 Doubling table for multiplication 21 × 24

Such was Ahmosé's fraction arithmetic in Thebes, 1550 BC. He fluently calculated with "fractured numbers," but his arithmetic was morphologically different from common fraction arithmetic as a cognitive and mathematical practice.

3 Babylon

When Hammurabi (1792–1750 BCE) elevated Babylon into one of the preeminent city-states of the world, his empire had already been the crossroads of cultures for millennia. In this milieu, the Sumerian base-60 numeration system and the Sumerian-Akkadian sexagesimal system of calculation evolved, probably to cope with the diversity of number bases and metrologies used for centuries by the peoples mingling there.

Hammurabi's scribe had 5 different numeral palettes for expressing measurements, down from 12 palettes used a thousand years before. His five numeral systems pertained to length, area and volume and bricks, liquid capacity, weight, and the counting numbers for sets of discrete objects (Robson 2008, 15). This meant, in context, a numeral referred not only to an amount of a quantity, but it also signified a type of quantity.

In the discrete counting palette of Old Babylon, the numerals in Fig. 3 were used:

Therefore, 7390 would be written as shown in Fig. 4:

This represents 3600 + 3600 + 60 + 60 + 60 + 10. Like the Egyptian system, the discrete numeral system was not a place-value system. While having some base-10 grouping traits, it was the world's only known base-60 system.

The Babylonian scribe also possessed a *sexagesimal place-value system* (**SPVS**). Here, the number 7390 was represented as a *sexagesimal*, shown in Fig. 5, using only ones and tens:

In today's standard notation, this represents $2 \times 60^2 + 3 \times 60^1 + 10 \times 60^0$. However, the scribe had no numeral for zero, nor a sexagesimal point for distinguishing fraction from integer. These missing elements seem like deficits until we realize,

Fig. 3 Palette of numerals representing discrete counts

Fig. 4 Babylonian numeral for 7390

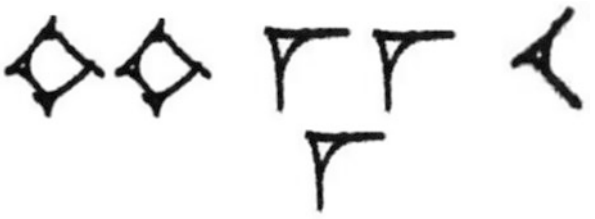

Fig. 5 Sexagesimal for 7390

"*The SPVS … was only a calculational device: it was never used to record measurements or counts*" (Robson 2008, 16). So, while the sexagesimal represented the number 7390, it could also represent $123\,\frac{1}{6}$ (i. e. , $2 \times 60^1 + 3 \times 60^0 + 10 \times 60^{-1}$) and countless other quantities.

SPVS evolved from calculations within the measurements systems of diverse Sumerian metrologies. By using smaller and smaller named and symbolized units in each metrology, they effectively dealt with fractional parts of a unit quantity without pursuing the path of Egyptian scribes. While Babylonians had a phrase for the equi-partitioning of a unit or the n^{th} *part of* a unit and indeed made tables showing the n^{th} parts of numbers like 60 for various *n's*, their scribes did not have a notation or arithmetic resembling our common fractions. Their palette of special symbols for fractional parts seemed to be limited to those most useful for their ordinary needs: $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, $\frac{1}{5}$, $\frac{1}{6}$, $\frac{1}{10}$, $\frac{2}{3}$, and $\frac{5}{6}$. These fractional parts were only used to estimate remainders or when rounding off a measurement. They were easily converted to sexagesimals when calculations were needed. For example, the *surveyor's rod* ($\approx$ 6 meters) equaled 12 cubits, and each cubit equaled 30 fingers. Thus, the compound measurement *3 rods 5 cubits 23 fingers* might be rounded to *3* $\frac{1}{2}$ *rods* or rounded to *3 rods* 5 $\frac{1}{2}\,\frac{1}{4}$ *cubits*.

By Hammurabi's time, the Babylonians had adjusted their major metrologies to form "*what might fairly be called the world's first metric system*" (Powell 1995, 1956). It was aligned to their base-60 numeration and used the rod-length as a common determinative element similar to the meter in our metric system. For example, the principal area unit, the *sar*, equaled one square rod. Fifty sar was 1 ubu, but, for calculation purposes using SPVS, sixty sar could be called a *big sar*, $\frac{1}{60}$ of a sar was called an *area shekel*, and $\frac{1}{60^2}$ (or $\frac{1}{3600}$) of a sar was called a *little shekel*. So, there are notable parallels to the metric system. Moreover, the use of *shekel* as the ubiquitous 60th of a measure unit, when no other name was standardized, allowed Babylonians to compute fractional quantities in terms of a "*generalized-compound-measurement" arithmetic*, the SPVS. Of common fraction arithmetic, this is not.

Babylonian calculations were performed on the side and not shown on the clay tablets (Robson, p. 78). However, error analysis of the results of sexagesimal calculations strongly suggests the scribes used a base-60 abacus, perhaps just lines on a table or grooves in the sand, along with tokens standing for tens and ones (Høyrup 2002, 193).

Imagine a scribe adding an area *1 ubu 13 sar 21* $\frac{1}{3}$ *shekels* to an area *47 sar 12* $\frac{5}{6}$ *shekels*. For simplicity, imagine the scribe placing Tens (T) tokens and Ones (|)

tokens on a contrived abacus to represent the two areas. See Fig. 6. With the first area, the $\frac{1}{3}$ shekel equals 20 little shekels and the ubu combines with 10 of the sar to make 1 big sar, leaving three Ones in the sar column. Similarly, *49 sar 12* $\frac{5}{6}$ *shekels* is represented in the second row: ($\frac{5}{6}$ *shekels* = *50 little shekels*).

At this stage, the specific metrology and its related numeral system, i.e., area measure, become irrelevant because the conversion ratio of 1 to 60, from column to column, is the same for all metrologies entered on this abacus. Thus, the scribe thinks of the columns simply as *generalized compound measurement units* during the calculation. The scribe combines the tokens in the two rows and simplifies to get the configuration shown in Fig. 7.

Having completed the calculation, the scribe jots on the clay tablet the sexagesimal measure number shown in Fig. 8.

The jottings exactly record the number and type of counting tokens in the abacus result. But the scribe is not finished. The answer should be reported as an absolute area measurement using the numeral palette for area. Therefore, since 50 sar combine to make an ubu, and 2 ubu equal *1* iku, the scribe records on the clay tablet *1iku 2 sar 34* $\frac{1}{6}$ *shekel,* using a roundoff fraction.

Thus, Babylon's sexagesimals indicate no particular absolute numbers, counts, or measurements except when being interpreted by a scribe within a particular context, usually after translation into the notation and metrology of the given problem (Robson 2008, 78). They were the inputs and outputs of formal calculations within a generalized compound-measurement arithmetic, peculiarly adapted to the

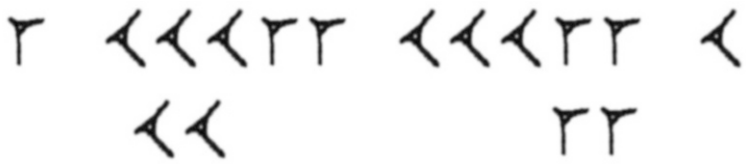

Fig. 8 Sexagesimal representing results on abacus

Babylonian "metric" system. In addition, the SPVS operations and algorithms on fractional parts of units like the sar were neither instances of nor justified by a broader arithmetic of fraction numbers. It was an arithmetic of 60s-progression numerals aided by an abacus. (This contrasts significantly with the decimal system today when it is treated as a "corollary" of the system of common fraction arithmetic due to the stipulation that a decimal is a common fraction.)

The Babylonians viewed sexagesimal division as multiplication by reciprocals and seemed to believe, on geometric grounds, that all sexagesimals had reciprocals, either exact or approximate, making no distinction between rational and irrational numbers. The product of the sexagesimals in a reciprocal pair was usually thought of as 60, which is easily viewed as an appropriately placed 1 in an abacus computation. For example, the reciprocal of 17; 46 40 is 3; 22 30, and the reciprocal of a whole number like 20 is 3, not a fraction $\frac{1}{20}$. From known reciprocals, the Babylonians used an area-based, geometric method to find new reciprocals (Robson 2008, 108). They were aware of rules like *the reciprocal of a product is the product of the reciprocals* since they frequently doubled one sexagesimal in a reciprocal pair while halving the other to produce a new reciprocal pair. The Babylonian SPVS, including its insights into the properties of sexagesimal reciprocals, had a significant indirect influence on the next city of our tale.

4 Alexandria

One thousand years after Ahmosé and Hammurabi, a Greek-centered Hellenistic culture emerged along the Mediterranean seaboard. Over several centuries, academies of learning and scholarship developed in prominent cities, with the greatest of these located in Alexandria, Egypt, at the Mouseion and Library created by Ptolemy 1 Soter (367–287 BCE). Two "fractional arithmetics" became prominent in this cosmopolitan city.

4.1 The DMSS System

The first arithmetic, the Degree-Minute-Second System (DMSS) or *astronomers' numbers*, found its home in the definitive work of the Alexandrian scientist Claudius Ptolemy (100–170 CE). Inspired by the Babylonian SPVS, Ptolemy and his immediate predecessors expressed measures of arcs and lengths in a sixties-based number system of degrees, minutes, seconds, thirds, etc. While we think of *degree* as a unit of angle measure indicating a known amount of rotation, Ptolemy's word for it was "section," and he applied it to circular arcs (i.e., 360 sections in the circumference of a circle) as well as diameters (120 sections in a diameter), both of which were considered "lines" by Greek mathematicians. In a given circle, a degree of arc length is *incommensurable* with a degree of diameter length, something Ptolemy might

have believed but could not have proven. His words for *minute* and *second* are literally translated "first sixty" and "second sixty."

Thus, DMSS is built upon the notion of a generalized unit of line measure. The *section* is a *generalized unit* in that it does not represent any absolute, known amount of length, like cubits. Also, DMSS was not a pure base-60 system since it expressed degrees in the base-10 integer scale. Unlike sexagesimals, it is built around measure numbers that refer to absolute numbers in a generalized unit, while retaining the sense of being compound measurements in known standard units (degrees, minutes, seconds, etc.) when taken on a particular circle or segment. One might call it a *compound-number arithmetic in generalized, denominatized units.* (A pint is a known amount in its own right but is "denominatized" when expressed as an eighth of a gallon.)

Even though Ahmosé's system of fractions was still dominant in Alexandria and had been adapted by the Greeks, Ptolemy and other Alexandrian astronomers preferred to use DMSS for their scientific calculations. He explains, "*In general, we shall use the sexagesimal system for the numerical calculations owing to the inconvenience of having fractional parts, especially in multiplications and divisions, and we shall aim at a continually closer approximation, in such a manner that the difference from the correct figure shall be inappreciable and imperceptible*." (Ivor Thomas 1993, 415). Ptolemy would use Egyptian fractions when rough estimates were sufficient and great precision not needed (Toomer 1984, 7).

As evidenced by Al Uqlidisi's tenth century *Arithmetic* (Saidan 1978), DMSS quickly adapted to Hindu-Arabic place-valued numerals for degrees, minutes, and seconds. Notably influenced by the Greek number theory found in Euclid, Al Uqlidisi viewed the numerical unit to be indivisible, which meant fractions, theoretically speaking, were not *numbers*, a position Ptolemy and all Greek mathematicians up to Diophantus seem to have taken (Gow 1968, 112). Al Uqlidisi wrote: "*All the preceding work* [referring to his own text] *on whole numbers and fractions and all that we have mentioned on parts of numbers refer in fact to this concept, namely, the degree. Number is indivisible, but the degree is divided into parts and parts of parts indefinitely without end*" (Saidan 1978, 84). Thus, the *compound-measurement* standpoint of the Babylonian system was carried forward into the *compound-number* arithmetic of the DMSS system, establishing it as a prototype of the positive real numbers. It finally bequeathed its position to the decimal system in the sixteenth and seventeenth centuries, the era when Egyptian fractions effectively went extinct and the use of common fractions in science started to recede.

It is worthwhile tracing into modern times the Wittgensteinian strand of decimals that entwines with the DMSS threads. Al Uqlidisi's *Arithmetic* is the earliest known Arab work that discusses decimal fractions and uses a notation similar to ours. Decimal arithmetic had evolved in Chinese and Indian cultures centuries before Al Uqlidisi and long before transmission to Europe. However, the efficiency and power of this arithmetic did not seem to be broadly appreciated in Europe until Simon Stevin published his influential pamphlet *De Thiende (The Tenth)* in 1585.

Significantly, Stevin, like Al Uqlidisi, modeled his development of decimals after the DMSS system. Stevin called each tenth part of unity a *Prime*, denoted with a ①,

each tenth part of a Prime a *Second* (denoted with a ②), each tenth part of a Second a *Third* (denoted with a ③), and so on. He would write 27.843 as 27⓪8①4②3③. Thus, in the words of Stevin, decimals consisted "*in characters of ciphers, whereby a certain number is described and by which also all accounts which happen in human affairs are dispatched by whole numbers, without fractions or broken numbers*" (Stevin 1608, First Definition).

Like Ptolemy's comparison of DMSS to Egyptian fraction arithmetic, Stevin lauded the simplicity of decimal computation over common fraction representations and computations. However, he recognized an advantage of common fractions. When reducing a compound measurement to a measure number with a single unit, such as *1 foot 7 inches* to *1* $\frac{7}{12}$ *feet* instead of *7.5833 feet*, common fractions had an advantage. But Stevin viewed this advantage as temporary and predicted sovereigns would eventually adopt measurement systems wherein the units formed progressions of powers of ten, paralleling decimal numeration. The French adopted the metric system a hundred years later.

It bears mentioning that Stevin, contra Euclid, believed number, and hence decimals flowed in a linear *continuum*. But Europe would have to wait for Descartes and Wallis in the seventeenth century before a real number line model was clearly articulated, particularly one that included negative and positive numbers. With his conveyance of the DMSS into the realm of decimal fractions, the symbols in a decimal suggest a conventional compound measurement in generalized, tens-based units analogous to degrees, minutes, and seconds. This conception of decimals is echoed in the research of Wearne and Hiebert (1988) where base-10 blocks, money, and metric measures provide the referents for decimal numerals. Interestingly, their research has shown such compound-measurement thinking benefits the semantic processing of decimal notations by fourth graders, leading to better abstraction of decimals as measure numbers.

4.2 Rational Expression Arithmetic

The second "arithmetic" that emerged in Alexandria, and practiced by Diophantus (200–284 CE), made use of "algebraic" reasoning in an arithmetic of numerical expressions containing one unknown. A close look at Diophantus' works reveals that many of the problems he investigated were likely drawn from subscientific traditions (Høyrup 1989) and shared by a diverse community of mathematicians for whom his work was definitive. Consider Problem 36 of Book IV (Heath 1910, 194; Christianitis 2004, 334–335): *To find three numbers such that the product of any two bears to the sum of those two a given ratio.* Diophantus knew that his trove of find-the-numbers puzzles typically had multiple solutions, but he would only offer one. He represented each problem in terms of one unknown number, which we might call "*x*" or "the unknown," and proceeded to reason algebraically, stipulating restrictions until he reduced the problem to a single equation.

In the above problem, Diophantus starts by stipulating that the product of the first and second numbers is three times their sum, the product of the second and third numbers is four times their sum, and the product of the first and third numbers is five times their sum. He designates the second number as his unknown, and therefore, the first number equals *three of the unknown in part of the unknown less three units*. In modern notation, where the first, second, and third numbers are denoted by *f*, *x,* and *t*, he is saying $f = \frac{3x}{x-3}$, and similarly, $t = \frac{4x}{x-4}$. Therefore, since the product of the first and third is five times their sum, $\frac{3x}{x-3} \times \frac{4x}{x-4} = 5\left(\frac{3x}{x-3} + \frac{4x}{x-4}\right)$.

For most of its history in Alexandria, "*2 in part of 7"* or "*of 2 the 7th part*" connoted not only Ahmosé's "*2 quantities each of partsize* $\frac{1}{7}$*,"* meaning an unsized "heaping," but also an *unclosed* operation of *2 divided by 7*. (Either way, in Alexandria, the closure was $\frac{1}{4}\ \frac{1}{28}$.) Because Diophantus was immersed in an arithmetic involving unknown numbers, closure was not an option. Therefore, he had rules for unclosed operations involving expressions in a single unknown number, analogous to *rational expression* arithmetic taught in high school algebra courses. Accordingly, he applies a rule for multiplying unclosed divisions to get $\frac{3x}{x-3} \times \frac{4x}{x-4} = \frac{12x^2}{x^2+12-7x}$. He then applies another rule to get $\frac{3x}{x-3} + \frac{4x}{x-4} = \frac{7x^2-24x}{x^2+12-7x}$. Thus, x must satisfy $12x^2 = 5(7x^2 - 24x)$, which he solves to get *120 in part of 23*. He is content with this answer, instead of closing it in the Alexandrian manner to get $5\frac{1}{6}\ \frac{1}{46}\ \frac{1}{69}\ \frac{1}{92}\ \frac{1}{276}$, a result so unsightly that it evokes an image of Diophantus concurring with Ptolemy's ghost on the inconvenience of Egyptian fraction divisions.

Was Diophantus participating in an established tradition of common fraction arithmetic? This is a disputed question (Christianitis 2004, 331–335). He clearly thinks the unit is divisible and that Egyptian fractions are numbers. He also thinks that unclosed divisions and unclosed heapings of addends determine unique numbers. However, there are several aspects of his work that increase prospects of the narrative stopping here, and not implying the embrace of a system of common fractions by Diophantus or by the mathematical literati of Alexandria.

First, in his solution to the above problem, Diophantus felt compelled to explain to his mathematical audience his rule for adding two unclosed divisions. Thus, after indicating $\frac{3x}{x-3} + \frac{4x}{x-4} = \frac{7x^2-24x}{x^2+12-7x}$, he explains: $\frac{3x}{x-3} + \frac{4x}{x-4} = \frac{3x(x-4)+4x(x-3)}{(x-3)(x-4)}$. This detour shows that Diophantus possessed a rule for adding rational expressions, and, ipso facto, a rule for adding common fractions. It also suggests that this rule was *not* very familiar to his mathematical audience, or he would not have mentioned it.

Second, Diophantus often expressed *m in part of n* with the shorthand notation m^n, a notation scheme for unclosed divisions that had been in use in Alexandria for several centuries by people who apparently were thinking in terms of Egyptian fractions (Fowler 2004, 370–371). Diophantus usage seems no different in this regard (Fowler 2004, 371fn). In his rare use of the mixed numeral form, he used Egyptian fractions. For example, he would express *6041 in part of 16* as $377\frac{1}{2}\ \frac{1}{16}$.

To summarize, it seems that Diophantus' arithmetic of rational expressions in one unknown was not a generalization of an undocumented practice of common-fraction arithmetic in the Hellenic world. Indeed, the historian David Fowler (2004, 368),

after an extensive review of primary sources, concluded: "*Nowhere do I find any convincing evidence for the proposal that 'the Greeks' used anything like our notations for common fractions and our ways of performing fractional arithmetic."* The earliest documentable prototype of common-fraction arithmetic is found in the Chinese bamboo text *Suàn shù shū* (Cullen 2007) circa 200 BCE. Diophantus evidently grasped the concepts underlying the operational rules of division that would eventually govern common fraction algorithms. However, these algebraic rules used in solving equations may well have been discovered through reasoning about unclosed divisions, invoking properties of reciprocals known and transmitted through subscientific traditions since Old Babylon. So, while Diophantus could operate with m^n expressions as if they were common fractions, it seems to be a pattern in the history of mathematics that concepts are often exploited long before their reference potentials are delimited with names and notations in mathematical definitions, and before they are constrained by systemic properties in rules or axioms (Kitcher 1984, 187–203). Hence, the most we can probably say about this second Alexandrian arithmetic, rational expression arithmetic in a single unknown it is, and common fraction arithmetic it is not.

5 Interweaving the Three Tales with Current Strands

5.1 Measurement Systems and Decimals

The Old Babylonian scribes were very proficient with the arithmetic of measure numbers, including highly precise calculations involving irrational numbers. They did this without the use of anything like common fractions or even Egyptian fraction arithmetic, a system they likely had encountered by Ahmosé's time. *The Babylonian experience suggests that decimal fluency does not depend on common fraction fluency, whether speaking mathematically, psychologically, or pedagogically.* It also suggests how the semantical underpinnings of decimals diverge from those of common fractions. They share cognitive roots in equi-partitioning and unitizing, leading to measure numbers in a single unit. But from there the semantics of decimals, like the sexagesimals of Old Babylon, is situated within that of *ideal measurement systems* and abstracts the sense of a conventional compound measurement as an enumeration according to a decreasing sequence of groupings in a single conversion ratio. Not so for common fractions.

When one thinks of a *system* of measurement like the apothecary pounds, ounces, drams, scruples, and grains, one appreciates that in this system the smaller units are divisors of all the larger units, but one frowns at the plethora of conversion ratios: 1: 12, 1:8, 1:3, and 1:20. More ideal are systems where the conversion ratios in the progression of units are a constant, like 1: 60 in the case of the DMSS system or 1:10 in the metric system. In the conceptualization of its groupings (tenths, hundredths, tens, hundreds, etc.), decimal semantics is thus rooted in an *ideal* measurement system whose powers-of-10 place values resemble units *used in actual metrologies*, where conversions of measurements to equivalent measurements are easily imagined

and comparisons of size easily established. Decimal operations and algorithms can thus be made very transparent as natural extensions of whole number operations and algorithms, but not without subtleties related to the uses of 0 and the decimal point.

Common fractions have a more abstract relation to actual measurement systems and processes. Smaller unit fractions are typically not divisors of larger unit fractions and typically have no correspondence with units used in actual measurement systems. Indeed, unit fractions seem like a counting system of general units where successive units differ by one in the denominator, obscuring not only the notion of equivalence, but also the associated conversion and comparison processes. This is reinforced when, in the effort to build conceptions of common fractions as a system of measure numbers, emphasis is placed on students creating equi-partitions of geometric figures and discrete sets to represent artificial measurement systems inhabitable by arbitrar*y* unit fractions. In these dissections, it is left to the student to "unitize" a component that they can count to create a measure number. To represent operations with their diagrams, students must then use highly variable, compound dissections with visual units merging to form other visual units. The sense of measurement by a decreasing sequence of units might easily be lost in all of this, particularly its approximate nature wherein the count of the final unit in the sequence is an estimate.

5.2 Common Fractions and Algebraic Reasoning

The best algebra of the Bronze Age, a notable algebra at that, was being done in Babylon with sexagesimals and geometrically based identities of area and length, without common fractions. More pertinently, Diophantus' story demonstrates that *algebraic reasoning about rational expressions does not depend on prior common fraction algorithmic competency, or even common fraction representations of fractional measures.* It also suggests that, once the connection is made between common fractions and the division operation in the elementary grades, proficiency in common fraction operations and algorithms can be developed much later as part of operating on real number fractions and rational expressions in a real variable, semantically anchored in the properties of the division operation. Indeed, after listing the usual "Why?" questions people have about the unique features of common fraction algorithms and their justifications, Lortie-Forgues et al. (2015), 208) explain: "*All of these questions have answers, of course, but the answers are not immediately apparent, and they often require understanding algebra, which is generally taught after fractions, so that students lack relevant knowledge at the time when they learn fractions and might never learn how algebra can be used to justify fraction algorithms after they gain the relevant knowledge of algebra*."

It is worth noting that the Dolciani high school algebra textbook series, perhaps the most popular textbook series in the USA between 1963 and 1986, derived the operational rules of rational expressions in real variables using carefully scaffolded lessons, while citing only token examples of common fractions to illustrate (and certainly not to validate) the rules. The derivations were simple and based on

assumptions about multiplicative inverses, i.e., reciprocals, and not common fractions, thereby supporting the notion that Diophantus might have derived his rules for unclosed divisions in a similar fashion (Dolciani et al. 1982).

5.3 The Number Line, Measure Numbers, and Precision

In one sense, as we survey the history of number, measure numbers were the result of successive abstractions from evolving measurement systems, often involving multiple numeral palettes depending on metrology. With traceable threads of meaning, this evolution connects our specie's earliest measurement systems to the very notion of "measure space" encountered in courses on real analysis. The notion of a measure space assumes two things, an underlying set of measurable quantities or magnitudes and a measure function assigning a size (a representation or description in terms of known quantities) to each measurable quantity.

For most historical measurement systems that evolved arithmetized fractional numbers, when a compound measurement was reduced to a single measure number in a single unit, the measure number *sized*, in a manner compatible with the particular historical system, the ratio of the quantity to the known quantity expressed by the unit. Therefore, the measure function connects to the idea of a *ratio scale*. Some measurement devices like rulers, spring scales, and graduated cylinders provide a visual sense of ratio scales that pair measurable quantities to measure numbers. All ratio scales have an origin, a unit, a built-in linear ordering of (quantity, size) pairs, and a gradation system that assumes the ratio of two quantities being measured is proportional to the ratio of their gradation-based numerical measures on the scale.

The historical development of the real number line can thus be characterized as an abstraction of an ideal ratio scale of measurement, *the ideal ruler* so to speak. It was not, at least in Western traditions, a generalization of the system of rational numbers. Indeed, the ancient Greeks discovered that the ratio of the diagonal of a square to the side of the square is inexpressible as a ratio of two counting numbers. This implied that counts of a fixed unit, and its n^{th} parts, were inadequate for the task of expressing the exact sizes of the magnitudes on a continuum with that unit. Simply put, ratios of integers, the precursors of rational numbers, fail to fully capture the essence of measure. Instead, the Eudoxian theory of proportions, commencing in Book V of Euclid, heralds the beginning of Greek measure theory and uses ratios of lines to represent the ratio of magnitudes.

A century after Simon Stevin, measure numbers on a ratio scale, like the DMSS scale, were being abstracted as real numbers in a linear continuum. Like the particle-wave duality of quantum objects, this abstraction supports the notion that a real number is a point on a graduated line and the notion that a real number is the address or "coordinate" of such a point. Perhaps the duality of perspectives can be bridged by simply saying a *real number* is a point on a number line, and an infinite decimal is an *idealized decimal measure number* associated with a point on a *decimal-scaled* number line. Both perspectives are important.

It is easy to get lost in arguments about what a real number is and forget the fundamental raison d'etre of real numbers, i.e., measurement. Long before the Greeks, ancient cultures were aware that physical measurements of continuous quantities were intrinsically approximate. Therefore, an important consideration in differentiating decimals and common fractions when taken as measure numbers is their pliancy in representing all real numbers, in computing-derived (indirect) measure numbers, and in determining the precision of derived measure numbers obtained from calculations.

Long ago, Ptolemy appreciated the infinite pliancy of the DMSS system for the indirect calculation of the chord sizes in his trigonometric table. Similarly, in modern school algebra, where the focus is on reasoning with continuous quantities, functions, and graphs, the Dolciani Modern Algebra Series chose to introduce real numbers using an infinite decimals approach, even stating a completeness axiom stipulating all real numbers have a decimal representation and all decimals represent real numbers. This was not a rational number approach, along the lines Richard Dedekind defined in the nineteenth century (Dedekind 1901) and was pedagogically speaking the better choice. While the notion of infinite decimals at first seems daunting, children encounter infinite decimals by necessity in the earliest grades when they attempt to complete simple long division problems of whole numbers or convert even the simplest common fractions to decimals. Furthermore, science instruction at the precollege level for the most part uses decimals for measure numbers, usually with metric units, and relatively simple "significant figure" rules for roundoff precision, testifying to the efficiency of decimals in deriving measure numbers and in determining the precision of such derived numbers.

In summary, history reveals that the real numbers grew from the needs of measurement, leading to the theories of geometric measure and to the algebra of operations needed for the indirect calculation of measures used in sciences like Ptolemy's astronomy, where exactness demanded better number tools. Although all physical measurements of continuous quantities are approximate and their associated measure numbers usually can be regarded as *rational*, the real number system was not abstracted from a defined system of rational numbers but was rooted in Euclidean measure theory and even more ancient traditions.

6 Collecting the Threads and Tying the Present to Its Recent History

6.1 A Current State of Affairs

In 1989, the National Council of Teachers of Mathematics (NCTM) lent its weight to the fledgling standards movement in the USA. Not afraid to challenge the status quo, the Council published its rather bold *Curriculum and Evaluation Standards for School Mathematics.* Unlike CCSSM, NCTM did not provide specific grade-level performance expectations. It set general goals for broad grade-level bands. The *Standards* did pronounce some controversial value statements in the form of topics

deserving increased or decreased attention. One topic designated for *decreased* attention in grades K-4 was "Paper-and-Pencil fraction computation." In grades 5–8, regarding common fraction operations, NCTM recommended mastery of a small number of basic facts, like $\frac{1}{4}+\frac{1}{4}=\frac{1}{2}$, and that proficiency in operations be limited to fractions "*with simple denominators that can be visualized concretely or pictorially and are apt to occur in real-world settings*" (NCTM 1989, 96). Many state supervisors of school mathematics, who were members of NCTM, used the NCTM Standards as a template for developing the standards in their own states during the 1990s.

In many respects, the CCSSM movement was a reaction to NCTM's 1989 standards, as well as state officials grappling with *No Child Left Behind* calls for grade-specific expectations and assessments. Like the New Math movement, much of the leadership behind CCSSM came from well-intentioned university mathematicians (Høyrup's scientific tradition) concerned about the failure of the elementary curriculum (subscientific tradition) to prepare students for algebra. Indeed, these deficiencies were at the heart of the National Mathematics Advisory Panel (NMAP) Report, which stipulated that all children should successfully complete the equivalent of Algebra II in high school. CCSSM embodies the changes called for in the Panel's Benchmarks (NMAP 2008, 20) by making fluency with common fraction operations and algorithms the most urgent (NMAP 2008, 18) of the three pillars identified by the Panel in the *critical* foundation of algebra.

While recommendations can be inspiring, actual assessments of student achievement are far more sobering. The 2019 National Assessment for Educational Progress (NAEP) revealed that mathematics scores for fourth and eighth graders have essentially flatlined since 2009, the year before CCSSM emerged as the dominant standards in the USA. In NAEP 1978, only 24% of eighth graders tested chose 2 as the whole number closest to $\frac{12}{13}+\frac{7}{8}$ when given the options 1, 2, 19, 21, and "I don't know." Lortie-Forgues et al. (2015), 202) posed this same item to 48 eighth graders enrolled in an algebra course in an affluent, suburban middle school, which had based its curriculum on CCSSM since 2010:

> In 2014, 27% of the 8^{th} graders identified '2' as the best estimate of $\frac{12}{13}+\frac{7}{8}$. Thus, after more than three decades, numerous rounds of education reforms, hundreds if not thousands of research studies on mathematics teaching and learning, and billions of dollars spent to effect educational change, little improvement was evident in students' understanding of fraction arithmetic.

The difficulties children in the USA have in mastering common fractions has been well known for several hundred years. Young adults are faring no better. Kloosterman (2010, 50), reporting on trends in NAEP data for 17-year-olds between 1978 and 2004, notes the percent correct declined from 66.7% to 45.3% on the item stated as "$3 \times 2\frac{1}{3} =?$" The decline typified all the common fraction items he was given access to. Kloosterman concluded: *"This makes sense given that exposure to common fractions outside of school is decreasing, whereas exposure to decimals fractions outside of school is increasing."*

Kloosterman is not the first to notice the decline, if not outright extinction, of common fractions in the world around the child. (A similar phenomenon is being noted by NAEP with regard to certain reading skills in the age of video and cell phones.) With metric tools and digital everything, the objections of the trade guilds to this extinction claim are not compelling. STEM professionals also object, but their counterexamples generally exist in the technical milieu of *real number fractions*, which include both rational and irrational fractions. Such STEM examples are critically important, but translating them into a deferred gratification argument justifying the CCSSM approach has serious problems, one being the "Free" in "Land of the Free" and another being the L.P. Benezet refutation of deferred gratification arguments.

Consider first the "Free." NAEP data is unsettling to some because students in East Asian countries fare much better on common fraction literacy. This was certainly on the minds of the National Mathematics Advisory Panel when it made its recommendations in 2008. However, if history reveals anything, it is that culture, geography, and social traditions matter in the mathematical values and practices of a people. Local control is part and parcel of the history and social fabric of education in the USA. *One might, by analogy, mention the same phenomenon of local control when assessing the outcomes of this nation's response to a pandemic in comparison to East Asian countries.* Indeed, once the CCSSM standards became "national" in 2010, the political blowback was substantial. Ultimately, local control translates into an enlarged role for parents and students in curriculum decision-making, in contrast to highly centralized educational systems. Indeed, according to some experts, parents and students might play the most important role (Klein and M. 1991). NAEP suggests how American students and parents are casting their ballots vis-à-vis the learned curriculum. To most of them, except for the most basic examples like a half and a fourth, common fractions are *hidden numbers*, absolutely of no use, and never encountered outside the classroom.

Though well written and the source of many improvements (e.g., nicely coherent learning progressions and minimal redundancy from grade to grade), CCSSM has not helped the situation by making common fraction computational fluency perhaps *the central imperative* of the K-6 elementary curriculum. In the CCSSM K-6 standards, the words *whole number(s)* and *integer(s)* appear less than 100 times; the words *decimal(s)* and *decimal fraction(s)* appear about 33 times, while (common) *fraction(s)* appears over 180 times! Decimals are defined by common fractions. Consequently, initial decimal experiences of students, instead of being grounded in measurement, presumably involve much work relating decimals back to their fraction definitions, operations, and notations, thereby creating a dependency of decimal understanding on a student's common fraction understanding, which all too often is fragile.

In a logical/structural sense, decimals can be defined by common fractions, and decimals algorithms can be viewed as simple corollaries of common fraction algorithms within CCSSM's well-thought-out common fraction development. But if we believe Morris Kline's (Kline 1974, 100) critique of the New Math of the 1960s, an earlier attempt by the scientific tradition to rigorize elementary

arithmetic, such structure "*cannot be significant (to the child) at this stage*." If anything, the history of mathematics surveyed above suggests the claims of the National Mathematics Panel about the critical pillars of school algebra need qualification. Furthermore, research by Hiebert, Wearne, and others clearly articulates the deep complexity of developing decimal competency, regardless of any work on common fractions.

This leads to "The Story of an Experiment" (Benezet 1935), an article which Harvard mathematics professor Dr. Andrew Gleason found so interesting that he shared it with many, including this author. Gleason is mentioned because he was a mathematics editorial adviser of the very popular Dolciani Modern Algebra Series previously mentioned and because he directed the Cambridge Conference of research mathematicians who met in 1963 to produce a set of recommendations, which will be discussed later, titled *Goals for School Mathematics*.

In 1924, Benezet was the superintendent in Manchester, New Hampshire, facing a crisis wherein 20% of the first graders were not promoted to second grade because they had failed arithmetic. *This was particularly pronounced in minority schools with immigrant families who often spoke limited English.* After many informal assessments in the district's schools, in which he asked children quantitative reasoning questions often dealing with fractions and rates, the embarrassing results of traditional instruction convinced half of the schools in the district, particularly the minority schools, to eliminate formal arithmetic until sixth or seventh grade (no use of primers, algorithms, etc.). They were, instead, to focus on relevant quantitative reasoning tasks, mediated by *math talks,* in all subjects taught. Benezet (Benezet 1935, 2410) wrote: *"... we waste much time in the elementary schools, wrestling with stuff that ought to be omitted or postponed until the children are in need of studying it...The whole subject of arithmetic could be postponed until the seventh year of school and it could (then) be mastered in two years by any normal child."*

After pre- and post-testing the children from the four experimental schools that resumed the use of primers in the sixth grade, the results were compelling. Upon entering sixth grade, the experimental children, who had yet to learn standard operation algorithms for whole numbers, fractions, and decimals, were far behind the traditional classes. By the end of the year, on the arithmetic skills expected of sixth graders, which included common fraction proficiency, the experimental students performed just as well as the traditionally trained children and were more fluent and confident in their thinking about numbers and operations.

Perhaps Benezet was a bit underhanded using fraction and rate problems in his demonstrations that something was amiss in his Manchester School District's elementary mathematics curriculum. But he at least deserves credit for making one question the traditions of that curriculum regarding common fractions and the demand for early fluency in fraction algorithms, *particularly the recurring negative effects of this curriculum on certain populations within school districts.* For that reason, several cursory remarks must be made about the history of the American precollege curriculum.

6.2 Observations from Recent History

At the end of the nineteenth century, according to Snyder (1993), the typical school district in the USA had 144 days in its school year. The typical student attended class 99 of those days and nearly completed eighth grade, with great disparities due to race and gender. (The typical black male completed fifth grade while the typical white male completed eighth grade.) Between 1800 and 1900, these numbers were much smaller, including length of school year and attendance levels. In 1900, few Americans completed a course in algebra or geometry and only about 7% ever graduated from high school. Algebra was considered utterly abstract and intended as a mental discipline for the college-bound, which was very few students.

To say the least, during the nineteenth century and early twentieth century, arithmetic was the terminal mathematics course for the vast majority of students, and it was designed to be just that: "to prepare the young for the common avocations in life" (Greenleaf 1845, Preface). It is worthwhile exploring samples of arithmetic texts written in English from the seventeenth to the twentieth century to gain a better appreciation of this goal. (See *Resourceaholic* in References.) As their terminal mathematics course, children encountered substantial work with compound numbers, fractions, and decimals. The diversity of measurement units in common use required fractions when expressing a compound number in terms of its largest unit. *Importantly, common fraction fluency was not intended nor generally thought of as an essential foundation for algebra.*

In the twentieth century, high school populations gradually expanded, especially during the Great Depression. By the mid-twentieth century, the surge of enrollments in colleges, driven by the G.I Bill, and the calls for universal high school graduation led to the reevaluation of the high school curriculum as a preparation for college. Mathematicians of prestigious universities became involved in the goals and redesign of secondary school mathematics as a preparation for college. Such efforts as the *University of Illinois Committee on School Mathematics*, founded in 1951, and the 1958 AMS *School Mathematics Study Group* began to produce sample high school text materials, eventually morphing into a K-12 reformation known as the *New Math* movement, which barely lasted into the 1970s at the K-8 level before being driven "Back to Basics."

A report produced at the time, the Goals for School Mathematics (1963), was distributed among mathematicians and mathematics educators at universities, across the country, but received little acclaim in part because its stated purpose was to be futuristic, which it definitely was. However, the report is pertinent. Dr. William Martin of MIT and Dr. Andrew Gleason of Harvard cochaired the four-week conference. Most participants were well-known mathematics researchers from prestigious American institutions. The purpose of the conference was to produce a coherent and radical set of long-term goals for K-12 mathematics.

Section 5 of the report is devoted to the K-6 mathematics curriculum. The first sentence of the section captures the spirit of their recommendations. "*As we have indicated above, the objective for mathematics instruction in the elementary grades*

[K-6] *is familiarity with the real number system and the main ideas of geometry.*" The report goes on to emphasize the following:

- Early use of the real number line in the context of much measurement activity.
- Reasoning with inequalities and "considerable" experience with approximations, including the effects of "round off" and significant figures.
- Fractions with small denominators to name additional points on the number line.
- "explicit study of the decimal system of notation including comparisons with other bases"
- Study of decimals for rational and irrational numbers.
- Early focus on mathematical properties of real number system with algorithms coming "considerably later in the curriculum".
- Study of geometric transformations, symmetries, and similarity of figures.

What is very clear in the report is that the real numbers, the properties of their operations, the number line, measurement, decimals, and the geometry of transformations and similarity are dominant in the vision of the Cambridge Conference for the elementary curriculum. Common fractions can help to populate the number line but seem otherwise not to be emphasized. Fluency with common fraction operations and algorithms is clearly not a "critical" priority, and possibly not even a goal of these K-6 recommendations of professional research mathematicians.

The back-to-basics movement in the 1970s pushed common fraction fluency back into the forefront of the elementary curriculum, until the ascendancy of the NCTM 1989 Standards and various systemic reform efforts of the 1990s seemed to stall the trend. But the backlash to the NCTM Standards and the related curricula spawned by systemic reform efforts was severe. As already mentioned, the CCSSM doubled down and firmly embedded fluency with common fractions and their standard algorithms as perhaps the central imperative of the K-6 curriculum. Along with the National Mathematics Panel pronouncement about the critical foundation of algebra, CCSSM lent weight to the sense that the tradition of early common fraction fluency was a *mathematical imperative*, a status it had never previously had in American education. While lifting the burden of very large denominators, the CCSSM common fraction standards lock in, among several newer practices, the traditional computational practices of the decades before the "New Math." So, while many in the country claimed the CCSSM standards were enforcing a national curriculum and stepping on states' rights and local control, the CCSSM standards, except for nominal changes in branding, remain the standards in nearly all states. One reason, not surprisingly, may be that the CCSSM demands for fraction and decimal computational fluency using standard algorithms have strong appeal to many adults based on long-standing American traditions.

Nonetheless, states are hard-pressed to enforce standards when faced with the low performance of their students on recognized exams like NAEP and the lack of improvement, if not the outright decline in the performance of a large portion of their students on topics emphasized in their standards, like common fractions. Local control is exercised at many levels, and state intrusions into the affairs of school

districts have their limits. Even with state backing, CCSSM advocates are now, after a decade of implementation, facing growing concerns by parents and local educators. These CCSSM advocates are resorting to calls for patience (Goldstein 2019). Though painted with sweeping strokes, this story of epicyclic motion within the thinking about common fraction fluency in American elementary education is salient.

6.3 Other Voices of Note

In his essays on *Measure of Magnitudes* published in a series between 1931 and 1935, Henri Lebesgue (1966) introduced a construction of the real numbers as infinite-decimal measures of segments on a number line. He sought to illuminate a pathway for the precollege curriculum to develop the real numbers while passing over the study of common fractions.

> "But would we still speak of fractions at the primary level or in the first two grades of the secondary level? No, since this is not essential for the theory and serves no practical purpose. I believe that people will agree with me when I say that performing operations on twenty-seconds and thirty-sevenths is a martyrdom that we inflict on twelve-year-olds out of pure sadism without any justification based on usefulness as an extenuating circumstance. Yes, I know that by searching hard, one can find certain "applications" of fractions, that certain mechanics make calculations with their fractions in cutting threads on screws. . . . ."

> ". . .The reform would be effective if we agreed to have the children no longer study two kinds of numbering, namely, numbering in terms of n^{ths} for commensurable numbers and the decimal numbering system, that is if we permitted them to answer 0.428 where the answer is 3/7."

> *"True, a divided by b or a/b is still read "a b^{ths}" when a and b are integers, but this way of speaking no longer compels us to develop the entire theory of fractions any more than the word quarte-vingt-douze [French word for 92, literally "four-twenty (plus) twelve"] compels us to study the numbering system with base twenty."* (Lebesgue 1966, 31–32)

Lebesgue's views impacted the Cambridge Conference thinking. They also influenced Russian psychologist V. V. Davydov and his colleagues as they developed an elementary curriculum based on measurement and the real numbers. The Davydov curriculum provides an existence proof that the elementary curriculum can embody the core recommendations regarding real numbers and fractions found in the Cambridge Conference Report and build real number arithmetic from the fundamental notions of measurement. One of the overarching principles Davydov (1975, 113) drew from Lebesgue is stated as follows:

> *But what this means in terms of curriculum design is no less than an end to the arithmetic of fractions as it is interpreted in the school. The shift from whole numbers to real numbers is a shift from arithmetic to "algebra," to laying the foundation for analysis.*

The first half of Davydov's first-grade curriculum starts with comparing, composing, and decomposing continuous quantities of the same kind, without numerical

associations, while identifying measurable traits like volume and area and mass, and representing their actions on quantities symbolically and with lines. Children thereby develop algebraic relations of equality and inequality between composed and decomposed *prenumeric* quantities represented in symbols and on a linear scale, akin to the properties of general magnitudes investigated by Euclid (e.g., if a, b, and c are magnitudes of the same kind, $a > b$ implies $a + c > b + c$).

Only near the end of first grade are numbers introduced as multitudes of units by using tokens or tally marks to communicate the amount of a unit in a measurement, based on a 1–1 comparison. Counting numbers are then introduced as a sequence of names for those multitudes of units. As with the prenumeric quantities, the focus of work with numeric quantities is to develop algebraic relations of equality and inequality between composed and decomposed quantities, but this time akin to the properties of multitudes of general magnitudes investigated by Euclid. (E.g., if m is a number, i.e., "multitude of unity," then $m(a + b) = ma + mb$.) On this foundation in the first grade, Davydov proceeds to expand his arithmetic of measure numbers, as he said, in a shift toward algebra and analysis.

Davydov's curriculum is sometimes classified as "early algebra" because of its early use of algebraic symbolism to express general patterns encountered by students in attempting to solve problems of measurement and quantity. The teacher's role in this is not a case of handing students fully baked a priori abstractions, but more akin to providing words and symbols for patterns children have exploited in their problem-solving activities as well as guiding them in stipulating the general scientific principles governing those patterns. In this regard, Davydov's Vygotsky-based social constructivism seems to be following the historical roots of mathematical learning as described in Kitcher's constructivist epistemology.

Informative examinations of the philosophical/pedagogical details, the mathematical foundations, and the successful classroom implementations of Davydov's curriculum can be found, respectively, in Schmittau and Morris (2004), Bass (2019), and Dougherty (2008). Dougherty's words deserve mention here. Summarizing the *Measure Up* (MU) Project, a longitudinal experiment immersing elementary children, regardless of prior achievement or "ability level," in a modified Davydov curriculum, she concludes:

> *An approach to elementary mathematics that focuses on non-specified, generalized quantities is often thought to be too abstract and thus, not accessible by young children. MU preliminary results, however, support Davydov's claims that it offers young children a meaningful foundation on which to build sophisticated and complex mathematics. Understanding the structure and properties of mathematics creates a way for children to construct solid underpinnings that lead to substantive mathematics. . .It builds confidence so that even within non-routine or unfamiliar situations, children can reason through the relationships in the problem.* (p. 411)

Davydov's approach is but one possible development of elementary mathematics on the basis of measurement and the real numbers without passing first through the gauntlet of common fraction operational fluency. Significant approaches to the elementary mathematics curriculum centrally founded on measurement, and not on

common fraction fluency, have already been developed and studied in this country, such as *Developing Mathematical Processes* (Romberg 1977). It seems reasonable that similar approaches to real number numeracy will prove more than viable if given a chance for development.

7 Conclusion

7.1 Suggestions for Consideration

The historical strands surveyed above underline the significant cultural variations in the fundamental concept of *measure number*. Indeed, successive abstractions employed in the human effort of expanding number to include the "continuous number domain," i.e., the real numbers, led Richard Dedekind to philosophize: *Numbers are free creations of the human mind; they serve as a means of apprehending more easily and more sharply the difference of things.* (Dedekind 1901, Preface to First Edition). This general portrayal of number is quite appealing as a summary of number's social history.

Since the time of Plato and Euclid, the final stages of a mathematical creation in the scientific tradition have been those of stipulation and systematization, with definitions and axioms. In the context of education, Poincaré (1952, 116) cautions as follows:

What is a good definition? For the philosopher or the scientist, it is a definition which applies to all the objects to be defined, and applies only to them; it is that which satisfies the rules of logic. But in education, it is not that; it is one that can be understood by the pupils.

So, if we are to believe Poincare and Dedekind, a major goal of the elementary curriculum, per the Cambridge Conference Report, is to guide students, brief stipulation by brief stipulation rooted in experimental facts, to a good definition of the continuous number domain. The task of pedagogy is to assure this is done with understanding and in a way that allows students to recognize that this free creation truly helps them in "apprehending more easily and more sharply the difference of things" *in their world*. To the child first developing understanding of magnitude, number, and measurement relationships, the *things* are in their physical environment, not simply the "manipulatives" used in school, and in the world of quantities and comparisons invoked by their parents and by their social groups.

In Kitcher's philosophy, the mathematical reality of the "ideal human subject" is clear: It resides in the "ings" of mathematical practice, ontologically and epistemologically prior to the "ions"; e.g., abstract mathematical notions like *collection* are derived from idealizations of mathematical activities like *collecting* (Kitcher 1984, 110). Constructivist philosophies in education are consistent with this view: The protomathematical learning of children is located in reflective operating on their world. To engage reflectively, their actions must be purposeful. By way of an analogy whereby numbers are paints on a palette, painting a picture of an actual object or scene chosen by the child with *a palette of colors actually visible in the*

setting is usually more purposeful than a painting-by-the-numbers of an artificial, random scene handed to them and using colors that are never seen. Curriculum standards must pay attention to this.

For years, educators involved with the learning issues surrounding minority students have called for curriculum practices that reflect relevant community, cultural, and social purposes in the learning activities of these students (e.g., Educating American Indian/Alaska Native Elementary and Secondary Students 1995). But such practices are needed by all students if they are to apprehend more easily and more sharply the difference of things actually in their world. Hence, given the near extinction of common fractions in the environment of the child, there needs to be a compromise between the thinking of the 1989 NCTM Standards and the 2010 CCSSM Standards. Here are some suggestions that hopefully can provoke discussions and lead to a better interface, with fewer epicycles, between the scientific mathematical tradition and the mathematical practices of elementary education in the USA.

1. (*Echoes of Ptolemy*) The real numbers are an appropriate milieu for all of school mathematics, starting in kindergarten. The decimal system, with its cognitive roots in the denominate thinking of ideal measurement systems and in the geometry of a number line, provides the appropriate numerical idiom. Properties of decimal operations can be developed by means of measurement activities and geometric definitions vis-à-vis the number line. Decimal algorithms can be developed from the very concrete compound measurement operations from which they arose historically without appeal to common fraction algorithms.
2. (*Echoes of Babylon*) Elementary school, through Grade 8, is the appropriate place to develop fluency in decimal operations and algorithms. Today's children live in a world of decimal numbers. Simple common fraction literacy, *without* the goal of fluency in standard fraction algorithms, is still a relevant backdrop at this level. However, with the place-value system, calculators, the metric system, and other decimal referents, such as percentages, commonplace in their environment, the potential is considerable for providing children with semantical support of decimals as measure numbers on a real number line.
3. (*Echoes of Diophantus*) Algebraic thinking can be developed throughout elementary school, particularly with the operational properties of real numbers; but the algebra of grades 8 through 10 is a proper setting for developing fluency in common fraction algorithms as a corollary of the broader development of real numbers and simple rational expressions. All young adults need this foundation for a world in which so many career options depend on mathematical literacy. Moreover, based on the recommended certifications practices at this level, teachers would be prepared to help students navigate the algebraic reasoning required.
4. (*Echoes of Benezet*) State standards must not preempt the advantage *responsible local control* can bring to education in America. Year by year, benchmarked proficiencies can entrench a well-intentioned but not ideal curriculum for generations, and stifle the resourcefulness exhibited by Superintendent L.P. Benezet in thinking outside the box to address serious learning challenges in local

environments. Regarding fractions, educational research (Moss and Case 1999) has found compelling evidence that the most effective progression for developing understanding of fractional measures is percentages – decimals – and then common fractions. Standards that are effectively national, like CCSSM, should not stifle such longitudinal approaches to curriculum experimentation.

7.2 The Lesson of Thebes

One of the important lessons of the tale of Thebes is the rather notable fact that the Egyptian fraction system survived untarnished for *many thousands* of years in even non-Egyptian cultures, well into the age of common fractions. It is a warning that the common-fractions-based, elementary curriculum, with its deep roots in American tradition, can outlive its usefulness for centuries, long after CCSSM standards are forgotten and regardless of the toll taken on large segments of the USA population. Looked at historically, the standards movement in the USA seems superficial when faced with the challenge of perturbing the deeper equilibrium of traditional practices. Even so, it is never too late to rethink what is being done. As Benezet discovered in his school district, *unnecessary* hurdles, like the demands of early computational fluency with common fractions, can only exacerbate inequities in the elementary education system and ultimately lead to very poor educational outcomes overall. This appears to be the case today. An agenda that prioritizes decimal number fluency and early algebraic reasoning, while delaying common fraction fluency, is a compromise that seems possible in spite of the stubbornness of traditional practices.

Abstract

Isaac Newton (1643–1727) is a polarizing figure in the history of mathematics (and science) because of the inordinate attention given to priority disputes with Hooke and Leibniz in his numerous biographies. Nevertheless Newton's *Opticks* endures and is remarkable for its adherence to the axiomatic style of classical Greek texts like the Elements. In this chapter, we examine influences in Newton's ensuing mathematical practices, and present examples of Newton's work which illustrate his genius and his place at the helm of the pantheon of natural philosophers. In particular, we examine Newton's use of arithmetic, his work on color, and his theory of light.

1 Sir Isaac Newton

Isaac Newton needs no introduction to the community of science. His name is ubiquitous with the force of gravity itself. There are scholars who specialize in Newton studies akin to those that do Leibniz studies, and numerous biographies that examine Newton's life and career. His work in mathematics, astronomy, and physics have provided fodder for centuries of scientific investigation culminating in advances in modern physics, construction of astronomical devices like telescopes, and last but not least initiating the modern view of the calculus of variations. This merely scratches the surface of the iceberg representing his entire body of work. No chapter can do justice to the scope and brilliance of Newton. Our attempt here is to delve into some of Newton's mathematical practices that systematically furthered the works of the ancient Greeks and ensuing generations of natural philosophers.

Sir Isaac Newton was born in Woolsthorpe, England, on December 25, 1642. He grew up separate from his mother (his father dying before his birth) and instead grew up with his grandparents after his mother remarried Westfall (2023). Newton was a reserved child, prone to potentially violent outbursts. He spent his time reading and learning, rather than being outside or with friends. After his grandparents passed in 1653, his mother insisted Newton move back in with her and eventually take over the farm and the estate. However, Newton wanted nothing to do with farm affairs, often reading on the job rather than watching the animals. His uncle saw that Newton not only preferred academia, but was incredibly good at it and convinced his mother to let him be enrolled at Trinity college in 1661 when he was nineteen Davidson (2015), Westfall (2023). After graduating, Newton was offered a professorship at the college teaching optics. Yet, Newton would not publish anything on optics for several years. Instead, during this time he developed his "method of fluxions" which would then become calculus Davidson (2015). However, Newton's fear of criticism would stop him from publishing his findings until Gottfried Leibniz published his own work independent of Newton. He accused Leibniz of plagiarizing his work, claiming himself as the sole inventor of calculus Davidson (2015), Westfall (2023). Newton's first published work came in 1672 when he presented some of his work light and color to the Royal Society. This began to form the basis for his optical treatise, *Opticks* Davidson (2015), which he published in 1702. Newton's *Philosophiae Naturalis Principia Mathematica* (often shortened to just *Principia*) was published in 1687. Newton's methods of calculus was hinted at in *Principia*, however, it would not be officially published until it was appended to a verion of *Opticks* in 1704 Westfall (2023).

Newton's advancements in science and mathematics were not constructed out of thin air. Newton build his developments from the works of those who came before him. Notably, he used the theory of proportions from Euclid's *Elements* to prove many of his works. These theories are thought to originate from Eudoxus and presented as a part of the *Elements* Joyce (1996). Euclid explains and uses proportions in the *Elements* to compare quantities of the same type through ratios. Magnitudes can only be proportional with other magnitudes. Likewise, areas can only be in proportion to areas, volumes to volumes, etc. Euclid expands on these

concepts too by introducing continued proportions to compare multiple quantities at once through a long ratio. Newton uses these concepts as a basis for his discoveries in both his *Principia* Wawrzycki (2021) and *Opticks*.

Newton's mathematical background goes beyond that of the Greeks. Newton had explored and read the works of many scientists and mathematicians as he studied and performed his experiments. This includes works written by Arab scientists, such as Alhazen who was one of the first people to work on telescopes Marshall (1950). Newton's intimate knowledge of various works allowed him to build his own theories which he proved (or at least attempted to prove) in his works.

Newton's philosophical background also allowed him reject popular philosophies at the time, including Aristotelian doctrine Albert (1997). Newton went against the popular Cartesian doctrine which emphasized hypoetheses, and instead argued for the use of analysis in his works, opting to prove his theories through experiments and observations rather than thought experiments Albert (1997). Newton wanted to support his science through mathematical arguments and observations. His adaptation of the "way of analysis" coupled with his mathematical background from the likes of the Greeks and the Arabs culminated in *Opticks* which became a stepping stone away from traditional natural philosophy and toward more modern scientific and mathematical research methods Albert (1997), Evans (1955).

2 *Opticks*: Book I

Opticks was originally published in 1704 and was published four times, with the fourth edition being published posthumously Davidson (2015). In it, Newton explained color, reflection, refraction, and diffraction. He did all this with what was at the time a new theory of light: he treated light as corpuscular (light is made of particles) Kumar (2006). The particle nature of light led to heavy use of geometry in his work. In fact, *Opticks* mimicked the set up and style of Euclid's *Elements*. The work begins with a series of axioms, followed by a series of definitions, and finally the propositions. Furthermore, *Opticks* is broken into three books, each with their own themes. The first book sets up the building blocks of optics and explains how light behaves in reflection and refraction.

Opticks is full of many interesting and useful propositions. For the scope of this chapter, however, only a few propositions will be examined both for their mathematical content and for their historical and modern relevance. Proposition VI, Theorem V in Part I of Book I states: "The Sine of Incidence of every Ray considered apart, is to its Sine of Refraction in a given Ratio" Newton (1730). This is a precursor to Snell's Law which states that $n_i \sin(\theta_i) = n_f \sin(\theta_f)$ where n_i is the index of refraction of the initial medium, n_f is the index of refraction of the second medium, θ_i is the angle of incidence of the initial ray, and θ_f is the angle of incidence of the final ray. Newton does not use the index of refraction, a property of the medium itself, in *Opticks* and thus could not derive Snell's law in its modern form directly using this method. However, Newton lays the groundwork by observing that the sines of the two angles form the same ratio when diffracted through the same pairs of

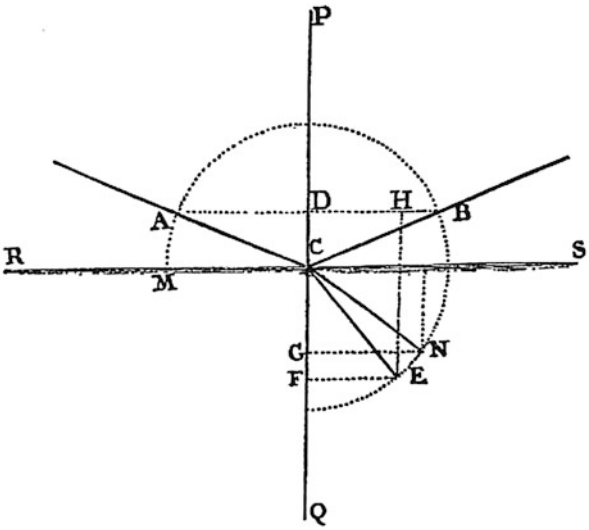

Fig. 1 The geometry behind Axiom V Newton (1730)

media. Newton uses his fifth axiom, "The Sine of Incidence is either accurately or very nearly in a given Ratio to the Sine of Refraction" Newton (1730) along with proportion and ratio properties from the *Elements* to prove this proposition.

Figure 1 is the diagram Newton uses to explain his fifth axiom and to prove this proposition. For this proposition, he lets AC and MC be two rays which are to be refracted through a medium along QP. Next he "let[s] MC, AD, be the Sines of Incidence of the two Rays, and NG, EF, their Sines of Refraction" Newton (1730). Then he breaks the "motion" or path of the ray up into a perpendicular part, AD, and a parallel part, DC. He breaks the motion of the refracted rays into parallel and perpendicular components as well: "whereof the perpendicular ones are MC/NG × CG and AD/EF × CF" Newton (1730). According to his previous proposition, since the perpendicular component of CN is $\frac{MC}{NG} \times CG$, then the perpendicular component of CE, $\frac{AD}{EF} \times CF = \sqrt{CDq + \left(\frac{MCq}{NGq} \times CGq\right)}$ for some q. Then, squaring both sides, adding ADq and $MCq - CDq$ to both sides, and dividing by $CFq + EFq$ and $CGq + NGq$ yields $\frac{MCq}{NGq} = \frac{ADq}{EFq}$. But AD is the sin of incidence and EF is the sin of refraction for the incident ray AC. So the sin of incidence is in a ratio with the sin of refraction. Newton uses this result in his next proposition: "The Perfection of Telescopes is impeded by the different Refrangibility of the Rays of Light" Newton (1730) where "refrangibility" is how much the light ray is refracted upon entering a new medium.

In part II of Book I, Newton begins to explore the physical differences of color. Newton explained that color, while relegated to light, was more of a mental construction Newton (1730). He observed the white light could be split into a rainbow, starting at red and moving through to violet. However, not all colors seemed to appear in this rainbow. Magenta was created by overlapping red light and violet light. It was not a "true" color, but rather one constructed in the mind as a result of

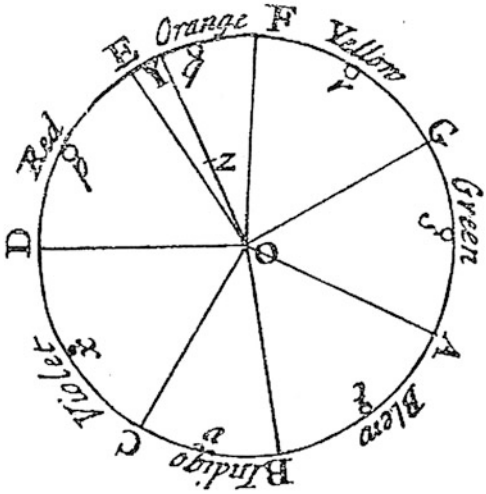

Fig. 2 Newton's color wheel (Newton 1730)

red and violet light overlapping. He links the seven "true" colors he observed – red, orange, yellow, green, blue, indigo, and violet – to seven song notes. He uses the differences in notes in harmonics to sort the colors sometimes in his experiments Newton (1730). Having defined each color, he begins to explore the physical differences in each, often using the musical notes analogy.

In proposition III, he finds that blue and violet light refract more than red light. Using this property, in proposition VI, he defines a color wheel which he uses as a tool to determine the color of light given its constituent parts. Figure 2 shows the color wheel Newton devised. First, Newton splits the color wheel into "seven Parts DE, EF, FG, GA, AB, BC, CD, proportional to the seven Musical Tones or Intervals of the eight Sounds, Sol, la, fa, sol, la, mi, fa, sol, contained in an eight, that is, proportional to the Number 1/9, 1/16, 1/10, 1/9, 1/16, 1/16, 1/9" Newton (1730). Then, he describes points p,q,r,s,t,u,x to be the "centers of gravity" of the arcs, with circles drawn around them proportional to the amount of color used. Then, finding the center of gravity (through a method he developed in *Principia*) between each of these seven circles yield a point z which gives the information of the final color. The wedge z is in dictates its color, while the distance from the center dictates its whiteness. If z is on the center of the circle, the light is white. The point Y is the point on the intersection of the circumference and the radius drawn from the center of the circle through z. The position of Y tells the information about color more precisely than z might. This method is merely an estimate, as Newton explains: "This Rule I conceive accurate enough for practice, though not mathematically accurate" Newton (1730). Despite this, it was still a useful tool to estimate the color of a product beam of light.

In one of the last propositions in Book I, Proposition IX Problem IV, Newton explores the optics behind rainbows. First, treating water droplets as perfect spheres, he shows the refractive and reflective processes occurring to bounce light toward an observer. He uses the diagram in Fig. 3 to explain the geometry behind the problem.

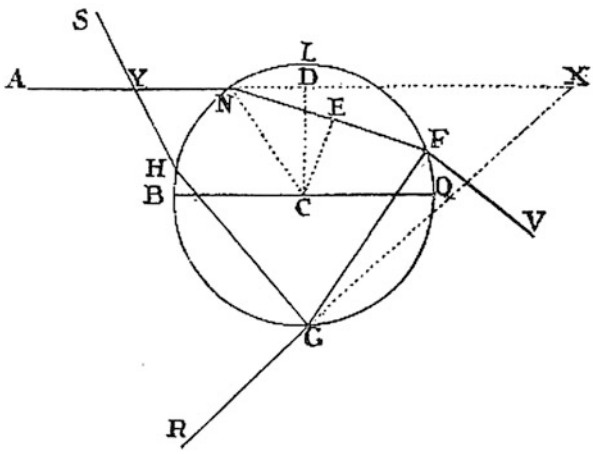

Fig. 3 Light bouncing in a water droplet as part of a rainbow Newton (1730)

First, he defines AN as a ray from the sun entering the raindrop. The ray refracts to F where it either refracts out of the drop to V or reflects to G where it either refracts out to R or reflects again to H. From H, the ray refracts out to S. AN and GR are produced to an intersection point, X. He examines the ratio of sine of incidence, I, and the sine of refraction, R. By moving the intersection point, B, toward L he notices that the arc QF, and thus the angle AXR will first decrease, then increase in size. He argues that the maximum of this angle and arc will be the biggest when $\frac{ND}{CN} = \frac{\sqrt{I^2-R^2}}{\sqrt{3R^2}}$. He also notes that the angle AYS will be smallest when $\frac{ND}{CN} = \frac{\sqrt{I^2-R^2}}{\sqrt{8R^2}}$. From there he is able to find a pattern about the angles of the emerging rays after n refractions inside the water droplet. The emergent angle will "continue to its limit" Newton (1730) when the ratio of ND to CN is $\frac{\sqrt{I^2-R^2}}{\sqrt{3R^2}}, \frac{\sqrt{I^2-R^2}}{\sqrt{8R^2}}, \frac{\sqrt{I^2-R^2}}{\sqrt{15R^2}}, \frac{\sqrt{I^2-R^2}}{\sqrt{24R^2}}$, etc. with the bottom number "being gather'd by continual Addition of the Terms of the arithmetical Progression 3, 5, 7, 9, & c" Newton (1730). He uses this series to predict where additional rainbows will appear in relation to the primary rainbow. He then goes out and measures the angle of the two rainbows he sees and shows why the colors appear in the order they do, one with an inverted order of colors compared to the other (Fig. 4). While Newton only sees two rainbows during his experiment, there are higher-order rainbows which get progressively fainter due to the high number of reflections needed, given that some light refracts out at each reflection point, so any rainbow above a secondary rainbow is hard to detect. These higher-order rainbows impressively follow the predictions Newton made with his infinite series.

In just Book I, Newton already heavily uses ratios and proportions to prove his theories on colors and reflections. Furthermore, he expands upon the ratios to construct infinite series to expand his theories into predictions that were later confirmed. Much of his work from Book I is still used today in geometrical optics Frank L. Pedrotti et al. (2007).

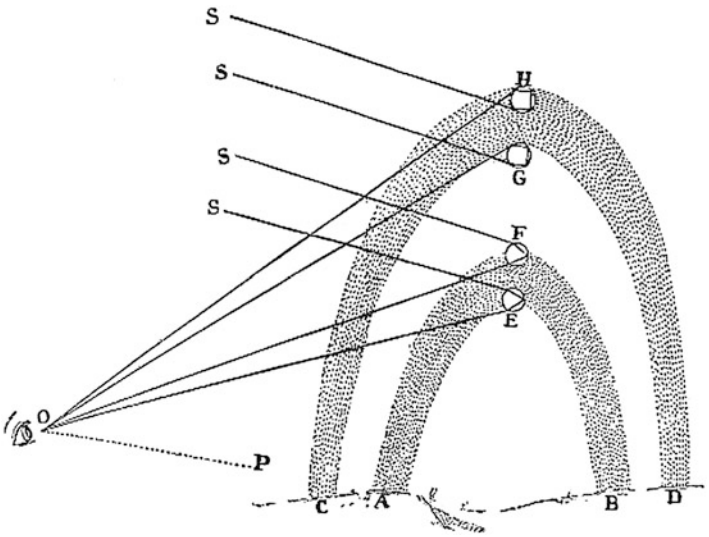

Fig. 4 A diagram of a rainbow Newton (1730)

3 *Opticks*: Books II and III

Newton's second book primarily addresses his work with thin films. Specifically, he seeks to find and quantify the color of thin films. First, however, Newton needed a way to measure the thickness of these thin films (so he could put a definition on "thin" to work with). Measuring thin films is difficult, and it was the key difference between his work and that of his contemporary Robert Hooke's Kumar (2006). To measure the thickness, Newton placed the films between a flat surface and a spherical surface dish resting on the flat surface. Then, knowing the diameter, the thickness of the film could be calculated as $d = \frac{D^2}{8R}$, where d is the thickness of the film, D is the diameter of the dish, and R is the radius of the sphere that the disk would be a part of Kumar (2006). In this setup, he shines light directly onto the center of the dish. The light refracts and reflects and forms circles of color around the center, which were periodic (Fig. 5).

Newton found that his corpuscular nature of light alone did not explain this phenomenon. So, he expanded his theory to include the ether (Kumar 2006). The ether was a hypothetical medium believed to exist that would have been the medium light propagated through (as waves needed a medium to travel through according to physics at the time). However, since Newton believed that light was not a wave, he did not use the ether as a medium through which light travels. Instead it served as a medium or field which only light interacts with and that interacts with the particles of light (Newton 1730; Kumar 2006). He explained that particles of light were different in size and strength and so interacted either weaker or stronger with the ether. This explained why different color bands seemed to be larger than other colors (Kumar

Abstract

"Terquem's problem" is a name, given in the twentieth century, to the problem of enumerating certain integer sequences whose entries alternate in parity. In particular, this problem asks for the count of strictly increasing length m sequences of positive integers bounded above by some integer n whose odd-indexed entries are odd and whose even-indexed entries are even. This problem and its generalizations have been well-studied. However, the putative original source for this problem, an 1839 paper by Olry Terquem, is subtly different from the problem that is now attributed to Terquem. In this chapter, we highlight this distinction and also make connections between Terquem's "forgotten" problem, the Fibonacci sequence, a one-player game of numbers, continuant polynomials, (an extended version of) the Euclidean Algorithm, and Bézout's Lemma.

1 Introduction

The personages to whom this volume is dedicated – Chandler Davis, Reuben Hersh, and Yuri I. Manin – held many consonant views on the nature of mathematical philosophy and practice, but perhaps none more salient than this: Mathematics is, above all else, a *human* experience to be shared with one another across time and space. The mere accumulation of new results might seem, to those with casual or cynical interest in our subject, to be the sole driving purpose of mathematical practice, but such advances only represent real progress to the extent that they move within the currents of our ever-cycling global and intergenerational mathematical colloquy. Indeed, the discovery of new results is almost never an isolated event: concepts are innovated, patterns are discerned, conjectures are proffered, methodologies are developed, and (often multiple) proofs are obtained in a great collaborative movement.

In the ebb and flow of these currents over time, ideas might slip beneath the surface, or idly drift beyond our ken. Their rediscovery might be momentous (such as George E. Andrews' recovery of Ramanujan's "lost" notebook) or only modestly diverting. The study we offer here, turning on what we call the "forgotten" problem of Olry Terquem, is of the modest variety, but also hopefully illustrative of the potential edification of renavigating well-mapped passages, even when relying on pedestrian, but perhaps mildly unconventional, observational accoutrement.

In this chapter, we revisit a problem well known to the ages – understanding greatest common factors and the concomitant tools for their calculation – from our perspective as enumeratively minded mathematicians and as teachers (and former students) of discrete-themed transitions courses for undergraduate mathematics majors at regional public universities in the Mid-South of the United States. This experience has seasoned us with an especial appreciation for "explicit" solutions to existential problems, i.e., solutions which are characterized by their transparency, by their immediate computational availability, and by what some might call their constructive nature. These dispositions therefore inform the discourse undertaken here on certain classical elementary number theory problems (e.g., how so-called continuant polynomials can be expressed explicitly as sums over certain integer sequences considered by Terquem). We invite the reader to consider how their own mathematical priorities might differently influence their understanding and presentation of the rudimentary topics we take up here.

Our narrative begins in medias res with a counting problem whose statement appears to go back to a nineteenth-century paper by Olry Terquem. But, before we "push off and smite the sounding furrows," as it were, we offer a word on the esthetics of enumeration. Richard P. Stanley – a former student of Reuben Hersh's

kindred spirit Gian-Carlo Rota – offers several notions of what comprises a satisfactory answer to a counting problem (Stanley 1986). The first is an explicit formula, such as the formula $\frac{n(n-1)\cdots(n+1-k)}{k(k-1)\cdots(1)}$ for the number, typically denoted '$\binom{n}{k}$,' of k-element subsets of an n-element set when n and k are nonnegative integers. The second is a recurrence relation, such as the Pascal recurrence $\binom{n}{k} = \binom{n-1}{k-1} + \binom{n-1}{k}$, where we take $\binom{0}{0}$ to be 1 and, for integers a and b, we take $\binom{a}{b}$ to be 0 when $b \notin [0, a]_{\mathbb{Z}}$. (We denote by $\mathcal{I}_{\mathbb{Z}}$ the set of integers within a given real number interval $\mathcal{I}$.). Another satisfactory answer is to present a one-to-one correspondence between the objects of the given counting problem and objects whose enumerative solution is known. For instance, by the multiplication rule of counting, one can place k students, chosen from amongst n students, in a line in $n(n-1)\cdots(n+1-k)$ ways. But, each such linear ordering of k students can be realized as the pairing of an unordered selection of k students, chosen in $\binom{n}{k}$ ways, together with one of the $k(k-1)\cdots(1)$ ways of placing k students in a line. A consequence of this bijective correspondence is the identity $n(n-1)\cdots(n+1-k) = \binom{n}{k} \cdot k(k-1)\cdots(1)$, from which we obtain the explicit formula $\binom{n}{k} = \frac{n(n-1)\cdots(n+1-k)}{k(k-1)\cdots(1)}$. Finally, one might offer what we call here a *(polynomial) refinement* of the problem. In this context, an enumerative solution might be presented as a uni- or multivariate polynomial (aka "generating function") whose monomial coefficients are the desired counts – such as the identity $(x+1)^n = \sum_{k=0}^{n} \binom{n}{k} x^k$ from the Binomial Theorem. Or, the solution might be a polynomial that specializes to the desired count – such as the identity $\binom{n}{k} = \left.\frac{[n][n-1]\cdots[n+1-k]}{[k][k-1]\cdots[1]}\right|_{x=1}$, where "$[m]$" is shorthand for the polynomial $\sum_{j=0}^{m-1} x^j = \frac{x^m-1}{x-1}$ for any $m \in [0, \infty)_{\mathbb{Z}}$ and where the rational function $\frac{[n][n-1]\cdots[n+1-k]}{[k][k-1]\cdots[1]}$ is a polynomial usually called a Gaussian binomial coefficient. These enumerative esthetics will guide much of our investigation of Terquem's forgotten problem.

Two asides before we move on: During our research on this topic, the third-listed author helpfully translated Terquem's original paper (Terquem 1839, in French) as well as Eugen Netto's rendering of Terquem's problem (Netto 1901, in German). Also, we use the symbol "□" throughout to demarcate the end of proofs as well as the completion of other formally presented ideas (such as definitions, etc.).

2 A Forgotten Problem

Olry Terquem was a nineteenth century polymath – a mathematician, historian, journal founder and editor, religious reformer, and officer of the French Legion of Honor (Singer 1906). He is known for mathematical contributions in geometry (for example, as a discoverer of properties of the nine-point circle, cf. MacKay 1892), but in combinatorics his name is associated with an enumerative question called "Terquem's problem." Contemporary renderings of Terquem's problem generally follow the classical introductory combinatorics text by John Riordan, who seems to have borrowed it from an early twentieth century combinatorics text by the German mathematician

Eugen Netto (see Netto 1901, §49 Ch. 3). Here is Riordan's version (Riordan 1958, Ch. 1 problem 15), with notation lightly modified to better fit our context:

> Terquem's problem. For combinations of n numbered things in natural (rising) order, with t(n, m) the number of m-combinations with odd elements in odd position and even elements in even positions, or, what is the same thing, with t(n, m) the number of combinations with an equal number of odd and even elements for m even and with the number of odd elements one greater than the number of even for m odd, show that t(n, m) has the recurrence $\mathrm{t}(n, m) = \mathrm{t}(n-1, m-1) + \mathrm{t}(n-2, m)$ [with] $\mathrm{t}(n, 0) = 1$, [that] $\mathrm{t}(n, m) = \binom{\lfloor \frac{n+m}{2} \rfloor}{m}$, [and that] $f_{n+1} = \sum_{m=0}^{n} \mathrm{t}(n, m) = f_n + f_{n-1}$.

The objects to be enumerated in this version of Terquem's problem are called "alternating parity subsets" in the entry A046854 of the OEIS (2023). (For example, when $n = 4$, we get $\mathrm{t}(4, 0) = 1$, $\mathrm{t}(4, 1) = 2$, $\mathrm{t}(4, 2) = 3$, $\mathrm{t}(4, 3) = 1$, and $\mathrm{t}(4, 4) = 1$, affording the refinement $1 + 2 + 3 + 1 + 1$ of the Fibonacci number "8.") Such alternating parity subsets have been well-studied and generalized; for a somewhat recent example, see the paper by Toufik Mansour and Augustine O. Munagi (2012) and references therein.

However, the above version of Terquem's problem omits a requirement originally imposed by Terquem (1839). That requirement was a *parity condition on the lengths* of the alternating parity subsets he considered. We will see, in the remainder of this chapter, that this somewhat subtle but forgotten difference in Terquem's original problem actually places his problem in close proximity to some very classical enumerative and number theoretic phenomena, namely, a right-triangular Fibonacci-type array of numbers, continuant polynomials, (a version of) the extended Euclidean algorithm, and Bézout's Lemma. (Indeed, Terquem was generally aware of such connections.)

Now, to Terquem's forgotten problem. Assume n is a positive integer and that m is a nonnegative integer. An *oe-sequence* $T \coloneqq (T_1, T_2, \ldots, T_m)$ *bounded by* n is a strictly increasing sequence of m positive integers *wherein* m *and* n *have the same parity* ("On suppose de plus que $[m]$ et $[n]$ sont tous deux simultanément pairs ou impairs," cf. Terquem 1839, part 1), T_1 is odd, $T_m \leqslant n$, and T_i and T_{i+1} have opposite parity for any $i \in [1, m-1]_{\mathbb{Z}}$. In this definition, the "oe" prefix is meant to suggest the alternating odd-even pattern of an oe-sequence. We say that T has length m and write $\ell(T) = m$. When $m = 0$, then T is the empty sequence, is denoted by $()$, is considered to have length zero, and is considered to be an oe-sequence. Let $\mathcal{OE}(n)$ be the set of oe-sequences bounded by n. For reasons to be made apparent shortly, we set $\mathcal{OE}(-1) \coloneqq \emptyset$ and $\mathcal{OE}(0) \coloneqq \{()\}$. Here are some other small sets of oe-sequences:

$$\mathcal{OE}(1) = \{(1)\}$$
$$\mathcal{OE}(2) = \{(12), ()\}$$
$$\mathcal{OE}(3) = \{(123), (1), (3), \}$$
$$\mathcal{OE}(4) = \{(1234), (12), (14), (34), ()\}$$
$$\mathcal{OE}(5) = \{(12345), (123), (125), (145), (345), (1), (3), (5)\}$$
$$\mathcal{OE}(6) = \{(123456), (1234), (1236), (1256), (1456), (3456), (12), (14), (16), (34), (36), (56), ()\}$$

For $0 \leq k \leq \left\lfloor \frac{n}{2} \right\rfloor$, let $\mathcal{OE}(n,k)$ be the set of sequences T in $\mathcal{OE}(n)$ with $\ell(T) = n - 2k$.

Definition 2.1 *Terquem's forgotten problem* is the problem of enumerating $\mathcal{OE}(n,\ k)$. □

Likewise, an *eo-sequence* has all the properties of an oe-sequence except that it begins with an even integer instead of an odd and its length has parity opposite that of n; we then define $\mathcal{EO}(n)$ to be the set of eo-sequences bounded by n. This time we set $\mathcal{EO}(-1) := \{()\}$ and $\mathcal{EO}(0) := \emptyset$. For $1 \leqslant n \leqslant 6$, we have

$$\begin{aligned}
\mathcal{EO}(1) &= \{()\} \\
\mathcal{EO}(2) &= \{(2)\} \\
\mathcal{EO}(3) &= \{(23), ()\} \\
\mathcal{EO}(4) &= \{(234), (2), (4)\} \\
\mathcal{EO}(5) &= \{(2345), (23), (25), (45), ()\} \\
\mathcal{EO}(6) &= \{(23456), (234), (236), (256), (456), (2), (4), (6)\}
\end{aligned}$$

For $0 \leqslant k \leqslant \left\lfloor \frac{n-1}{2} \right\rfloor$, let $\mathcal{EO}(n,k)$ be the set of $T \in \mathcal{EO}(n)$ with $\ell(T) = (n-1) - 2k$. From here on, we refer to oe- and eo-sequences generically as *oereo sequences* (pronounced "OH-ree-oh").

If we extend the above data just a bit, we see that the arrays of numbers $(\mathcal{OE}(n,k))$ and $(\mathcal{EO}(n+1,k))$ match the rows of the right-triangular array depicted in Fig. 1, at least for $n \in [0,\ 11]_{\mathbb{Z}}$. To solve Terquem's forgotten problem, we will investigate this array.

Now, it is well-known that the sequence of sums of certain diagonals of Pascal's triangle is exactly the Fibonacci sequence $f_0 = 1, f_1 = 1, f_2 = 2, f_3 = 3, f_4 = 5$, etc.

			ETC.		

Fig. 1 Depiction of row zero through row 11 of the right-triangular Fibonacci array $\boldsymbol{F}$

This is credited to Edouard Lucas; for discussion, see Ch. 12 of the text by Thomas Koshy (2018). The rows of the right-triangular array of Fig. 1 coincide with those diagonals from Pascal's triangle. We call this the *right-triangular Fibonacci array* (or simply the *Fibonacci array*) and denote it by $\boldsymbol{F}$. We label the kth entry of the nth row as $f_{n,k}$, so that

$$\boldsymbol{F} = \left(f_{n,k}\right)_{n\in\{0,1,2,\ldots\},k\in\left\{0,1,\ldots,\left\lfloor\frac{n}{2}\right\rfloor\right\}}.$$

Formally, let us build $\boldsymbol{F}$ by declaring $f_{0,0} := f_{1,0} := 1$ and then applying the recurrence

$$f_{n,k} := f_{n-1,k} + f_{n-2,k-1} \tag{1}$$

for integers k and n with $n \geqslant 2$ and with the understanding that $f_{n,k} := 0$ when $k < 0$ or $k > \left\lfloor\frac{n}{2}\right\rfloor$. The following lemma is easily proved using this defining recurrence and is left as an exercise.

Lemma 2.2 *For any integers n and k with $0 \leqslant k \leqslant \left\lfloor\frac{n}{2}\right\rfloor$, we have*

$$f_{n,k} = \binom{n-k}{k} \quad \text{and} \quad \sum_{i=0}^{\left\lfloor\frac{n}{2}\right\rfloor} f_{n,i} = f_n. \tag{2}$$

□

Therefore, the sequence of entries on the *nth* row of $\boldsymbol{F}$ can be viewed as a refinement of the *nth* Fibonacci number. Indeed, some collections of polynomials, such as those studied by Lucas (1878, p. 186) and Ernst Jacobsthal (see Koshy 2018, Ch. 39), have coefficients from the rows of $\boldsymbol{F}$. OEIS entry A011973 (2023) offers many enumerative interpretations of the numbers comprising these refinements. Immediately below (Interpretation 2.3), we recall one such interpretation of the Fibonacci array numbers as counts of certain sequences of positive integers. We then solve Terquem's forgotten problem in Theorem 2.4 using a one-to-one correspondence between the sequences of Interpretation 2.3 and oereo sequences. (Recently, we added a comment to OEIS entry A011973 (2023) providing our interpretation of Fibonacci array entries as counts of oereo sequences.)

Interpretation 2.3: A Classical Enumerative Interpretation of the Fibonacci Array Fix a positive integer n and a nonnegative integer m. A *consecutive-free sequence* $S = (S_1, S_2, \ldots, S_m)$ *strictly bounded by* n is a strictly increasing sequence of m positive integers wherein $S_m < n$ and $S_{i+1} - S_i \geqslant 2$ for any $i \in [1, m-1]_{\mathbb{Z}}$. We say that S has length m and write $\ell(S) = m$. When $m = 0$, then S is the empty sequence, is denoted by (), is considered to have length zero, and is considered to be a consecutive-free sequence. Let $\mathcal{CF}(n)$ be the set of consecutive-free sequences strictly bounded by n. So, for example,

$$\mathcal{CF}(5) = \{(), (1), (2), (3), (4), (13), (14), (24)\}$$
$$\mathcal{CF}(6) = \{(), (1), (2), (3), (4), (5), (13), (14), (15), (24), (25), (35), (135)\}$$

Further, let $\mathcal{CF}(n,k)$ denotes the subset of sequences in $\mathcal{CF}(n)$ having length k, when k is a nonnegative integer. Now, if $\mathcal{S}(n-k,k)$ denotes the k-element subsets of $\{1, 2, \ldots, n-k\}$, we can think of each such subset as a sequence of length k by listing its elements in increasing order. With this convention, observe that the function $\mathcal{S}(n-k,k) \to \mathcal{CF}(n,k)$ given by $(S_1, S_2, \ldots, S_k) \mapsto (S_1+0, S_2+1, \ldots, S_k+k-1)$ is a bijection. So, we have $|\mathcal{CF}(n,k)| = |\mathcal{S}(n-k,k)| = \binom{n-k}{k} = f_{n,k}$ for all positive integers n and all integers k with $1 \leqslant k \leqslant \left\lfloor \frac{n}{2} \right\rfloor$. In particular, $|\mathcal{CF}(n)| = f_n$, the nth Fibonacci number. □

Our bijective solution to Terquem's forgotten problem (Theorem 2.4) will utilize the following notions. When entries of a given sequence are distinct, we may regard the sequence as a set and apply set operations. When n is a positive integer, we observe that a strictly increasing sequence $(T_1, \ldots, T_m)$ of integers with $1 \leqslant T_1$ and $T_m \leqslant n$ is an oe-sequence if and only if $\{1, 2, \ldots, n\} \setminus \{T_1, \ldots, T_m\}$ is the union of even-length subsequences of consecutive integers. For a nonnegative integer $k \leqslant \left\lfloor \frac{n}{2} \right\rfloor$, we define a function $\phi : \mathcal{CF}(n,k) \to \mathcal{OE}(n,k)$ in the following way. Given $S = (S_1, \ldots, S_k) \in \mathcal{CF}(n,k)$, let

$$T := \phi(S) := \{1, 2, \ldots, n-1, n\} \setminus \left(\bigcup_{i=1}^{k} \{S_i, S_i + 1\} \right).$$

Clearly $\ell(T) = n - 2k$, and therefore $\ell(T)$ has the same parity as n. Since T is formed from $\{1, 2, \ldots, n\}$ by removing consecutive pairs of integers, then the set of numbers between any two successive entries of T is an even-length (and possibly length zero) string of consecutive integers; so, T is an oe-sequence. These processes reverse, allowing us to begin with an oe-sequence bounded by n and with length $n - 2k$ and convert it to a length k consecutive-free sequence strictly bounded by n. Next, we define a function $\psi : \mathcal{EO}(n,k) \to \mathcal{OE}(n-1,k)$ as follows. Let $m := (n-1) - 2k$. Declare that $() \overset{\psi}{\mapsto} ()$ Otherwise, when $T = (T_1, \ldots, T_m)$, we set $\psi(T) := (T_1 - 1, T_2 - 1, \ldots, T_m - 1)$. It is evident that $\psi(T) \in \mathcal{OE}(n-1,k)$. We can reverse ψ by taking an oe-sequence bounded by $n-1$ and with length $(n-1) - 2k$ and adding "1" to each of its entries to obtain an eo-sequence bounded by n and with length $(n-1) - 2k$.

Theorem 2.4 (Solution to Terquem's Forgotten Problem) *Let n and k be integers with n positive and $0 \leqslant k \leqslant \left\lfloor \frac{n}{2} \right\rfloor$. Then the functions $\phi : \mathcal{CF}(n,k) \to \mathcal{OE}(n,k)$ and $\psi : \mathcal{EO}(n,k) \to \mathcal{OE}(n-1,k)$ defined above are bijections. Therefore $|\mathcal{OE}(n,k)| = f_{n,k}$ and $|\mathcal{EO}(n,k)| = f_{n-1,k}$, so the arrays of numbers $(\mathcal{OE}(n,k))$ and $(\mathcal{EO}(n+1,k))$ match the right-triangular Fibonacci array.*

Proof It is observed above that the procedures employed by each of ϕ and ψ are reversible, thereby producing inverse functions $\phi^{-1} : \mathcal{OE}(n,k) \to \mathcal{CF}(n,k)$ and

$\psi^{-1} : \mathcal{OE}(n-1,k) \to \mathcal{EO}(n,k)$. That is, ϕ and ψ are bijections. The remaining claims follow from the fact that $|\mathcal{CF}(n,k)| = f_{n,k}$, cf. Interpretation 2.3 above. □

The bijective proofs of Theorem 2.4 establish that Eqs. (1) and (2) above – which are a recurrence and an explicit formula – apply to counts of oereo sequences, thereby fulfilling several of the esthetic criteria for enumeration proposed in our Introduction. But, what of polynomial refinements? It will be helpful, for the sequel, to render some collections of oereo sequences as generating functions. The definitions to follow are effected by the following general notion: For any strictly increasing positive integer sequence $T = (T_1, \ldots, T_m)$, set $\mathrm{x}_T := x_{T_1} x_{T_2} \cdots x_{T_m}$ (where the x_i's are commuting indeterminates), with $\mathrm{x}_{()} := 1$ for the empty sequence.

Definition 2.5 For any integer $n \geqslant -1$, set

$$g_n := \sum_{T \in \mathcal{EO}(n)} \mathrm{x}_T \quad \text{and} \quad h_n := \sum_{T \in \mathcal{OE}(n)} \mathrm{x}_T,$$

where of course an empty sum is zero. Note that g_n and h_n are polynomials in $x_1, \ldots, x_n$ with unit coefficients. Call g_n an *eo-polynomial* and h_n an *oe-polynomial*; together, these are generically referred to as *oereo polynomials*.

For the record, here are the first several eo- and oe-polynomials:

$$g_{-1} = 1$$
$$g_0 = 0$$
$$g_1 = 1$$
$$g_2 = x_2$$
$$g_3 = x_2x_3 + 1$$
$$g_4 = x_2x_3x_4 + x_2 + x_4$$
$$g_5 = x_2x_3x_4x_5 + x_2x_3 + x_2x_5 + x_4x_5 + 1$$

$$h_{-1} = 0$$
$$h_0 = 1$$
$$h_1 = x_1$$
$$h_2 = x_1x_2 + 1$$
$$h_3 = x_1x_2x_3 + x_1 + x_3$$
$$h_4 = x_1x_2x_3x_4 + x_1x_2 + x_1x_4 + x_3x_4 + 1$$
$$h_5 = x_1x_2x_3x_4x_5 + x_1x_4x_5 + x_3x_4x_5 + x_1x_2x_3 + x_1x_2x_5 + x_1 + x_3 + x_5$$

A consequence of Theorem 2.4 is that when $n \geqslant 1$, the Fibonacci number f_{n-1} counts the number of terms in the polynomial g_n, and the Fibonacci number f_n counts the number of terms in h_n. Moreover, the number of terms of degree $(n-1)-2k$ (respectively $n-2k$) for $0 \leqslant k \leqslant \left\lfloor \frac{n-1}{2} \right\rfloor$ (resp. $0 \leqslant k \leqslant \left\lfloor \frac{n}{2} \right\rfloor$) within g_n (resp. h_n) is $f_{n-1,k}$ (resp. $f_{n,k}$). Given that these polynomials have an underlying Fibonacci-like structure, it is not surprising that they can be constructed using simple recurrence relations, as in our next result. We use the notation $g_n(c_1, \ldots, c_n)$ to indicate that each x_j has been specialized to some given (possibly complex) quantity c_j, and similarly for h_n.

Proposition 2.6 *The eo-polynomials* $\{g_n\}_{n \geqslant -1}$ *are uniquely determined by the recurrence relations* $g_{-1} = 1$, $g_0 = 0$, *and* $g_{n+1} = g_{n-1} + x_{n+1}g_n$ *for* $n \geqslant 0$. *Similarly,*

the oe-polynomials $\{h_n\}_{n \geqslant -1}$ *are uniquely determined by the recurrence relations* $h_{-1} = 0$, $h_0 = 1$, *and* $h_{n+1} = h_{n-1} + x_{n+1}h_n$ *for* $n \geqslant 0$. *For a positive integer n and complex numbers* $c_1, \ldots, c_n$, *we have* $h_{n-1}(c_2, \ldots, c_n) = g_n(c_1, c_2, \ldots, c_n)$ *and* $c_1 h_{n-1}(c_2, \ldots, c_n) + g_{n-1}(c_2, \ldots, c_n) = h_n(c_1, c_2, \ldots, c_n)$. *Moreover,* $h_n(c_1, c_2, \ldots, c_{n-1}, c_n) = h_n(c_n, c_{n-1}, \ldots, c_2, c_1)$.

Proof The claims in the first two sentences of the proposition follow from routine induction arguments, which we leave to the reader. The claims of the penultimate sentence follow from the definitions of g_n and h_n as sums over sets of eo- and oe-sequences. The last sentence follows from the fact that when k and n have the same parity, then the mapping $\sigma : \mathcal{OE}(n,k) \to \mathcal{OE}(n,k)$ given by $\sigma(S_1, S_2, \ldots, S_k) = (n+1-S_k, \ldots, n+1-S_2, n+1-S_1)$ is a bijection. □

The recurrence in Proposition 2.6 allows us to identify oe-polynomials as the so-called "continuant polynomials" of §4.5.3 of Donald E. Knuth's canonical work on *The Art of Computer Programming* (1997). There, Knuth exposits how such polynomials are related to continued fractions (hence their name) and also to the Euclidean Algorithm. (For a concrete illustration of this connection, see Example 4.4 below.) Knuth attributes to Leonhard Euler (presumably referring to Euler 1764) the following iterative derivation of the terms of the oe-polynomial h_n: They are obtained from $x_1x_2 \ldots x_n$ by "deleting zero or more nonoverlapping pairs of consecutive variables x_jx_{j+1}." As observed above, these correspond exactly to the oe-sequences bounded by n.

3 The Networked-Numbers Game

Before we connect oereo polynomials to the Euclidean Algorithm, we briefly digress to consider another natural occurrence of the Fibonacci array. In particular, we will see how the (univariate) *sign-alternating Fibonacci polynomials* defined by

$$\overline{F}_n(x) := \sum_{k=0}^{\lfloor n/2 \rfloor} (-1)^k f_{n,k} x^{\lfloor n/2 \rfloor - k}$$

for each $n \in [0, \infty)_{\mathbb{Z}}$ occur within the context of a certain "node-firing" game and lead us to an explicit characterization of a desired property of game play (Theorem 3.3). It is easy to see that these sign-alternating Fibonacci polynomials are uniquely determined by the recurrence relations $\overline{F}_{-1}(x) = 0$, $\overline{F}_0(x) = 1$, and $\overline{F}_{n+1}(x) = -\overline{F}_{n-1}(x) + x^{n \bmod 2}\overline{F}_n(x)$ for $n \geqslant 0$.

This section can be skipped or lightly browsed on a first reading. However, it informs some of the considerations of the next several sections and, as a bonus, presents perhaps the simplest entry point – a node-firing game – to what we believe is the most sublime classification theorem in all of mathematics: *La Florado Klasado*. Node-ring games, including the "Chips Game" of Anders Björner, László

Lovász, and Peter Shor (1991) and the Networked-numbers Game of this section are considered in more generality by Kimmo Eriksson (1994). Our analysis here of a certain two-node game borrows ideas from a paper by Donnelly et al. (2021).

The *Networked-numbers Game (NG)* is a one-player game in which the player begins by choosing a finite simple graph (so, no loops and no multiple edges) and an assignment of real numbers, one to each node (i.e., vertex) of the graph. The only move afforded to the player is to *fire* at a chosen node by adding the number at the chosen node to the number at each adjacent node and then changing the sign of the number at the chosen node. A firing move is only *legal* in NG play if the number at the node-to-be-fired is positive. Game play continues until there are no legal moves remaining. See Fig. 2 for an illustration of NG play on a three-node graph. With just a bit more NG play, one can see that for the graph and initial numbers of Fig. 2, all games terminate with the same terminal numbers and in the same number of moves.

Let us add one further wrinkle to NG play. Say the underlying graph Γ has nodes $\{\gamma_i\}_{i\in I}$ indexed by a finite set I. We assign to each pair $(i, j) \in I \times I$ a real number $M_{i,j}$ satisfying

$$M_{i,j}\begin{cases} = 2 & \text{if } i = j \\ = 2 & \text{if } i \neq j \text{ and } \gamma_i \text{ is no adjacent to } \gamma_j \text{ in } \Gamma \\ < 0 & \text{if } \gamma_i \text{ and } \gamma_j \text{ are adjacent in } \Gamma \end{cases}$$

We view the $|M_{i,j}|$'s as multipliers for firing moves in the following way: If $\{\lambda_j\}_{j\in I}$ are the numbers at nodes $\{\gamma_j\}_{j\in I}$ of Γ and if node γ_i is fired, then the number at node γ_j is changed to $\lambda_j - M_{i,j}\,\lambda_i$. (If all negative $M_{i,j}$'s are "–1," then NG play proceeds as in the previous paragraph.) We call the pair $\Gamma = \{\gamma_i\}_{i\in I}$ and $(M_{i,j})_{i,j\in I}$ a *graph-with-multipliers*. To visually indicate the presence of such multipliers, we depict an edge between adjacent nodes γ_i and γ_j as $\gamma_i \overset{p}{\underset{q}{\bullet\!\!-\!\!\bullet}} \gamma_j$, where $p = |M_{i,j}|$ and $q = |M_{j,i}|$. We will also use the picture $\gamma_i \overset{\text{m}}{\bullet\!\!-\!\!\bullet} \gamma_j$ to represent such an edge when $pq = M_{i,j}M_{j,i} = 4\cos^2(\pi/m)$ and m is an integer exceeding two; for convenience we omit "③" and just represent our edge as $\gamma_i \bullet\!\!-\!\!\bullet \gamma_j$ when $m = 3$. Now let $\varrho := \frac{1+\sqrt{5}}{2}$, which is, of course, the golden ratio satisfying the relation $\varrho^2 = \varrho + 1$. The latter observation helps

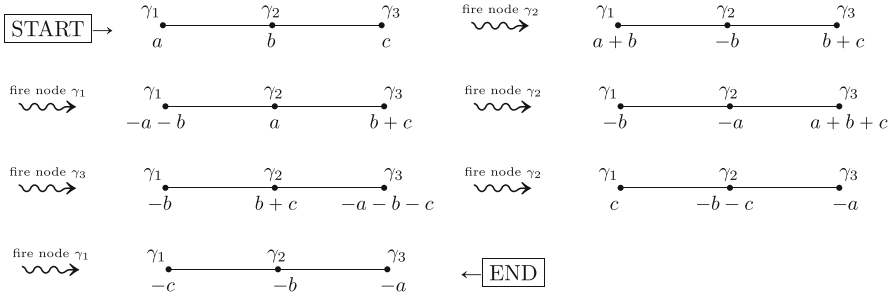

Fig. 2 Only nodes γ_1 and γ_3 are nonadjacent, and we assume a, b, and c are positive real numbers

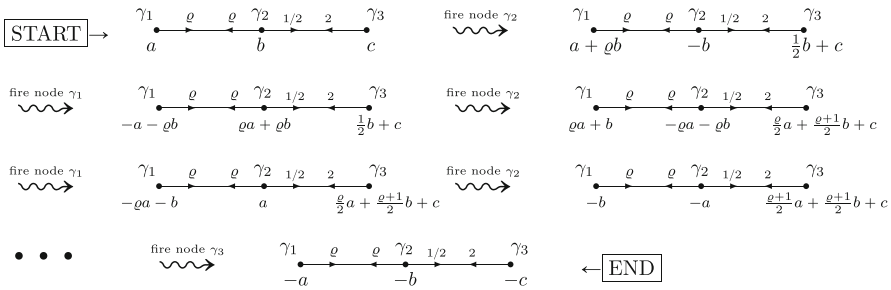

Fig. 3 Several of the node-firings of a networked-numbers game whose fifteen-node-firing sequence is (γ_2, γ_1, γ_2, γ_1, γ_2, γ_3, γ_2, γ_1, γ_2, γ_1, γ_3, γ_2, γ_1, γ_2, γ_3). (Here, a, b, and c are positive real numbers)

simplify certain quantities arising in NG play in Fig. 3 on a certain three-node graph-with-multipliers. As with the game illustrated in Fig. 2, one can (with patience!) see that all possible Networked-numbers Games played from the initial numbers in Fig. 3 terminate with the same terminal numbers and in the same number of moves.

Two natural questions arise concerning length of NG play: First, given a graph-with-multipliers, what conditions on the $M_{i,j}$'s will guarantee that any two games played from any given initial set of real numbers will require the same number of node-firings? Such a graph-with-multipliers is called *strongly convergent*. Second, for a given strongly convergent graph-with-multipliers, does there exist a game that terminates when all initial real numbers are nonnegative with at least one being positive? Call such a strongly convergent graph-with-multipliers *NG finitistic*.

The first question is answered by Eriksson (1996).

Eriksson's Strong Convergence Theorem *A connected graph-with-multipliers is strongly convergent if and only if on each edge of the graph, the product of its multipliers is in the set of real numbers* $\{4\cos^2(\pi/m) | m \in [3, \infty)_{\mathbb{Z}}\} \cup [4, \infty)$. □

In Theorem 3.3 below, we use sign-alternating Fibonacci polynomials to give a new proof of the "only if" part of the preceding equivalence.

The answer to the second of our questions is but one part of a broad and multifaceted classification result the authors (somewhat whimsically) call *La Florado Klasado*, which is Esperantese for "The Flowering Classification." We view *La Florado Klasado* as an assemblage of classification problems whose answers correspond to all (or some subset) of the graphs-with-multipliers in Fig. 4. Wilhelm Killing (1889) and Elie Cartan (1894) were the first to discern an aspect of this classification result (although not in the graphical form presented here) in their discovery of the finite-dimensional simple Lie algebras over the complex numbers; see Coleman (1989) for a lively recounting of this history. For exposition on and explicit statements of other parts of *La Florado Klasado* – including some very well-known and some less well-known results relating to Weyl groups, root systems, symmetric functions, Kac–Moody Lie algebras, posets, etc. – see §9 of the

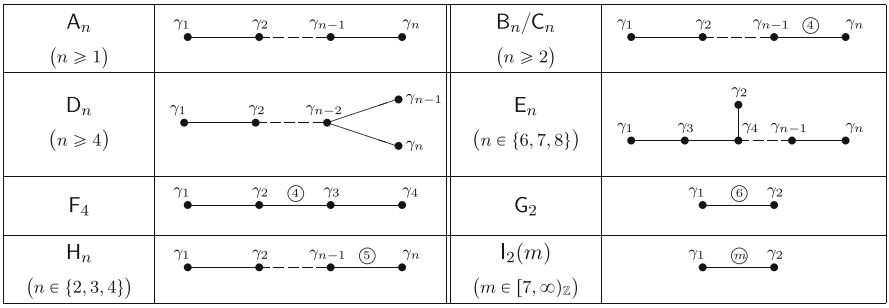

Fig. 4 Coxeter–Dynkin diagrams, rendered as graphs-with-multipliers, of types A through I. (Assume each edge has a "③" unless otherwise indicated)

manuscript by Donnelly (2022). Eriksson (1993, 1995) was the first to connect the NG and Coxeter groups. The "only if" part of the following equivalence is original to Donnelly (2008) and might be the most accessible of the many equivalences comprising this astoundingly rich classification result.

Theorem: An Equivalence from *La Florado Klasado* *A connected and strongly convergent graph-with-multipliers is NG finitistic if and only if it corresponds to one of the Coxeter–Dynkin diagrams associated with the finite irreducible Coxeter groups. That is, such a graph must be from one of the types of families of graphs-with-multipliers in* Fig. 4. □

For example, the graph-with-multipliers of Fig. 2 corresponds to the Coxeter–Dynkin diagram of type A_3 whose associated Coxeter group is the 24 element symmetric group on four letters, and the graph-with-multipliers of Fig. 3 corresponds to the Coxeter–Dynkin diagram of type H_3 whose associated Coxeter group is the group of symmetries of an icosahedron or dodecahedron.

And now to the main point of our Networked-numbers Game digression. We can demonstrate the necessity of Eriksson's strong convergence criteria by analyzing the Networked-numbers Game on two-node graphs-with-multipliers. The key to our analysis is to understand the role played by sign-alternating Fibonacci polynomials. To help make this connection, consider Fig. 5. Evidently, at each stage of game play, the numbers at the nodes are linear combinations of a and b with coefficients explicitly expressed in terms of sign-alternating Fibonacci polynomials evaluated at the product pq. We formalize this observation as the following fact, whose proof is deferred to §5 (see Corollary 5.2).

Fact 3.1 *Assume k is an odd positive integer. The formulas proposed in* Fig. 5 *are indeed valid expressions for the numbers at the nodes after the k^{th} and $(k+1)^{st}$ Firing moves of the two-node NG played in that figure.*

Explicit formulas for roots of certain univariate Fibonacci polynomials closely related to our sign-alternating Fibonacci polynomials were first obtained by Verner

Node-firing move	Progressive state of NG play on a two node graph-with-multipliers	
START	γ_1 p q γ_2 a b

$(k+1)^{\text{st}}$ node firing	$-\overline{F}_{k-1}(pq)a-q\overline{F}_k(pq)b$ **?**	$p\overline{F}_k(pq)a+\overline{F}_{k+1}(pq)b$ **?**
$\vdots$	$\vdots$	$\vdots$

Fig. 5 Part of a networked-numbers game on a two-node graph-with-multipliers. (In this figure, the NG is played from positive starting numbers a and b on a generic two-node graph-with-multipliers whose nodes are $\{\gamma_1, \gamma_2\}$ and whose multipliers are the negative real numbers $M_{1,2} = -p$ and $M_{2,1} = -q$. Assume here that k is odd. Question marks "**?**" indicate that the formulas will be proved later)

E. Hoggatt and Marjorie Bicknell in 1973. From that work, one can obtain the following explicit description of the roots of sign-alternating Fibonacci polynomials (see Corollary 3.2 of Donnelly et al. (2021) for another approach).

Proposition 3.2 *The roots of the degree* $\lfloor n/2 \rfloor$ *sign-alternating polynomial* $\overline{F}_n(x)$ *are the* $\lfloor n/2 \rfloor$ *distinct real numbers comprising the set* $\left\{4\cos^2\left(\frac{j\pi}{n+1}\right) \middle| j \in [1, \lfloor n/2 \rfloor]_{\mathbb{Z}}\right\}$. □

Knowledge of these roots effects our new proof of the following result.

Theorem 3.3 (Necessity of Eriksson's Strong Convergence Criteria) *Suppose a connected graph-with-multipliers is strongly convergent. Then on any edge, the product of its multipliers is in the set of real numbers* $\{4\cos^2(\pi/m) | \ m \in [3, \infty)_{\mathbb{Z}}\} \cup [4, \infty)$.

Proof Without loss of generality, suppose there is an edge between nodes γ_1 and γ_2 with multipliers as in Fig. 5. Further, suppose $pq < 4$. Since $4\cos^2(\pi/2) = 0$ and the sequence $\left\{4\cos^2(\pi/m)\right\}_{m=2}^{\infty}$ strictly increases with limit 4, then there exists an integer $k \in [2, \infty)_{\mathbb{Z}}$ such that $4\cos^2(\pi/k) < pq \leqslant 4\cos^2(\pi/(k+1))$. If $pq = 4\cos^2(\pi/(k+1))$, we are done, so suppose pq is strictly between $4\cos^2(\pi/k)$ and $4\cos^2(\pi/(k+1))$. Now, for each $m \in [3, \infty)_{\mathbb{Z}}$, $4\cos^2(\pi/m)$ is the largest root of the monic polynomial $\overline{F}_{m-1}(x)$, and $4\cos^2(2\pi/m)$ is the second largest root, etc. (Proposition 3.2). Also, observe that since $2\pi/(k+1) > \pi/k$, then $4\cos^2(2\pi/(k+1))$

$< 4\cos^2(\pi/k)$. In particular, $\overline{F}_{m-1}(x) > 0$ when $x > 4\cos^2(\pi/m)$ and $\overline{F}_{m-1}(x) < 0$ when $4\cos^2(2\pi/m) < x < 4\cos^2(\pi/m)$. From these facts, we deduce that $\overline{F}_k(pq) < 0$ and that $\overline{F}_{m-1}(pq) > 0$ for each $m \in [3, k]_{\mathbb{Z}}$.

Suppose for the moment that k is odd. Let us begin a game by assigning to nodes γ_1 and γ_2 respectively an arbitrary positive number a and a positive number $b = 1 + \max\left\{\frac{-\overline{F}_{k-1}(pq)a}{q\overline{F}_k(pq)}, \frac{-p\overline{F}_k(pq)a}{\overline{F}_{k-1}(pq)}\right\}$, and by assigning to all other nodes negative numbers that are very large in magnitude (so as to be mostly unaffected by game play on γ_1 and γ_2). Since $b > \frac{-a\overline{F}_{k-1}(pq)}{q\overline{F}_k(pq)}$, then $\overline{F}_{k-1}(pq)a + q\overline{F}_k(pq)b < 0$. Then, by Fact 3.1 in concert with Fig. 5, we see that this NG terminates after the kth node-firing, if we begin by firing γ_2. To understand what happens when we fire γ_1 first, we can simply take the information from Fig. 5 and interchange the roles of a and b and of p and q. So, starting with γ_1, after the kth node-firing the numbers at nodes γ_1 and γ_2 are, respectively, $-q\overline{F}_{k-2}(qp)b - \overline{F}_{k-1}(qp)a$ and $\overline{F}_{k-1}(qp)b + p\overline{F}_k(qp)a$. Since $b > \frac{-p\overline{F}_k(pq)a}{\overline{F}_{k-1}(pq)}$, then $\overline{F}_{k-1}(qp)b + p\overline{F}_k(qp)a > 0$, in which case there is at least one more firing move available. Thus, when k is odd, the assumption that $pq \notin \{4\cos^2(\pi/m) \mid m \in [3, \infty)_{\mathbb{Z}}\}$ contradicts our strong convergence hypothesis. We can similarly obtain a contradiction in the case that k is even.

We conclude that if an edge of our connected and strongly convergent graph-with-multipliers has a multiplier product less than four, then the product must take the form $4\cos^2(\pi/m)$ for some $m \in [3, \infty)_{\mathbb{Z}}$. □

4 A Version of the Extended Euclidean Algorithm

The Euclidean Algorithm is an ancient procedure for computing the greatest common divisor of two integers without factoring them. This algorithm is Euclid's in that it famously appears in his great treatise, the *Elements*, as Proposition 2 of Book VII. However, most likely this result was known before Euclid, perhaps by the Pythagoreans, as contended by (among others) the mathematician and historian Bartel Leendert van der Waerden. From p. 115 of van der Waerden (1975):

> . . . Book VII is not a later reconstruction, but a piece of ancient mathematics. . . . Thus we have acquired an important insight: *Book VII was a textbook on the elements of the Theory of Numbers, in use in the Pythagorean school.*

Knuth writes that the Euclidean Algorithm is "the granddaddy of all algorithms, because it is the oldest nontrivial algorithm that has survived to the present day" (1997, §4.5.2). In this section, we explore commonalities between the Euclidean Algorithm and the Networked-numbers Game, a new perspective that hopefully adds something worthwhile to such a venerable piece of mathematics.

We begin by formulating a version of the Euclidean Algorithm as a pseudocode procedure that calculates the greatest common divisor and keeps track of some

important intermediate data. We will soon see how oereo polynomials allow us to recover from this data, any information that is yielded by what is often called the "extended Euclidean Algorithm." We take as our input a pair of positive integers a and b with $a \geqslant b$. (Positivity is assumed for the sake of simplicity.) The procedure applies the Division Algorithm in successive steps, producing at each step a quotient and a remainder, and returns the last nonzero remainder as the greatest common divisor. The motivating observation for the Euclidean Algorithm is the following simple lemma.

Lemma 4.1 *Let u and v be nonzero integers, and suppose $u = qv + r$ with $q \in \mathbb{Z}$ and $r \in [0, \mid v \mid)_{\mathbb{Z}}$. Then* $\gcd(u, v) = \gcd(v, r)$.

Proof From the relation $u = qv + r$, we see that any common divisor of v and r is a divisor of u, so $\gcd(u, v) \geqslant \gcd(v, r)$. From $r = u - qv$, we see that any common divisor of u and v is also a divisor of r, hence $\gcd(u, v) \leqslant \gcd(v, r)$. □

So, by applying the Division Algorithm to a pair of integers (u, v) as in the lemma statement, we obtain a "simpler" pair of numbers (v, r) with the same greatest common divisor. We codify this idea as follows.

Definition 4.2 The *Euclidean Algorithm (EA)* is the following pseudocode procedure:

Input: Positive integers a and b with $a \geqslant b$.
Initialization: Set $r_{-1} \coloneqq a$ and $r_0 \coloneqq b$, to be regarded as de facto remainders. Let i be our interation-counting index, initialized with $i \coloneqq 1$.
Step 1: Applying the Division Algorithm, we obtain unique integers q_i and r_i wherein $0 \leqslant r_i < r_{i-1}$ and

$$r_{i-2} = q_i r_{i-1} + r_i.$$

Step 2: If $r_i = 0$, then Return the following data: GCD $\coloneqq r_{i-1}$, NUM_STEPS $\coloneqq i$, REM_LIST $\coloneqq (r_{-1}, r_0, \ldots, r_i)$, and QUO_LIST $\coloneqq (q_1, \ldots, q_i)$.
Step 3: Otherwise, with $r_i > 0$, replace i with $i + 1$ and return to Step 1.
Output: A positive integer GCD (that will be shown to be the greatest common divisor of a and b), a positive integer NUM_STEPS that records the number of times we apply the Division Algorithm, the list REM_LIST of nonnegative integer remainders indexed from -1 up to NUM_STEPS, and the list QUO_LIST of positive integer quotients indexed from 1 through NUM_STEPS.

(We use the notation EA(a, b)[GCD] to denote the last nonzero remainder returned by the EA, EA(a, b)[NUM_STEPS] to denote the number of times EA applies the Division Algorithm, EA(a, b)[REM_LIST] to denote the list of remainders, and EA(a, b)[QUO_LIST] to denote the list of quotients.) □

As with any algorithm, we should certify that it actually terminates and prove that it returns the desired output. This is the content of the following theorem.

Theorem 4.3 (Boundedness and Correctness of the Euclidean Algorithm) *Let a and b be positive integers with $a \geqslant b$. With this input, the Euclidean Algorithm terminates, and the output value* EA(a, b)[GCD] *is the greatest common divisor of a and b.*

Proof Consider the sequence of remainders $r_{-1} \geqslant r_0 > r_1 > \ldots$. Now, $b = r_0 > 0$, $b - 1 \geqslant r_1 \geqslant 0$, $b - 2 \geqslant r_2 \geqslant 0$, etc. Since $b - b = 0$, the largest possible index of the remainder sequence is b, so the algorithm terminates in no more than b iterations. Let $n \coloneqq$ EA(a, b)[NUM_STEPS]. By Lemma 4.1, $\gcd(a, b) = \gcd(r_{-1}, r_0) = \gcd(r_0, r_1) = \cdots = \gcd(r_{n-2}, r_{n-1}) = \gcd(r_{n-1}, r_n)$. Since $r_{n-1} > 0$ and $r_n = 0$, then $\gcd(r_{n-1}, r_n) = r_{n-1} =$ EA (a, b)[GCD]. □

Example 4.4 For purposes of illustrating this version of the Euclidean Algorithm, we sought input numbers a and b such that the algorithm would terminate in exactly seven steps, i.e., seven applications of the Division Algorithm. How we found such a and b – and why we wanted this exact number of steps – will be revealed shortly. With this in mind, consider $a = 4449$ and $b = 935$. When the procedure call EA(a, b) is invoked, the following sequence of computations occurs:

$$\begin{aligned} 4449 &= 935 \cdot 4 + 709 \\ 935 &= 709 \cdot 1 + 226 \\ 709 &= 226 \cdot 3 + 31 \\ 226 &= 31 \cdot 7 + 9 \end{aligned} \qquad \begin{aligned} 31 &= 9 \cdot 3 + 4 \\ 9 &= 4 \cdot 2 + 1 \\ 4 &= 1 \cdot 4 + 0 \end{aligned}$$

EA output is as follows: EA(a, b)[GCD] = 1, EA(a, b)[NUM_STEPS] = 7, EA(a, b)[REM_LIST] = (4449, 935, 709, 226, 31, 9, 4, 1, 0), and EA(a, b)[QUO_LIST] = (4, 1, 3, 7, 3, 2, 4). Notice that from this data, we easily obtain an expression for $\frac{4449}{935}$ as a continued fraction:

$$\frac{4449}{935} = 4 + \frac{709}{935} = 4 + \frac{1}{935/709} = 4 + \frac{1}{1 + \frac{226}{709}} = 4 + \frac{1}{1 + \frac{1}{709/226}} = 4 + \frac{1}{1 + \frac{1}{3 + \frac{31}{226}}}$$

$$= \cdots = 4 + \cfrac{1}{1 + \cfrac{1}{3 + \cfrac{1}{7 + \cfrac{1}{3 + \cfrac{1}{2 + \frac{1}{4}}}}}}.$$

□

Let us now execute the Euclidean Algorithm from a generic starting point as if it were an arithmetic game akin to the Networked-numbers Game on two nodes. We

will call this the *Euclidean Remainders Game (ERG)*, although it is really a computational process rather than a game. We start with a pair of positive integers a and b such that $a \geqslant b$. The only move afforded to us in the Euclidean Remainders Game is to replace the larger of our two positive numbers, say u, by the remainder obtained when we divide the larger number by the smaller number, say v, using the Division Algorithm. That is, once we obtain $q \in [1, \infty)_{\mathbb{Z}}$ and $r \in [0, v)_{\mathbb{Z}}$ such that $u = qv + r$, then the pair (u, v) is replaced by the pair (r, v). This process is illustrated in Fig. 6 and carried out from a generic starting point.

With knowledge of the sequences of remainders and quotients, we can reverse the steps of the EA to recover the original input. Let us formulate this latter computational process as another diversion we call the *Dual Remainders Game (DRG)*. This game starts with a pair of nonnegative integers, exactly one of which is positive. At any step of the Dual Remainders Game, the only move allowed is to add to the smaller of the two numbers, the product of the larger number, and some chosen positive integer. We refer to the integers arising as pairs in DRG play as *dual remainders*. The DRG is illustrated in Fig. 7 and carried out from a generic starting point.

Fig. 7 The dual remainders game: a "node-firing" process for reconstructing EA input from output. (Start with the pair $r'_{-1} = 0$ and $r'_0 \in [1, \infty)_{\mathbb{Z}}$. We take as given some positive integer sequence $q'_1, q'_2,$ etc. The jth move replaces the dual remainder pair $\left(r'_{j-2}, r'_{j-1}\right)$ with $\left(r'_j, r'_{j-1}\right)$ when j is odd and replaces $\left(r'_{j-1}, r'_{j-2}\right)$ with $\left(r'_{j-1}, r'_j\right)$ when j is even. Here, k is odd. Question marks "**?**" indicate that the formulas will be proved later)

Observe that at each stage of the ERG, each remainder seems naturally expressible as an integer linear combination of the initial integers a and b with each of the coefficients presented as the specialization of an oereo polynomial. Observe also that at each stage of the DRG, each dual remainder appears to be expressible as the product of the first nonzero dual remainder and some specialization of an oe-polynomial. Our proof demonstrating these two observations is enjoined with our proof of Fact 3.1 and is deferred to the next section (see Corollary 5.2). For now, we record these two verities as the following fact.

Fact 4.5 *Assume k is an odd positive integer. The proposed identities at steps k and $k + 1$ of the ERG played in* Fig. 6 *and the DRG played in* Fig. 7 *are indeed valid identities.*

Equipped with this knowledge, we can easily prove our next result, which has much overlap with what is known as Bézout's Lemma (more on this shortly). Moreover, our explicit understanding of outcomes in the Euclidean and Dual Remainders Games not only yields efficient proofs but also leads directly to the identities stated in Theorem 4.6.

Theorem 4.6 *Keep the hypotheses of Theorem 4.3, so* $\gcd(a, b) = \mathrm{EA}(a, b)$ [GCD]. *Now set* $n := \mathrm{EA}(a, b)$[NUM_STEPS], $(r_{-1}, r_0, \ldots r_n) := \mathrm{EA}(a, b)$[REM_LIST], *and* $(q_1, \ldots, q_n) := \mathrm{EA}(a, b)$[QUO_LIST].

1. *For any* $j \in [-1, n]_{\mathbb{Z}}$, *set* $\overrightarrow{g_j} := g_j(q_1, \ldots, q_j)$, $\overleftarrow{g_j} := g_j(q_{n+1-j}, \ldots, q_n)$, $\overrightarrow{h_j} := h_j(q_1, \ldots, q_j)$, *and* $\overrightarrow{h_j} := h_j(q_{n+1-j}, \ldots, q_n)$, *and momentarily allow* $r_{n+1} := \gcd(a, b)$. *For each such* j, $r_j = (-1)^{j+1}\overrightarrow{g_j}\, a + (-1)^j \overrightarrow{h_j}\, b$, $r_{n-j} = \overleftarrow{g_j} \cdot \gcd(a, b)$, *and* $r_{n-1-j} = \overleftarrow{h_j} \cdot \gcd(a, b)$.
2. *The set* $\{ax + by \mid x, y \in \mathbb{Z}\}$ *consists exactly of the integer multiples of* $\gcd(a, b)$. *In particular,* $\gcd(a, b)$ *is the smallest positive integer expressible as an integer linear combination of* a *and* b. *Moreover,* $\gcd(a, b) = (-1)^n g_{n-1}(q_1, \ldots, q_{n-1})a + (-1)^{n-1} h_{n-1}(q_1, \ldots, q_{n-1})b$, $b = g_n(q_1, \ldots, q_n) \cdot \gcd(a, b)$, *and* $a = h_n(q_1, \ldots, q_n) \cdot \gcd(a, b)$.

Proof In *(1)*, the assertion that $r_j = (-1)^{j+1}\overrightarrow{g_j}\, a + (-1)^j \overrightarrow{h_j}\, b$ follows from the ERG part of Fact 4.5. In Fig. 7, set $r'_j := r_{n-1-j}$ and $q'_j := q_{n+1-j}$. Then $r'_j = h_j\left(q'_1, \ldots, q'_j\right) \cdot r'_1 = h_j\left(q'_j, \ldots, q'_1\right) \cdot r'_1$, where the first equality follows from the DRG part of Fact 4.5 and the second equality follows from Proposition 2.6. So, $r_{n-1-j} = \overleftarrow{h_j} \cdot \gcd(a, b)$. By Proposition 2.6, $h_{j-1}(q_{n+1-(j-1)}, \ldots, q_n) = g_j(q_{n+1-j}, \ldots, q_n)$. So,

$$\begin{aligned} r_{n-j} = r_{n-1-(j-1)} &= h_{j-1}\left(q_{n+1-(j-1)}, \ldots, q_n\right) \cdot \gcd(a, b) \\ &= g_j(q_{n+1-j}, \ldots, q_n) \cdot \gcd(a, b), \end{aligned}$$

i.e., $r_{n-j} = \overleftarrow{g_j} \cdot \gcd(a, b)$.

For part *(2)*, note that every element of the set $\{ax + by \mid x, y \in \mathbb{Z}\}$ is a multiple of $\gcd(a, b)$; this set will consist of all the multiples of $\gcd(a, b)$ if we can show that $\gcd(a, b)$ is an integer linear combination of a and b. Of course, this latter fact is just the $j = n - 1$ case of *(1)*. □

To conclude this section, we recall a question from our earlier Example 4.4: How did we find integers a and b such that the Euclidean Algorithm would terminate in exactly $n = 7$ steps, and why $n = 7$? Well, in seeking examples to illustrate the algorithm to students in Discrete Mathematics courses, we thought that having students perform calculations that involve g_7 and h_7 – which have 13 and 21 terms respectively – would be sufficient to strongly suggest our proposed connection between the Euclidean Algorithm and our Fibonacci array. According to part 1 of Theorem 4.6, we can find such a and b simply by choosing a sequence $q_1, q_2, \ldots, q_7$ of quotients and then taking $b := g_7(q_1, q_2, \ldots, q_7)$ and $a := h_7(q_1, q_2, \ldots, q_7)$. Using the sequence 4, 1, 3, 7, 3, 2, 4 of quotients in Example 4.4, we got $b = 935 = g_7(4, 1, 3, 7, 3, 2, 4)$ and $a = 4449 = h_7(4, 1, 3, 7, 3, 2, 4)$. (Without executing the EA, how do we know a priori that these numbers a and b are relatively prime?)

Maarten Bullynck observes in §3.1 of Bullynck (2009) that certain number theory discourses written separately by Euler and Abraham Gotthelf Kästner in the later eighteenth century illustrated the Euclidean Algorithm with input integers requiring at most five or six applications of the Division Algorithm in order to return the gcd., although Kästner mentions a case "where one has to divide 54 times, before one finds the greatest common measure." Bullynck further notes that this latter question was a classic recreational problem originally due to Leonardo Pisano, whose alias we leave it to the reader to discern. (What is the simplest answer to this riddle?)

5 A Generic Game

The NG, as played in Fig. 5, and the ERG/DRG, as illustrated in Figs. 6 and 7, involve alternating moves of similar types. We capture this idea formally as follows. Fix complex numbers c_1, c_2, etc., and fix another number ε that will typically assume one of the values ± 1. Our *generic game* begins with a chosen pair (a, b) of real numbers. Let j be a positive integer. What we call the $(2j-1)$st *generic game move* changes an ordered pair of numbers (u, v) to $(u - \varepsilon c_{2j-1} v, \varepsilon v)$, and the $(2j)^{\text{th}}$ *generic game move* changes (u, v) to $(\varepsilon u, -\varepsilon c_{2j} u + v)$. That is,

$$\begin{pmatrix} u \\ v \end{pmatrix} \xrightarrow{(2j-1)^{\text{st}}\ \text{move}} \begin{pmatrix} 1 & -\varepsilon c_{2j-1} \\ 0 & \varepsilon \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} u - \varepsilon c_{2j-1} v \\ \varepsilon v \end{pmatrix}$$

$$\begin{pmatrix} u \\ v \end{pmatrix} \xrightarrow{(2j)^{\text{th}}\ \text{move}} \begin{pmatrix} \varepsilon & 0 \\ -\varepsilon c_{2j} & 1 \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} \varepsilon u \\ -\varepsilon c_{2j} u + v \end{pmatrix}.$$

Notice that when $\varepsilon = -1$, $c_1 = c_3 = \cdots = q$, and $c_2 = c_4 = \cdots = p$, then the $(2j\text{–}1)^{\text{st}}$ (respectively, $(2j)$th) NG move played in Fig. 5 is exactly the $(2j\text{–}1)$st (respectively, $(2j)$th) generic game move. Also, when $\varepsilon = +1$ and $c_m = q_m$ for each index m, then the $(2j\text{–}1)$st (respectively, $(2j)$th) ERG move played in Fig. 6 is exactly the $(2j\text{–}1)$st (respectively, $(2j)$th) generic game move. And, when $\varepsilon = +1$ and $c_m = -q'_m$ for each index m, then the $(2j\text{–}1)$st (respectively, $(2j)$th) DRG move played in Fig. 7 is exactly the $(2j\text{–}1)$st (respectively, $(2j)$th) generic game move.

Our analyses of the NG, ERG, and DRG in the preceding sections led us to the following general result which, though somewhat tedious to formulate, is fairly easy to prove by induction. This result grants us some insight as to when and how certain computational processes involve oereo polynomials.

Theorem 5.1 *Let n be a positive integer, and let a and b be real numbers. For convenience, let $n_{\text{m}} := \lfloor (n-1)/2 \rfloor$ and $n_z := \lfloor n/2 \rfloor$. The result of applying the first n generic game moves to the column vector $\binom{a}{b}$ is*

$$\begin{pmatrix} \varepsilon^{n_z} \widehat{g}_{2n_{\text{m}}+1} & -\varepsilon^{1/2} \varepsilon^{n_z} \widehat{h}_{2n_{\text{m}}+1} \\ -\varepsilon^{1/2} \varepsilon^{n_{\text{m}}} \widehat{g}_{2n_z} & \varepsilon^{n_{\text{m}}+1} \widehat{h}_{2n_z} \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} \left(\varepsilon^{n_z} \widehat{g}_{2n_m+1}\right) a - \left(\varepsilon^{1/2} \varepsilon^{n_z} \widehat{h}_{2n_m+1}\right) b \\ -\left(\varepsilon^{1/2} \varepsilon^{n_{\text{m}}} \widehat{g}_{2n_z}\right) a + \left(\varepsilon^{n_{\text{m}}+1} \widehat{h}_{2n_z}\right) b \end{pmatrix},$$

where the quantities $\widehat{g}_k := g_k\left(\varepsilon^{1/2}c_1, \ldots, \varepsilon^{1/2}c_k\right)$ *and* $\widehat{h}_k := h_k\left(\varepsilon^{1/2}c_1, \ldots, \varepsilon^{1/2}c_k\right)$ *are specializations of oereo polynomials.*

Proof At $n = 1$, $\begin{pmatrix} \varepsilon^{n_z}\widehat{g}_{2n_m+1} & -\varepsilon^{1/2}\varepsilon^{n_z}\widehat{h}_{2n_m+1} \\ -\varepsilon^{1/2}\varepsilon^{n_m}\widehat{g}_{2n_z} & \varepsilon^{n_m+1}\widehat{h}_{2n_z} \end{pmatrix}$ becomes $\begin{pmatrix} \widehat{g}_1 & -\varepsilon^{1/2}\widehat{h}_1 \\ -\varepsilon^{1/2}\widehat{g}_0 & \varepsilon\widehat{h}_0 \end{pmatrix}$, which is exactly the matrix $\begin{pmatrix} 1 & -\varepsilon c_1 \\ 0 & \varepsilon \end{pmatrix}$. When $n = 2$, the matrix $\begin{pmatrix} \varepsilon^{n_z}\widehat{g}_{2n_m+1} & -\varepsilon^{1/2}\varepsilon^{n_z}\widehat{h}_{2n_m+1} \\ -\varepsilon^{1/2}\varepsilon^{n_m}\widehat{g}_{2n_z} & \varepsilon^{n_m+1}\widehat{h}_{2n_z} \end{pmatrix}$ becomes $\begin{pmatrix} \varepsilon\widehat{g}_1 & -\varepsilon^{3/2}\widehat{h}_1 \\ -\varepsilon^{1/2}\widehat{g}_2 & \varepsilon\widehat{h}_2 \end{pmatrix}$, i.e., $\begin{pmatrix} \varepsilon & -\varepsilon^{3/2}\left(\varepsilon^{1/2}c_1\right) \\ -\varepsilon^{1/2}\left(\varepsilon^{1/2}c_2\right) & \varepsilon\left(\varepsilon c_1 c_2 + 1\right) \end{pmatrix}$. The latter matrix also arises as the product $\begin{pmatrix} \varepsilon & 0 \\ -\varepsilon c_2 & 1 \end{pmatrix}\begin{pmatrix} 1 & -\varepsilon c_1 \\ 0 & \varepsilon \end{pmatrix}$. These computations confirm the theorem statement for $n = 1$ and $n = 2$.

Suppose that for some odd positive integer n, the matrix $\begin{pmatrix} \varepsilon^{n_z}\widehat{g}_{2n_m+1} & -\varepsilon^{1/2}\varepsilon^{n_z}\widehat{h}_{2n_m+1} \\ -\varepsilon^{1/2}\varepsilon^{n_m}\widehat{g}_{2n_z} & \varepsilon^{n_m+1}\widehat{h}_{2n_z} \end{pmatrix}$ represents the transformation corresponding to the first n generic game moves, with $n_m = \frac{n-1}{2} = n_z$. For the first $n+1$ moves, then, the representing matrix is

$$\begin{pmatrix} \varepsilon & 0 \\ -\varepsilon c_{n+1} & 1 \end{pmatrix}\begin{pmatrix} \varepsilon^{(n-1)/2}\widehat{g}_n & -\varepsilon^{1/2}\varepsilon^{(n-1)/2}\widehat{h}_n \\ -\varepsilon^{1/2}\varepsilon^{(n-1)/2}\widehat{g}_{n-1} & \varepsilon^{(n+1)/2}\widehat{h}_{n-1} \end{pmatrix}$$

$$= \begin{pmatrix} \varepsilon^{(n+1)/2}\widehat{g}_n & \varepsilon^{(n+2)/2}\widehat{h}_n \\ -\varepsilon^{(n+1)/2}c_{n+1}\widehat{g}_n - \varepsilon^{n/2}\widehat{g}_{n-1} & \varepsilon^{(n+2)/2}c_{n+1}\widehat{h}_n + \varepsilon^{(n+1)/2}\widehat{h}_{n-1} \end{pmatrix}$$

$$= \begin{pmatrix} \varepsilon^{(n+1)/2}\widehat{g}_n & \varepsilon^{(n+2)/2}\widehat{h}_n \\ -\varepsilon^{n/2}\left(\varepsilon^{1/2}c_{n+1}\widehat{g}_n + \widehat{g}_{n-1}\right) & \varepsilon^{(n+1)/2}\left(\varepsilon^{1/2}c_{n+1}\widehat{h}_n + \widehat{h}_{n-1}\right) \end{pmatrix}$$

$$= \begin{pmatrix} \varepsilon^{(n+1)/2}\widehat{g}_n & \varepsilon^{(n+2)/2}\widehat{h}_n \\ -\varepsilon^{n/2}\widehat{g}_{n+1} & \varepsilon^{(n+1)/2}\widehat{h}_{n+1} \end{pmatrix} = \begin{pmatrix} \varepsilon^{(n+1)_z}\widehat{g}_{2(n+1)_m+1} & -\varepsilon^{1/2}\varepsilon^{(n+1)_z}\widehat{h}_{2(n+1)_m+1} \\ -\varepsilon^{1/2}\varepsilon^{(n+1)_m}\widehat{g}_{2(n+1)_z} & \varepsilon^{(n+1)_m+1}\widehat{h}_{2(n+1)_z} \end{pmatrix},$$

as desired. Similar computations verify the result when n is even.

Here are specific consequences for the Networked-numbers and the Euclidean and Dual Remainders Games.

Corollary 5.2 *Let k be an odd positive integer. The formulas and identities in each statement below refer to* Figs. 5, 6, and 7.

(NG part) In the Networked-numbers Game, the numbers after k node-firings are:

$$\begin{array}{ll} k^{\text{th}} \text{ node firing} & \overline{F}_{k-1}(pq)a + q\overline{F}_k(pq)b \qquad -p\overline{F}_{k-2}(pq)a - \overline{F}_{k-1}(pq)b \\ (k+1)^{\text{st}} \text{ node firing} & -\overline{F}_{k-1}(pq)a - q\overline{F}_k(pq)b \qquad p\overline{F}_k(pq)a + \overline{F}_{k+1}(pq)b \end{array}$$

(ERG part) In the Euclidean Remainders Game, the remainder pairs after k applications of the Division Algorithm in the Euclidean Algorithm are:

$$\begin{array}{ll} r_{k-2} = q_k r_{k-1} + r_k & r_k = g_k(q_1, \ldots, q_k)a - h_k(q_1, \ldots, q_k)b \qquad r_{k-1} = -g_{k-1}(q_1, \ldots, q_k)a + h_{k-1}(q_1, \ldots, q_k)b \\ r_{k-1} = q_{k+1} r_k + r_{k+1} & r_k = g_k(q_1, \ldots, q_k)a - h_k(q_1, \ldots, q_k)b \quad r_{k+1} = -g_{k+1}(q_1, \ldots, q_{k+1})a + h_{k+1}(q_1, \ldots, q_{k+1})b \end{array}$$

(DRG part) In the Dual Remainders Game, the dual remainder pairs after k DRG moves are:

$$\begin{array}{ll} r'_k = q'_k r'_{k-1} + r'_{k-2} & r'_k = h_k(q'_1, \ldots, q'_k)\, r'_0 \qquad r'_{k-1} = h_{k-1}(q'_1, \ldots, q'_{k-1})\, r'_0 \\ r'_{k+1} = q'_{k+1} r'_k + r'_{k-1} & r'_k = h_k(q'_1, \ldots, q'_k)\, r'_0 \qquad r'_{k+1} = h_{k+1}(q'_1, \ldots, q'_{k+1})\, r'_0 \end{array}$$

Proof We observed, in the second paragraph of this section, that the NG, ERG, and DRG are special cases of our generic game. So, we only need to confirm that the generic outcome of Theorem 5.1 specializes to the outcomes described in the corollary statement for each of our three games.

For the NG, we have $\varepsilon = -1, p = c_2 = c_4 = \text{etc.}$, and $q = c_1 = c_3 = \text{etc.}$ There are two cases to consider: For some nonnegative integer ℓ, we have $k = 4\ell + 1$ or $k = 4\ell + 3$. To begin, suppose $k = 4\ell + 1$. Then $k_{\text{m}} = (k-1)/2 = k_{\text{z}}$ and $i^{k-1} = 1$ (for the imaginary number i). By Theorem 5.1, the numbers after k node-firings are $\left(\varepsilon^{k_{\text{z}}}\widehat{g}_{2k_{\text{m}}+1}\right)a - \left(\varepsilon^{1/2}\varepsilon^{k_{\text{z}}}\widehat{h}_{2k_{\text{m}}+1}\right)b$ and $-\left(\varepsilon^{1/2}\varepsilon^{k_{\text{m}}}\widehat{g}_{2k_{\text{z}}}\right)a + \left(\varepsilon^{k_{\text{m}}+1}\widehat{h}_{2k_{\text{z}}}\right)b$, which simplify to $\left(i^{k-1}\widehat{g}_k\right)a - \left(i^k\widehat{h}_k\right)b$ and $-\left(i^k\widehat{g}_{k-1}\right)a + \left(i^{k+1}\widehat{h}_{k-1}\right)b$. Now, $\left(i^{k-1}\widehat{g}_k\right)a - \left(i^k\widehat{h}_k\right)b = \widehat{g}_k a - i\widehat{h}_k b$. By definition $g_k = \sum_{j=0}^{(k-1)/2}\sum_{T\in\mathcal{EO}(k,j)} x_{T_1}\cdots x_{T_{(k-1)-2j}}$. When we set $x_{2m} := ip$ and $x_{2m+1} = iq$ for each m, then g_k specializes to $\widehat{g}_k = \sum_{j=0}^{(k-1)/2} f_{k-1,j}\, i^{(k-1)-2j}(pq)^{\frac{k-1}{2}-j} = \sum_{j=0}^{(k-1)/2}(-1)^j f_{k-1,j}\,(pq)^{\frac{k-1}{2}-j} = \overline{F}_{k-1}(pq)$. Similarly, $h_k = \sum_{j=0}^{(k-1)/2}\sum_{T\in\mathcal{O}\mathcal{E}(k,j)} x_{T_1}\cdots x_{T_{k-2j}}$, so that $\widehat{h}_k = \sum_{j=0}^{(k-1)/2} f_{k,j}\, iq\, i^{k-1-2j}(pq)^{\frac{k-1}{2}-j} = iq\sum_{j=0}^{(k-1)/2}(-1)^j \ f_{k,j}\,(pq)^{\frac{k-1}{2}-j} = iq\overline{F}_k(pq)$. Therefore, $\widehat{g}_k a - i\widehat{h}_k b = \overline{F}_{k-1}(pq)a + q\overline{F}_k(pq)b$, as desired. Also, $-\left(i^k\widehat{g}_{k-1}\right)a + \left(i^{k+1}\widehat{h}_{k-1}\right)b = -i\widehat{g}_{k-1}\,a - \widehat{h}_{k-1}\,b$. The eo-polynomial given by $g_{k-1} = \sum_{j=0}^{(k-3)/2}\sum_{T\in\mathcal{EO}(k-1,j)} x_{T_1}\cdots x_{T_{(k-2)-2j}}$ specializes to $\widehat{g}_{k-1} = \sum_{j=0}^{(k-3)/2} f_{k-2,j}\, pi^{(k-2)-2j}(pq)^{\frac{k-3}{2}-j} = -ip\overline{F}_{k-2}(pq)$. Similarly see that the

oe-polynomial $h_{k-1} = \sum_{j=0}^{(k-1)/2} \sum_{T \in O\mathcal{E}(k-1,j)} x_{T_1} \cdots x_{T_{(k-1)-2j}}$ specializes to $\widehat{h}_{k-1} = \overline{F}_{k-1}(pq)$. Then, $-i\widehat{g}_{k-1}a - \widehat{h}_{k-1}b = -p\overline{F}_{k-2}(pq)a - \overline{F}_{k-1}(pq)b$, as desired. To complete our analysis of the $k = 4\ell + 1$ case, we must also show that the numbers at nodes γ_1 and γ_2 after $k + 1$ node-firings are $-\overline{F}_{k-1}(pq)a - q\overline{F}_k(pq)b$ and $p\overline{F}_k(pq)a + \overline{F}_{k+1}(pq)b$. To confirm this, it suffices to verify the following matrix identity:

$$\begin{pmatrix} -1 & 0 \\ p & 1 \end{pmatrix} \quad \begin{pmatrix} \overline{F}_{k-1}(pq)a + q\overline{F}_k(pq)b \\ -p\overline{F}_{k-2}(pq)a - \overline{F}_{k-1}(pq)b \end{pmatrix} = \begin{pmatrix} -\overline{F}_{k-1}(pq)a - q\overline{F}_k(pq)b \\ p\overline{F}_k(pq)a + \overline{F}_{k+1}(pq)b \end{pmatrix}.$$

This follows easily from the facts that $\overline{F}_k(pq) = -\overline{F}_{k-2}(pq) + \overline{F}_{k-1}(pq)$ and that $\overline{F}_{k+1}(pq) = -\overline{F}_{k-1}(pq) + pq\overline{F}_k(pq)$. This completes our analysis of the case $k = 4\ell + 1$. Analysis of the $k = 4\ell + 3$ case is entirely similar.

For the ERG, we have $\varepsilon = +1$ and $c_m = q_m$ for each m. As in the preceding paragraph, $k_{\mathrm{m}} = (k - 1)/2 = k_{\mathrm{z}}$. Then $\left(\varepsilon^{k_{\mathrm{z}}}\widehat{g}_{2k_{\mathrm{m}}+1}\right)a - \left(\varepsilon^{1/2}\varepsilon^{k_{\mathrm{z}}}\widehat{h}_{2k_{\mathrm{m}}+1}\right)b$ and $-\left(\varepsilon^{1/2}\varepsilon^{k_{\mathrm{m}}}\widehat{g}_{2k_{\mathrm{z}}}\right)a + \left(\varepsilon^{k_{\mathrm{m}}+1}\widehat{h}_{2k_{\mathrm{z}}}\right)b$, which simplify to $\widehat{g}_k a - \widehat{h}_k b$ and $-\widehat{g}_{k-1}a + \widehat{h}_{k-1}b$ respectively, confirming the first two of the four ERG-related identities in the corollary statement. From the computation

$$\begin{pmatrix} 1 & 0 \\ -q_{k+1} & 1 \end{pmatrix} \quad \begin{pmatrix} \widehat{g}_k a - \widehat{h}_k b \\ -\widehat{g}_{k-1}a + \widehat{h}_{k-1}b \end{pmatrix} = \begin{pmatrix} \widehat{g}_k a - \widehat{h}_k b \\ -\widehat{g}_{k+1}a + \widehat{h}_{k+1}b \end{pmatrix}$$

we confirm that the numbers resulting from the $(k + 1)$st application of the Division Algorithm in the ERG are as claimed.

For the DRG, we have $\varepsilon = +1$ and $c_m = -q'_m$ for each m. We also regard $a =$ 'r'_{-1}' $= 0$ and $b = r'_0$. For our odd number k, $k_{\mathrm{m}} = (k - 1)/2 = k_{\mathrm{z}}$. Then $\left(\varepsilon^{k_{\mathrm{z}}}\widehat{g}_{2k_{\mathrm{m}}+1}\right)a - \left(\varepsilon^{1/2}\varepsilon^{k_{\mathrm{z}}}\widehat{h}_{2k_{\mathrm{m}}+1}\right)b$ immediately simplifies to $-\widehat{h}_k r'_0$. Specializing $h_k = \sum_{j=0}^{(k-1)/2} \sum_{T \in O\mathcal{E}(k,j)} x_{T_1} \cdots x_{T_{k-2j}}$ by exchanging each x_m with $-q'_m$ gives us $\widehat{h}_k = \sum_{j=0}^{(k-1)/2} \sum_{T \in O\mathcal{E}(k,j)} (-1)^{k-2j} q'_{T_1} \cdots q'_{T_{k-2j}} = -h_k(q'_1, \ldots, q'_k)$, so $-\widehat{h}_k r'_0$ is just $h_k(q'_1, \ldots, q'_k)r'_0$. Also, $-\left(\varepsilon^{1/2}\varepsilon^{k_{\mathrm{m}}}\widehat{g}_{2k_{\mathrm{z}}}\right)a + \left(\varepsilon^{k_{\mathrm{m}}+1}\widehat{h}_{2k_{\mathrm{m}}}\right)b$ immediately simplifies to $\widehat{h}_{k-1}r'_0$. Setting $x_m := -q'_m$ in $h_{k-1} = \sum_{j=0}^{(k-1)/2} \sum_{T \in O\mathcal{E}(k-1,j)} x_{T_1} \cdots x_{T_{(k-1)-2j}}$ yields $\widehat{h}_{k-1} = \sum_{j=0}^{(k-1)/2} \sum_{T \in O\mathcal{E}(k-1,j)} (-1)^{(k-1)-2j} q'_{T_1} \cdots q'_{T_{(k-1)-2j}} = h_{k-1}(q'_1, \ldots, q'_{k-1})$. This means that $\widehat{h}_{k-1}r'_0 = h_{k-1}(q'_1, \ldots, q'_{k-1})r'_0$. Our work so far in this paragraph confirms the first two of the four DRG-related identities in the corollary statement; the remaining two identities follow from entirely similar computations. □

6 Is Bézout's Lemma a Constructive or Nonconstructive Result?

The result traditionally known as Bézout's Lemma is the following assertion:

Lemma 6.1 (Bézout's Lemma) *Given integers a and b, not both of which are zero, there exist integers s and t such that* $\gcd(a, b) = as + bt$.

Integers s and t satisfying the existence claim of Lemma 6.1 are called *Bezout coefficients.* One of our motivations for presenting oereo polynomials is to showcase how they yield a straightforward and "constructive" proof of Bézout's Lemma by giving us immediate and transparent formulas for Bézout coefficients.

A Constructive Proof of Lemma 6.1 In the notation of part 2 of Theorem 4.6, we see that one pair of Bézout coefficients is $s = (-1)^n g_{n-1}(q_1, \ldots, q_{n-1})$ and $t = (-1)^{n-1} h_{n-1}(q_1, \ldots, q_{n-1})$. □

Although the result of Lemma 6.1 is attributed to Étienne Bézout (1766), a version of it was discovered more than a century prior by Claude Gaspard Bachet (1624). Working within the context of the Euclidean Algorithm from Euclid's Book VII, Bachet used symbolic algebra to describe a general solution to the Diophantine equation $ax - by = 1$, when a and b are co-prime (i.e., $\gcd(a, b) = 1$), by backtracking through the quotients and remainders produced by the steps of the algorithm. But it was with Bézout's work that the more general notion of solving $ax + by = \gcd(a, b)$ over the integers was recognized as a key result within elementary number theory (see, for example, the wonderfully readable account in Bullynck (2009) of the European history of such remainder problems in the centuries preceding Carl Friedrich Gauss).

But what might be practical about Bézout's Lemma? Here is a modern application. Cryptosystems often utilize modular arithmetic and, in particular, can require the computation of multiplicative inverses within this environment. Suppose, for example, we know that a and b are co-prime and wish to compute $\overline{b}^{-1}$ within the quotient ring $\mathbb{Z}_a := \mathbb{Z}/a\mathbb{Z}$, if such an inverse exists at all. (Here, $\overline{x}$ denotes the coset $x + a\mathbb{Z}$ in $\mathbb{Z}_a$.) Well, write $1 = as + bt$, where (s, t) is a pair of Bézout coefficients. Then $\overline{1} = \overline{as + bt} = \overline{a}\,\overline{s} + \overline{b}\,\overline{t} = \overline{b}\,\overline{t}$, so $\overline{b}\,\overline{t} = \overline{1}$. That is, $\overline{b}$ has a multiplicative inverse in $\mathbb{Z}_a$, and $\overline{b}^{-1} = \overline{t}$.

Given such computational contexts, it is curious that contemporary treatments of Bézout's Lemma are often nonconstructive. At least, this is our experience based on the five discrete-oriented textbooks we have used in recent years in undergraduate mathematics courses – by Burton (2010), Gallian (2015), Richmond and Richmond (2004), Rosen (2012), and Sundstrom (2022). Among these texts, only Gallian (2015) has no treatment of the Euclidean Algorithm. Only Burton (2010), Richmond and Richmond (2004), and Sundstrom (2022) consider linear Diophantine equations in two variables, which are worth noting since, of course, knowledge of a particular

pair of Bézout coefficients is needed to formulate a general solution to the Diophantine equation $ax + by = \gcd(a, b)$. Nonconstructive treatments of Bézout's Lemma can be found in Theorem 2.3 of Burton (2010), in Theorem 0.2 of Gallian (2015), and in Theorem 4.3.6 of Rosen (2012) (with a proof of the latter outlined in §5.2 Exercise #36). These nonconstructive approaches appeal to the Well-Ordering Principle of the positive integers, which asserts, without any computational specificity, that *any nonempty set of positive integers contains a smallest integer.* Here is a typical argument.

A Nonconstructive Proof of Lemma 6.1 Assuming a and b are not both zero, then $\{ax + by \mid x, y \in \mathbb{Z} \text{ and } ax + by > 0\}$ is nonempty and we may, by invoking the Well-Ordering Principle, declare d to be the smallest element in this set. Clearly $\gcd(a, b) \mid d$, so $\gcd(a, b) \leqslant d$. To see that d is a divisor of a, write $a = dq + r$ with $0 \leqslant r < d$, whence $r = dq - a = a(xq - 1) + b(yq)$, forcing $r = 0$. We similarly see that $d \mid b$, and we may conclude now that $d \leqslant \gcd(a, b)$. So, $d = \gcd(a, b)$. □

The "transitions" textbook by Sundstrom (2022) states a version of Bézout's Lemma in Theorem 8.8, but without proof (although an induction argument is indicated). Within our sample, only the text by Richmond and Richmond (2004) offers a constructive proof of Bézout's Lemma; this is done by providing an iterative procedure for computing Bézout coefficients as part of a correctness proof for the Euclidean Algorithm (see the proof of Theorem 3.2.1 in that text).

Curiously, none of our five sample texts gives a constructive proof of the Division Algorithm, and all of them follow the convention stated in Rosen (2012):

> We use the traditional name for this theorem even though the division algorithm is not actually an algorithm.

Theorem 6.2 below offers a typical statement of this theorem along with a typical nonconstructive proof of the theorem's existence claim (we take the uniqueness claim to be routine). While this theorem is conventionally known as the "Division Algorithm," we believe it ought to be called the "Quotient and Remainder Theorem."

Theorem 6.2 (Quotient and Remainder Theorem aka the Division Algorithm) *Given integers a and b with $b \neq 0$, there exist unique integers q and r such that $r \in [0, |b|)_{\mathbb{Z}}$ and $a = bq + r$.*

A Nonconstructive Proof of Existence in Theorem 6.2 Clearly the set $\{a - bk \mid k \in \mathbb{Z} \text{ and } a - bk \geqslant 0\}$ is nonempty. By the Well-Ordering Principle, it therefore contains a smallest element r of the form $a - bq$, from which we easily deduce that $0 \leqslant r < |b|$. □

It seems that a significant motivation for such nonconstructive approaches to the Division Algorithm is to present an early example of a use of the Well-Ordering Principle. By contrast, Sundstrom (2022) treats the Division Algorithm as an axiom,

in part for the reason that the natural numbers are not formally defined in his text and therefore the Well-Ordering Principle is regarded as unavailable (2022, §3.5, §4.1, and §8.1).

However, there seems to be merit in viewing the Division Algorithm as an actual algorithm. Such a process is intuitive and easy to articulate when a and b are positive integers with $a \geqslant b$: Repeat the process of subtracting b from a until the difference is smaller than b, and then the quotient q is the number of subtractions performed and the remainder r is the difference $a - qb$. Allowing the input integers a and b to be more generic makes the algorithm only slightly more involved, but this is relatively easy to handle. For any integer m, we let $\operatorname{sgn}(m) \coloneqq \begin{cases} |m|/m & \text{if } m \text{ is nonzero} \\ 0 & \text{if } m = 0 \end{cases}$. Note that $\operatorname{sgn}(|m| - m) = \mathbf{1}_{(-\infty,0)_{\mathbb{Z}}}(m)$, where $\mathbf{1}_{(-\infty,0)_{\mathbb{Z}}}$ denotes the so-called "indicator function" for the negative integers as a subset of $\mathbb{Z}$.

Definition 6.3 The *Division Algorithm (DA)* is the following pseudocode procedure:

Input: Integers a and b with $b \neq 0$.
Initialization: Let k be our iteration-counter, also to be viewed as a multiplier for $|b|$ and initialized with $k \coloneqq 0$. Let c be the difference between $|a|$ and the current multiple of $|b|$, initialized with $c \coloneqq |a|$.
Step 1: If $c < |b|$, let $q \coloneqq \operatorname{sgn}(ab) \cdot \left(k + \mathbf{1}_{(-\infty,0)_{\mathbb{Z}}}(a)\right)$ and $r \coloneqq a - bq$, and Return the following data: QUO $\coloneqq q$ and REM $\coloneqq r$.
Step 2: Otherwise, replace k with $k + 1$ and c with $c - |b|$, and return to Step 1.
Output: An integer QUO to be called the *quotient when a is divided b* and an integer REM to be called the *remainder*.

(We use the notation DA(a, b)[QUO] to denote the quotient returned by the Division Algorithm and DA(a, b)[REM] to denote the remainder. It must be shown that DA(a, b)[REM] is in the interval $[0, |b|_{\mathbb{Z}})$.) □

As we did with the Euclidean Algorithm, we certify in the following theorem that the DA terminates and prove that it returns the desired output. In particular, this theorem provides a constructive proof of the existence claim in Theorem 6.2.

Theorem 6.4 (Boundedness and Correctness of the Division Algorithm) *Let a and b be integers with $b \neq 0$. With this input, the Division Algorithm terminates, and for the output values $q \coloneqq$ DA(a, b)[QUO] and $r \coloneqq$ DA(a, b)[REM], we have $a = bq + r$ and $r \in [0, |b|)_{\mathbb{Z}}$.*

Proof The "current difference" measure c takes on, in succession, the values in the sequence $(|a|, |a| - |b|, |a| - 2|b|, \ldots)$. The algorithm terminates when $c < |b|$. Since the inequality $|a| < (|a| + 1)|b|$ is true for all integers a and b with $b \neq 0$, then $|a| - |a|$ $|b| < |b|$, confirming that there is some number in the sequence $(|a|, |a| - |b|, |a| - 2|b|,$

...) that is less than $|b|$. That is, the algorithm will terminate in no more than $|a|$ iterations.

Since $r \coloneqq \mathrm{DA}(a, b)[\textsc{rem}]$ is defined by the algorithm to be $a - b(\mathrm{DA}(a, b)[\textsc{quo}]) = a - bq$, then we get $a = bq + r$ automatically. So, we only need to check now that $r \in [0, |b|)_{\mathbb{Z}}$. It suffices to analyze the following four cases: $(++)$ $a \geqslant 0$ and $b < 0$, $(+-)$ $a \geqslant 0$ and $b < 0$,$(-+)$ $a < 0$ and $b > 0$, and$(--)$ $a < 0$ and $b < 0$. For case $(+-)$, let k be the value of our counter when $a - k|b| < |b|$ but $a - (k-1)|b| \geqslant |b|$. In this case, $q = \operatorname{sgn}(ab)\left(k + \mathbf{1}_{(-\infty,0)_{\mathbb{Z}}}(a)\right) = (-1)\ (k + 0) = -k$. Then $|b| > a - k\,|b| = a + q|b| = a + q(-b) = a - bq = r$. Also, $0 \leqslant a - (k-1)\,|b| - |b| = a - k\,|b| = a + q|b| = a + q(-b) = a - bq = r$. The $(++)$,$(-+)$, and$(--)$ cases can be analyzed similarly. □

7 Conclusion

There are many possible ways to extend the foregoing discussions. For example, we might play the Euclidean Remainders Game with three or more positive integers. What should be our requirement for termination of the game? Will every game terminate? What might "strong convergence" mean in this context? In another direction, we might consider oereo sequences and polynomials relating to the right-triangular *Lucas array* of Fig. 8, cf. OEIS entry A034807 (2023). To this end, we define *Lucasian oereo sequences* as the following sets, when $n \in [2, \infty)_{\mathbb{Z}}$: We let $\mathcal{OE}^{\mathrm{Lucas}}(n) \coloneqq \{T \in \mathcal{OE}(n+1) \mid T \text{ contains at least one of 1 or } n+1\}$, and we let $\mathcal{EO}^{\mathrm{Lucas}}(n) \coloneqq \{T \in \mathcal{EO}(n+1) \mid T \text{ contains at least one of 2 or } n+1\}$. Then define *Lucasian oereo polynomials* as

$$k_n \coloneqq \sum_{T \in \mathcal{EO}^{\mathrm{Lucas}}(n)} \mathrm{x}_T \quad \text{and} \quad l_n \coloneqq \sum_{T \in \mathcal{OE}^{\mathrm{Lucas}}(n)} \mathrm{x}_T.$$

What can be said about these Lucasian oereo polynomials?

$$\begin{array}{ccccc}
2 & & & & \\
1 & & & & \\
1 & 2 & & & \\
1 & 3 & & & \\
1 & 4 & 2 & & \\
1 & 5 & 5 & & \\
1 & 6 & 9 & 2 & \\
1 & 7 & 14 & 7 & \\
1 & 8 & 20 & 16 & 2 \\
1 & 9 & 27 & 30 & 9 \\
 & & \text{ETC.} & &
\end{array}$$

Fig. 8 Depiction of some rows of the right-triangular Lucas array

Our effort to better understand the historical record concerning Terquem's problem led us to connect his ideas with Fibonacci numbers, a one-player game of numbers, continuants, the Euclidean Algorithm, and Bézout's Lemma. In particular, we have a newfound, or at least now-unforgotten, interpretation of the numbers of the Fibonacci array and combinatorially explicit descriptions of continuants as oereo polynomials. All these ideas have antecedents in the literature, but, taken together as presented here, we believe they provide an explicit and combinatorially compelling account of these elementary number theoretic notions that might be advantageously accommodated in introductory discourses on these topics.

Abstract

This chapter examines the role and need for ethics in mathematical practice. Mathematics is one of the few areas of study in which ethics is widely perceived as irrelevant. Many mathematicians and others resist the idea that we need to consider the ethics of both pure and applied mathematics. The foundations of this

resistance are analyzed and located in background philosophies and ideologies of purism and neutrality. The range of social practices is investigated, and different ethical problems and issues are brought to light. It is argued that virtuous mathematicians can legitimately pursue mathematics for its own sake, but as citizens they also have a responsibility to care about the social impacts of mathematics. A review of the literature on the social responsibility of science and mathematics reveals that, although long neglected, concerns about the ethics of mathematics are starting to emerge in publications and training practices. Some of the more ethically sensitive areas are explored and three problematic categories are distinguished and exemplified. These are (1) mathematics in public communications, (2) overt applications of mathematics with powerful social impacts, and (3) the hidden performativity of mathematics in restructuring society, institutions, and social practices.

Keywords

Ethics of mathematics · Absolutism · Social constructivism · Purism · Social responsibility · Mathematical practice · Social applications · Performativity

1 Introduction: A Vignette

An artist, a physicist, and a mathematician are interviewed for a late night TV show. The compere asks each of them two questions. What is the point of your practice? What are your social responsibilities?

The artist begins: "The point of art is to make artefacts or performances that explore the domain of beauty, and that push my craft to the limit in trying to achieve beauty. But it is also to explore the boundaries of what is art, and push them back without worrying about transgressing the limits of polite society approval. In short, to pursue art for art's sake. The social responsibility of art is merely to pursue these missions fearlessly without worrying about morality and ethics. Artistic expression is part of freedom, and this freedom should not be limited by bourgeois taste or the dead hand of the past."

The physicist answers: "The point of physics is to observe, describe and map the world in terms of its basic physical components and processes. We build theories that describe as accurately as possible the behaviour of matter, energy, space and time. Our overwhelming duty is to truth, and so we test all our theories with crucial experiments that try to falsify them, in order to approach truth more closely. Our social responsibilities arise from the power of our theories. Because we can predict and hence control the huge forces of nature and the world, including electromagnetic, nuclear, and gravitational energy, we have to be cautious and aware of the applications of physics and through it, technologies. We pursue basic theories to the limit, but it is right that scientists and society are aware of and control the impacts of applications on the social and material worlds. We have a duty to truth, but also to the good."

The mathematician answers: "The point of mathematics is to pursue mathematical truth. This is truth about the perfect world of mathematical objects, which are

timeless, perfect and exist in their own realm, untouched by material changes and decay. The truth we pursue can be exquisitely beautiful, but we are merciless in our rigour and only the most robust proofs can be accepted as demonstrating the truth of our results. Our responsibility is to pursue mathematical knowledge and beauty beyond all earthly bounds, knowing that we enrich human culture inestimably. Although our responsibilities end with the pursuit of mathematics for its own sake, it often turns out that the most abstract theories have surprising and very fruitful applications in science, technology and in modelling the physical world. But this is a happy accident, discovered only after we have revealed the truth. We pursue truth and beauty, but the only good we have to worry about is being good *mathematicians*."

Is this right? Does mathematics only have to concern itself with truth and beauty and not with the good of humanity in a broader sense? Has mathematics no social responsibilities, no debt to the society that nurtures and funds it? Is ethics irrelevant to pure mathematics, as many mathematicians think? In order to answer these questions I need to clarify the main philosophical answers to the question *what is mathematics*? There are also important subsidiary questions *where is mathematics*? And *what is mathematical practice?* which also have a profound bearing on ethical issues.

2 Philosophies of Mathematics

One of the major determinants of belief in whether ethics is relevant to mathematics is the philosophy of mathematics held by a mathematician. There is a range of opinions, beliefs, and schools of thought about what mathematics is that can be simplified into a dichotomy between absolutist and social constructivist philosophies. Here there is an enduring controversy over whether pure mathematics is objective and universal, or whether it is a humanly made construction (Hersh 1997; Ernest 1998). Both sides of this dispute have legitimacy, but they are incompatible philosophies of mathematics. The two sets of views are as follows.

First, there are what can be termed absolutists, who subscribe to the view that mathematics is an objective, universal, and absolute science.

Absolutists claim that the following are true about mathematics:

1. Mathematics is universal and unique, and all systems of mathematics can be translated into modern classical mathematics.
2. Mathematics is invariant and timeless and that mathematical concepts apply and mathematical results hold in all places and at all times. Even results that are several millennia old, such as Pythagoras' theorem and Euclid's proof of the infinity of prime numbers, are still valid.
3. Mathematics is objective, as there are fixed rules for determining its truths independent of subjective opinion or differing cultural outlooks.
4. Mathematics is discovered rather than invented. This is illustrated by simultaneous discoveries, and by the rich interconnectedness and overall unity of the disparate branches and topics of pure mathematics, no matter how far they are independently developed.

5. Above all else, Mathematics is based on an objective, universal, eternal, and absolute conception and definition of truth.
6. Values and ethics are irrelevant to pure mathematics, for they do not impinge on its zone of objectivity.

Absolutists and Platonists in the philosophy of mathematics, who adhere to some or all these views, are many and include the following notable mathematicians and philosophers: Paul Erdős and Kurt Gödel (Wikipedia 2020a), Hardy (1929), Penrose (1989), and Balaguer (1998).

In contrast, the opposing social constructivist philosophy, a minority view, takes the following position about mathematics:

1. Mathematics only exists as a complex product and element of social practices, and thus in definite material form comprises human activities and their productions: for example, inscriptions, texts, institutions, and agreements (Cole 2013).
2. Mathematics is not a unique and unified discipline, for mathematics is made up of many different and changing specialist social practices.
3. Classical mathematics as represented in standard texts is not the only possible science of mathematics, and there exist alternatives that are equally real-world applicable such as constructive mathematics.
4. Mathematics is not forced upon us through necessity, neither empirically nor logically. But once we accept the premises of a theory and its rules, then the results follow by necessity.
5. Mathematics rests upon definitions of truth, logic, reasoning, and proof that are not necessary, universal, or invariant across time and space, although they are regarded as so within mathematical practices.
6. Mathematics is a historical, social construction and is thus contingent on historical actions and human choices and interests, and is neither necessary nor arbitrary.
7. Mathematics is a human invention imbued with the values and interests of its makers and hence is not above or beyond ethical values (Ernest 1998; Hersh 1997).

As an example of the values mentioned in (7), pure mathematics may be claimed to be open and democratic because the calculations and proofs upon which its knowledge and applications depend must be open to scrutiny by others. Unlike authority-based areas such as religion, mathematical claims can only be founded on open, accessible, and persuasive demonstrations. Thus, mathematics is necessarily open and democratic, and these are values greatly prized in Western and other societies. (Harris (2015) argues that mathematics is caught on the horns of a dilemma. It is both democratic, as I argue here, and anti-democratic and elitist, because only a privileged few judge the correctness or value of new knowledge contributions.) However, this argument assumes that truth depends on its demonstrations. Absolutists argue that the truth of a theorem is absolute and precedes its human verification. Proofs are devices to demonstrate this truth to mathematicians. So this example does not represent a definitive way of choosing between the two competing philosophies of mathematics.

The contrast between the views of Absolutists and Platonists, on the one hand, and social constructivists, on the other hand, is brought into sharp focus in the controversy over whether mathematics is discovered or invented. For example, consider the field of Number Theory. This is a well-defined topic in mathematics that rests since Peano's formulation on a single element (0, in modern formulations), a single unary operation (S, the successor function), a single binary relation (=), and a handful of axioms (and a background logic and with a metatheory that allows the definition of further functions). On the basis of this rather limited foundation, the huge edifice of modern Number Theory has been erected, encompassing results stretching from Andrew Wiles' solution to the Fermat Conjecture to Gödel's Incompleteness Theorems. These results admittedly draw on concepts from beyond Number Theory, in the strict sense, in their proofs.

Results such as these are constructed with human ingenuity, including the invention of many subsidiary concepts, functions, and methods, within the constraints imposed by working within Number Theory with its axioms and rules of proof. Thus, they can be seen as marvelous products of spontaneous human invention. They can also be viewed as results discovered by an explorer mathematician within the pre-existing field of number once the gate to Number Theory has been opened for human access. They can be viewed as discoveries within the pre-existing domain of mathematical knowledge.

3 Where Is Mathematics? (M)athematics Versus (m)athematics

Some authors like to distinguish between what is termed *Mathematics* and *mathematics* (Bishop 1988). Mathematics with a capital *M* is the sum or body of formal mathematical knowledge and mathematical objects that exist independently of mathematicians. The lower case *m* in the term mathematics signifies that it refers to and comprises human mathematical practices. The distinction is an ontological one, about existence. Mathematics with a capital M is claimed to be real, made up of independently existing concepts, objects, proofs, truths, and theories. This is the traditional realist ontological position, as was traditionally opposed to Conceptualism (mathematics is made up of concepts that exist only in people's minds) and Nominalism (mathematics consists only of linguistic names, signs, and symbols).

Two forms of realism can be distinguished. First, there is Social Realism, which understands that Mathematics is something created by people but which has an existence beyond any individual or group of persons, but not beyond the sum of human culture and history. Thus, the answer to *where is Mathematics?* is that it is located in the cultural matrix of human activity embedded in the human society and history. Mathematics is culturally real, but does not exist independently of humans and human activity, and in particular, the social practices of mathematics (Ernest 1998; Hersh 1997).

Second, there is Platonism, which claims that Mathematics is real, but it exists independently of humanity and is to be found in some abstract, superhuman realm.

According to this view, mathematics is timeless, having always been true, and objective, not affected by human actions, let alone by human subjective beliefs. Thus, this abstract Platonic realm provides the answer to the question *where is Mathematics?* Platonists subscribe to the view that mathematical objects and truths are real and exist in an independent supraphysical realm to which mathematicians have access and from which they can gain knowledge.

It is of course possible to be a realist without subscribing to social constructivism or Platonism, by simply asserting that mathematics and its objects are real without specifying where mathematics is to be found.

It is clear that the question of where mathematics is has a direct bearing on the issue of ethics. For if mathematics is of another world, as in Platonism, then ethical and other human concerns are irrelevant. But if mathematics is socially located, then it is imbued with values and ethics like all other human activities and practices.

A further relevant question is whether mathematics is a single identifiable entity. Is it a unified collection of mathematical knowledge and mathematical objects (*Mathematics*), or is it a social practice or set of social practices (*mathematics*)?

4 The Myth of Mathematics as a Unique and Unified Subject

Ever since Plato, or before, humans have been inclined to view nouns as denoting some real or ideal object. London is a real place, albeit with vague boundaries. But to extend this view to all nouns – proper, general, or abstract – is a linguistic and philosophical fallacy. Apart from concrete particulars, far from only naming pre-existent objects, nouns create fictive objects that correspond to their names, such as Harry Potter, the Equator, or as I wish to argue here Mathematics. So what can the term "mathematics" denote? Epistemologically, it denotes a body of knowledge. But a body is a unified and connected material corpus, and there is no organized and unified system of mathematical knowledge. Within academic mathematics, just pure mathematics alone refers to hundreds of subfields and topics (Davis and Hersh 1980; Lerman 2010) that at best share a family resemblance (Wittgenstein 1953). There is no shared set of symbols, concepts, theories across most, let alone all, of mathematics. The study and theories of number constitute a central theme in the history of mathematics. But there are plenty of mathematical theories that do not use number in any essential way, such as Euclidean geometry.

A further question is whether all of mathematics uses the same methods of verification of its truth, the same system of proof? But not only have proof styles varied greatly over the past two millennia plus since Euclid, but many different proof styles and method coexist simultaneously in different branches of and specialisms within mathematics. Consider only the differences between Number Theory, Classical Analysis, Axiomatic Set Theory, Category Theory, Topology, and Non-standard Analysis. There is no central set of shared symbols, proof methods, or rhetorical styles (Knuth 1985). Thus, mathematics is made up of a family of overlapping but disparate practices.

This is bad enough. But the disparate collection of subfields, topics, and practices that make up pure mathematics far from exhausts mathematics. Beyond pure mathematics there are to be found practices of applied mathematics, theoretical physics, statistics, computer mathematics, school mathematics, accountancy mathematics, banking mathematics, the mathematics of trading and the markets, mathematics in economic theory, street mathematics, ethnomathematics, numerology, and so on. We cannot say that these all share the same basic ideas. Consider number again. There are many different systems and structures we label as number (this term itself is another fiction of unified referent). But even if we allow that number is a unified set of concepts for counting and ordering, there are areas of knowledge constituted by patterning, geometry, argumentation that are mathematics but do not involve number (Bishop 1988).

So there are no universally shared concepts of mathematics, and there is no central set of shared proof methods across all the specialisms within mathematics. Mathematics lacks epistemic and even epistemological unity. Looking at mathematics throughout history and across cultures, present and past, there are huge variations in what we term mathematics and its methods of justification.

Culturally, in terms of social practices, there is even less reason to claim that mathematics constitutes a unity. For in addition to all the above disparate knowledge fields, it cannot be said that mathematics originates in a single or unified set of mathematical practices. According to Bishop (1988), all of mathematics evolves from six basic areas of human activity which occur in all societies. These are counting, locating, measuring, designing, playing, and explaining. These practices do not even share a family resemblance, and since what we call mathematics originates in these activities, and no subsequent total unification takes place, mathematics remains a multiplicity, a plurality, and a motley of disparate knowledge fields, subspecialisms, and practices (Wittgenstein 1956; Lerman 2010).

But mathematics does exist. Instead of being a unified referent, a single body of knowledge, it is a vast and growing collection of different ideas and practices, some connected, some not, with a fuzzy boundary.

5 Epistemological Versus Social Models of Mathematics

Despite this critique, there is a traditional absolutist perspective of mathematics as a unity, a single entity, which is part of the absolutist ethos of mathematics. According to this perspective, the central paradigm for mathematics is represented by a skyscraper model. This has successive, rising stories made up of even more complex theories, based on and supported by those beneath, and built on the unshakeable foundations of mathematical axioms and logic at the bottom. This is a beautiful, powerful, and seductive image, subscribed to by Logicists, Formalists, and other Foundationalists in the philosophy of mathematics. But it fails epistemologically, as history has shown. For technical reasons, it fails to represent mathematics, because there is no unique logico-mathematical foundation for the whole of mathematics. Even if a candidate for one were to be found, it is impossible for this would-be foundation to be demonstrated to be safe and beyond all doubt, in other words, to

provide a proper foundation (Ernest 1991, 1998). Gödel's (1931) Incompleteness Theorems demonstrate that formal mathematics from arithmetic onward, in terms of increasing complexity, can never be complete nor shown to be demonstrably consistent.

In terms of social representation, the skyscraper metaphor also fails. In the world, mathematics has many locations and contexts. Some of the many social practices that make up mathematics were mentioned above. Elaborating further in this vein, an alternative to the skyscraper model, and offering a better representation of mathematics is the image of a dynamic, growing modern city.

Within such a city, we will find the following architecture, businesses, and districts:

1. Multiple skyscrapers, comprising the different formal theories in mathematics (some enduring and some demolished and replaced);
2. Universities and academic centers, representing different branches and practices of research mathematics; as well as other departments applying mathematics in physics, biology, psychological and social science research methods, computer science, and so on;
3. A business district, representing various applications of mathematics and accountancy, banking, stock market, cryptocurrency, and business mathematics;
4. Computers and the city-wide Internet, illustrating the increasingly important presence of computer-based mathematics, both in theory and in practice;
5. Shops, street markets, and *favelas*, representing informal mathematical practices on the streets, in the shops, and ethnomathematics (Probability coupled with finance even has its own street presence in betting shops (legal gambling premises on high streets in the UK), although probability, statistics, finance, and financial models are also central to banking and brokering businesses, including high-level actuarial models.) (D'Ambrosio 1985);
6. Schools, representing school mathematics and mathematics education.

The city model works epistemically, for it represents the different domains of knowledge, including both academic and informal, as well as the associated practices. It also works socially, indicating the conceptual geography, the varied societal locations, and human practices making up mathematics as it is performed in social practices. Thus, the city model captures the shape of mathematics far more accurately than the skyscraper model. Within it, I have used the idea of a mathematical practice. But what is a mathematical practice, one of the most central concepts that hold this book together?

6 What Is Mathematical Practice?

A social practice is an organized social activity that has an identity, members, and agreed forms of participation, both implicit and explicit, and has, above all, goals shared by all participants as the overarching focus. All aspects of a social practice can change over its lifetime, including membership, rules of active participation, the overall

structure, and even the goals. But if the goals change significantly, it becomes a different social practice, for they determine the whole point and direction of the practice.

In the context of ethics, Alasdair MacIntyre defines a social practice as follows:

> By a 'practice' I am going to mean any coherent and complex form of socially established cooperative human activity through which goods internal to that form of activity are realised in the course of trying to achieve those standards of excellence which are appropriate to, and partially definitive of, that form of activity, with the result that human powers to achieve excellence, and human conceptions of the ends and goods involved, are systematically extended. (MacIntyre 2007: 111)

Social practices are always situated in space and time, in living, historical traditions. Mathematical practices are specialized social practices, and the city model described above illustrates the wide range of mathematical practices, which are so broad as to incorporate most, if not all citizens, of humanity. The practices can be classified into pure and applied, theoretical and practical, and with the mathematics utilized explicit or implicit. Categorizing them in this way helps to distinguish the main differences among the range of social practices of mathematics that exist.

1. *Pure theoretical practice with mathematics explicitly the main goal*
   A pure theoretical mathematical research practice with mathematics foregrounded as the explicit focus of research (e.g., research into group theory) is perhaps the first and paradigmatic mathematical practice that springs to mind. It is largely academic, comprising university-based researchers exploring the problems, theorems, methods, and theories of pure mathematics, individually or in groups and sharing their findings formally through journal publications and conference presentations.
2. *Applied theoretical practice with mathematics explicit*
   An applied theoretical mathematical research practice with mathematics foregrounded as the explicit focus of research (e.g., applied statistics research) is probably very similar to the pure mathematical research practices except for the types of problems addressed. One possible difference apart from the subject matter is that direct users of applied mathematics may consult these researchers over problems of application, such as using statistics in research methods. A further difference is the existence of commercial research tanks developing applied theory outside of the academy, as well as research conducted within it.
3. *Applied and theoretical practices with mathematics backgrounded*
   These are the academic practices of theory building and development in advanced physics such as quantum and relativity theory in which advanced mathematics may be backgrounded, but it remains present as an important language and tool. Such practices will often use mathematical concepts, models, and methods at extremely high levels and may even extend the mathematical theory employed.
4. *Pure practical practices with mathematics explicit*
   Pure practical mathematical practices in which mathematics is foregrounded can include teaching and writing school and college mathematical text-books,

together with the related activities of mathematics curriculum and examination development. In such practices, no existing mathematical theory is extended, but new ways of expressing, representing, and recontextualizing mathematical ideas and knowledge are developed (Dowling 1998).

5. *Pure and applied theoretical work, mathematics backgrounded*
   Such work includes the development of Apps and computer applications where mathematics is submerged and backgrounded simply as a set of tools, a necessary language in which the developers are fluent. This includes the development of the tools behind commercial apps, including the technical underpinnings of surveillance capitalism (Zuboff 2019), as well as those of social surveillance, regulation, and governance (O'Neil 2016). Increasingly, the public interfaces of governmental departments with the public are a series of Apps and web-based programs.
6. *Applied and practical practices, with mathematics explicit*
   This includes the practices of practical applied mathematics with mathematical knowledge explicitly foregrounded. It can include business mathematics, computer mathematics, actuarial statistics, and so on, where the novelty lies in the development of new practical applications.
7. *Pure and applied practical work, with mathematics backgrounded*
   This includes the practices of everyday or street mathematics conducted in businesses, shops, street trading, bank mortgage and loan calculations, architectural practices, and so on. Since virtually all businesses and commercial transactions are based on money, the mathematics of money, expressed in customer purchases and loans, as well as in financial spreadsheets, double-entry accounting are all part of the day-to-day running of businesses. The mathematics is submerged behind the purposes and goals of the social practice. On a larger scale, this also includes the practices of data-based businesses, surveillance capitalism, as well as data capture and mining in social surveillance, regulation, and governance.

I do not claim that this typology is definitive, for there may well be overlaps and indeed significant distinctions that are glossed over. For example, categories 3 and 5 represent applied theoretical practices with the mathematics backgrounded in pursuit of their different main goals, one within the academy and one without. Furthermore, there may be additional mathematical practices imperfectly covered by the typology including recreational mathematics and the production of mathematical or mathematically inspired art. Nevertheless, the listing serves to illustrate the existence of, and to distinguish between, the wide variety of different mathematical and mathematics-related practices both within the academy and outside of the academy across the breadth of social and cultural life. Each of these types of practice potentially raises different ethical problems and issues. However, for the purposes of this chapter, I shall focus on practices in which specialist mathematicians take the lead.

6.1 The Ethics of Mathematical Practices

In each specialist mathematical practice, I wish to distinguish four main domains of application of ethics, although more are possible.

(A) **Ethics of the institution**. First, there is the ethics of the institution that supports the mathematical research or development activities; how it treats the participants, and how it structures and regulates the social practice? There is also the issue of institutional ownership of intellectual property rights; who has ownership of any products of research? It may be left to their creators, or the institutions may take ownership and do marketing of or otherwise directly benefit in material terms from the products. In addition to the explicit ethical framework of the institution, there is the ethics of how the work is conducted in practice, for example, openness, participation in decision making, explicitness of rules, regulations, and contracts. Are mathematicians represented on the institutional bodies that make internal research grants, hire or promote mathematicians? (There is virtually no mathematics-specific literature on these first issues, presumably because the ethics of departments is understood to be independent of the discipline involved. Thus, codes of ethical conduct in mathematics such as AMS (2019) and EMS (2012) focus on individual ethics and responsibilities.)

(B) **Personal ethics of the participants**. Second, there is the personal ethics of the participants in the social practice the individuals involved. This concerns how they interact ethically with each other and with further persons outside of the practice but still within their professional orbit. For example, many if not most university mathematics departments involve teaching with both personal and institutional ethical obligations to students. Researchers and mathematical practitioners also have personal ethical obligations to both colleagues in the home institution and other international-based scholars in the specific field of mathematical practice with whom they collaborate or interact. Ethical rules of conduct include giving fair credit to colleagues, not plagiarizing others' work, and reviewing and refereeing fairly without fear, favor, or other inequities. Such ethical norms and how they are respected, monitored, and maintained are vital, and affect good practices within the institutions as well as affecting the individual mathematicians' work.

(C) **Explicit ethics of the content or subject matter**. Third, there is the ethics of the subject matter, the content and focus of the research and development. This is the ethics of the mathematical products, pure or applied, that emerge from any research and development conducted. To what extent are the ethical implications of these products considered explicitly and do ethical values and considerations play a part in shaping them? Do pure theoretical developments have easy to anticipate uses or possible applications outside of the practices? What are the ethical dimensions of this? What are the potential social and practical outcomes of applied projects and developments?

(D) **Hidden ethical outcomes**. Fourth, there are the unforeseen, implicit, or hidden ethical outcomes of the products of research and development. Pure developments in mathematical theory may have unanticipated ethical applications. Advances in pure Number Theory such as prime numbers have been seen to have implications for national and personal security, cryptography, cryptocurrencies, and the like. Applied developments such as the 2020 algorithm for adjusting student grades during the Covid lockdown in the UK (Ofqual 2020) had a significant negative impact on the grades of students from traditionally lower attaining examination centers, and were rejected after public outrage. Who is responsible for such unanticipated negative outcomes, causing disadvantage? Who takes responsibility for such outcomes, if anyone? Issues of social justice that may arise are of necessity also ethical issues.

This last is the most controversial area since it depends on philosophical views over whether mathematical knowledge products are value-laden including ethical values, as well as the ethics of applications of mathematics. If a mathematician is working on a faster algorithm or process for factorizing large numbers, can this be viewed as pure values- and ethics-free research? Given how codes based on large prime numbers and factorization contribute to military security, privacy, and financial security, can a procedure that enables faster identification of prime divisors still be regarded as ethically neutral?

7 The Personal Ethics of Mathematicians

Above, in subsection B, I raised the issue of the personal ethics of the participants in the social practices of mathematics. The issues mentioned go beyond the ethics of mathematics because they also have epistemic significance. Mathematics together with all the sciences depends on the trust and trustworthiness of mathematicians and scientists. The construction of mathematical and scientific knowledge goes through the phases or origination, testing and expression (write-up), submission to review and peer scrutiny, followed by publication in recognized and approved channels. At every phase, virtuous intention and honest procedures and actions are both expected and necessary for the good – that is the ethical as well as the effective – production and development of knowledge. Once knowledge productions are published, they gain the status of approved and warranted knowledge, at least provisionally, if not absolutely. Thus, trust and ethics are part of the knowledge warranting procedures.

Of course, there are epistemic and rhetorical safeguards built in. Scientific results must be accompanied by full accounts of the methodology and data gathering conducted so that the observations or experiments can be replicated. Mathematical claims must be substantiated by full and detailed proofs of the results so that they can be verified by expert mathematicians. Approved formats must be followed for the submissions, and these rhetorical requirements also help to maintain scientific standards and bring out the key steps in the warranting of knowledge.

Scientific write-ups, including mathematical papers, must be submitted to peer review and revised and ultimately evaluated so as to satisfy referees and editors, before their publication is sanctioned. The submitted account be as transparent and honest as possible, within the required rhetorical framework. In addition, the assessors and evaluators of any submission are expected to review and referee it fairly, and often blindly, to conceal the identity and status of authors. Normally, several referees judge submissions independently, and the editor weighs up the balance of their critical reports to deliver a verdict of rejection, required improvements, or acceptance. All such judgments are expected and required to be given dispassionately, without fear of the power or the desire to curry favor from established and senior mathematicians (and scientists). The judgments must be made without favoring family, friends, colleagues, or ideological compatriots, and conflicts of interest are widely required to be declared and reported (EMS 2012). Submitters are expected to give fair credit to colleagues, not to copy or plagiarize others' work, and to submit only what they are entitled to call their own (AMS 2019). These ethical norms are sometimes breached, and work that is not rightly that of the author may manage to get through the review process and be published. In such cases, other mathematicians are likely to recognize the misattribution and possible dishonesty and will contact the publishers and show disapprobation and censure toward the author, usually leading to a correction of the official record.

A related issue is what is termed the "theorem-credit economy in mathematics," whereby mathematicians obtain rewards and advancement from gaining credit for new results. Morris (2020) argues that in the competitive world of mathematics, some mathematicians try to rush their results into print in order to gain priority. She argues that some senior mathematicians are slow to publish exhibiting "intellectual generosity" in allowing others to gain the credit. From the virtue theoretic perspective of MacIntyre rushing for theorem-credit is pursuing external goods, not the internal goods of the mathematical practice. But as Morris (2020) indicates, withholding results is also ethically problematic as it may slow down advances in the mathematical practice.

The warranting of new mathematical results sometimes lets incomplete or even erroneous proofs, and thus, unproven results slip through into the realm of published knowledge. To avoid this, mathematicians prefer new results that have support from as many experts as possible (Andersen et al. 2020). However, the commitment of mathematicians and mathematical practices to the virtues of correct proofs and truth mean that such errors are almost inevitably uncovered and publicized. While it is a virtue to find and disseminate mathematical errors and infelicities, it is not a vice to publish genuine mistakes. The history of mathematics (and science) is strewn with mistakes, and indeed, they contribute positively to the growth and development of knowledge (Lakatos 1976).

In addition, most mathematicians employed by a college or research department have additional responsibilities because job also involves teaching mathematics or supervising students. These responsibilities include treating students with care and respect, teaching mathematics in an effective way that benefits the students, and engaging in self-evaluation and listening to feedback. It almost goes without saying that the responsibilities of mathematicians include being engaged with the profession

and keeping up to date with research and developments in their specialisms and maintaining their own interest and enthusiasm. Mathematicians have these ethical responsibilities because they are part of the contract accepted voluntarily in taking up employment in a mathematics department. That is, they should carry out their professional duties to the best of their abilities, including respecting clients, practicing their profession well, and enhancing their profession overall (Ernest 2019b). (Tanswell and Kidd (2020) suggest that possibly vicious teaching practices can prove to be epistemically productive, for example, the aggressive adversarialism of the Gelfand seminar in post-war Moscow. Without endorsing such practices, this illustrates that judgments about virtuous teaching need to take into account broader contextual factors including the goals of the social practices, rather than just the issues of ethics.)

Having introduced ethical aspects of mathematical practice and personal ethics of mathematicians, it is appropriate to look a bit more deeply into ethics and ethical theory itself.

8 Ethical Theory

Ethics is that branch of philosophy that treats the Good in a theoretical and systematic way. The most immediate relevant form is applied ethics, which treats the ethics of professional practices such as medicine. There are also further more theoretical schools of ethics, and I shall be considering one of them subsequently, namely virtue ethics.

8.1 Medical Ethics

Medical ethics is a good example of applied ethics since it has been developed over two millennia, from the time of Hippocrates (Wikipedia 2020b). It is based on a set of values that form the basis for ethical medical practice and which professionals can refer to in the case of any confusion or conflict. These values include the respect for autonomy, non-maleficence, beneficence, and justice (Beauchamp and Childress 2001). They can be expressed as the four following principles:

Beneficence. This is expressed in actions that promote the well-being of others, especially the others directly involved in any medical action or intervention.

Non-maleficence. This is the principle of not being the cause of harm. It can be interpreted in two ways. First, it is more important to do no harm than to do good, and it is also important to know how likely it is that your actions will be harmful even if intended to do good. Second, there is the utilitarian interpretation – to promote more good than harm.

Respect for autonomy. This is the principle that the rights of an individual person to self-determination should be maintained.

Justice. This concerns the distribution of outcomes and benefits of actions, and the decision of who gets what benefits. Ideally, a commitment to justice implies the unselfish wish to provide benefits equally for all, universally.

Now the question arises, do these apply to mathematical practices? If not, what principles would or should the mathematics community adopt as the basis for their ethics?

The principles of medical ethics all concern how to treat other humans and living creatures (such as laboratory animals) and how to safeguard them. Thus, medical ethics offers valuable examples for the ethics of the institutions and social practices of mathematics on the human side. It does the same for the personal ethics of the participants including mathematicians, students, and others in direct contact with mathematicians. But medical ethics in general does not offer direct guidance on the central activities of mathematical practices.

However, the principle of non-maleficence in its first sense does seem relevant. Mathematical developments and applications should not be the cause of harm. Judgments are involved as to first whether a mathematical application is the cause of an observed outcome, and second whether that outcome is in fact harmful. If applied mathematicians construct a range of models and one is used that turns out to be harmful, is the responsibility not that of the person or body choosing to deploy that particular model, rather than that of the mathematicians? Surely, the answer must involve examining the range of models provided and the mathematicians' narratives about their effects. In addition, determining what is harmful involves judgment related to a value-system. For example, has the development of the applied mathematics involved in nuclear physics proved harmful? This is open to debate because the huge power unleashed can be used for good or ill. Currently, different models of applying new Covid-19 vaccines in the population might result in varying probabilities in the balance of good and harm. There are judgments to be made about how soon such vaccines can be broadly used after their development and which sub-populations should be prioritized. Elsewhere I have argued that applications of mathematics both in education and in wider society cause harm to some, in addition to the undoubted good outcomes and benefits to many (Ernest 2018).

Thus, medical ethics, although well established, clear, and exemplary, offers limited suggestions for the main and central domains of ethics in mathematical practice beyond the considerations of beneficence and non-maleficence. If I was considering mathematics education here, where there are clients to whom one has responsibility, just as in medicine, then further values would apply. In addition to beneficence and non-maleficence, the principles of having respect for the dignity and autonomy of mathematics students, and justice in the fair distribution of teaching and benefits among students are relevant. Such issues can arise tangentially in the social practices of research mathematics where graduate students may be involved and working in collaboration with and under a mathematician's supervision.

9 Ethics in Science

Within science it is claimed that the principles of ethics are part of the bedrock of scientific activity. Society trusts that the results and the projected outcome of any scientific activity are based on an honest and conscientious attempt by the scientific

community to further knowledge disinterestedly. The moral principles of science require that it be conducted independently, without favoring or distorting any findings to satisfy outside, extrinsic or personal interests. In addition, ethics in science requires the fair treatment of all colleagues, especially junior colleagues and students (Sharma 2015). Such an account of ethics in science represents an internalist view of the ethics of science. That is, one that focuses on the ethics of the activities and processes within the scientific community, solely within scientific practices, without looking to broader ethical issues such as the social responsibility of science.

The concerns and principles of this ethics-in-science approach remain at the personal and institutional level, as does medical ethics, but bring in the additional issues of fairness and trust. It is widely assumed that ethical norms and principles will be followed during the conduct of scientific research so that it will be done in a replicable way with its reporting both honest and trustworthy. Fairness and trust are central to any scientific practice, and it is also assumed that the process of publication with its refereeing and editorial judgments will be done fairly. Scientific contributions including mathematical publications are critically scrutinized by gatekeepers, and the results of this process of warranting and validation are generally trusted. (However, the big financial stakes involved in medical and in particular pharmaceutics research and testing have resulted in unethical distortions of the objective scientific method to cherry-pick or exaggerate positive results and suppress negative results for financial gain (Goldacre 2012).) Because of the wide diversity of mathematical specialisms, most mathematicians have to take on trust the results and proofs published in areas outside of their own expertise. This requires trust in the institutions of mathematics including its conferences, journals, and book series. This trust covers not only the restriction of publication to those results and proofs that have been found sound and correct by expert mathematicians in the refereeing process. It also includes the publication of corrections and disclaimers when errors and falsehoods are found to have slipped through the net, for such is inescapable in all human processes and institutions.

Overall, the ethics-in-science approach I have described here offers principles for the ethical conduct within the institution and social practices of mathematics, as well as principles underpinning the personal ethics of the participants. But it does not treat the explicit ethics of mathematical knowledge and its applications, nor any hidden ethical consequences of mathematics itself or of the invisible or unacknowledged applications of mathematics outside of itself.

10 Social Responsibility of Science

A further area of applied ethics concerning science is the movement for the social responsibility of science. It is widely argued that the Promethean power of modern science and technology warrants an extended ethic of social responsibility. The Russell–Einstein Manifesto called for scientists to take responsibility for developing weapons of mass destruction and urged them to "[r]emember your humanity, and forget the rest" (Russell and Einstein 1955). A Hippocratic Oath for scientists has been proposed by Karl Popper (1969) and others (Wikipedia 2020c). Popper argues

that scientists should take professional responsibility to further the growth of knowledge; students of science should respect others engaged in science and their teachers, but the overriding loyalty of scientists is owed to humanity as a whole.

There are many publications and organizations stressing the social responsibility of science. For example, Mark S. Frankel (2013) from the American Association for the Advancement of Science argues that scientists need to think more deeply about their ethics beyond their "internal" professional responsibility of sticking to the research standards agreed upon by the scientific community. They must also address their "external" social responsibilities toward the larger community, because science affects policy decisions and offers risks and benefits to society. This should be done both through the ethical actions of scientists and through and being integrated into their graduate education. In particular, Frankel stresses that being a socially responsible scientist means looking beyond themselves to appreciate the global dimension of science. They should use their skills to help with global problems, not only applying their knowledge and skills, but also considering the value of what they do for others. This is an overall human responsibility and stems from a social debt and obligation because scientists' education and research are subsidized by society, he argues.

Mathematicians can learn a lot from such contributions on the social responsibility of science. Indeed, Bertrand Russell who co-authored Russell–Einstein Manifesto was a mathematician, logician, and philosopher, rather than a scientist. Although he knew mathematics played a big part in the development of nuclear weapons as a subscriber to a purist philosophy of mathematics, he was primarily calling for empirical scientists such as physicists to take responsibility for developing weapons of mass destruction (Russell and Einstein 1955).

A further development has been the proposal of the Archimedean Oath. This is an ethical code of practice for engineers and technicians, similar to the Hippocratic Oath. This includes a commitment to using one's knowledge for the benefit of humankind, respect for the environment, bearing the entire responsibility for all of one's actions and not putting one's skill to the service of people who do not respect human rights, not using one's knowledge for destructive purposes and not permitting considerations regarding religion, nationality, race, sex, wealth, and politics to harm people affected by one's actions (Wikipedia 2020d).

Overall, organizations and individuals supporting movements for the social responsibility of science and Hippocratic-type Oaths for science and technology add an external ethical concern with the impact on and responsibility to all of humankind to the internal concerns about maintaining ethics just within the social practice of science. But despite the widespread nature of such concerns, as yet, there is no widespread recognition of the social responsibility of mathematics.

11 Social Responsibility of Mathematics

Mathematicians have been slow to recognize the social responsibility of mathematics as a dimension of the applied ethics of mathematics. Although there is a British society for the social responsibility of science, and even a group called Radical Statistics (n.d.) concerned with social responsibility in statistics, there is no society

for the social responsibility of mathematics (pure or applied). Indeed, the very idea of the social responsibility of pure mathematics will seem to many a contradiction in terms, on account of mathematics being viewed as objective, neutral, and value free. There are notable exceptions. Hersh (1990) has long called for attention to ethics in mathematics, and Harris (2017) asks "Do Mathematicians Have Responsibilities?" raising many of the same issues as this chapter. Even in the present day, the American Mathematical Society (2019) interprets the social responsibility of mathematicians in an individualistic way that concerns only the professional behavior of mathematicians inside the mathematics community, with no ethical concerns about the impacts of mathematics on wider society.

It has been suggested that there should be a Hippocratic Oath for mathematicians (Davis 1988). Unsurprisingly, given the widespread views of the neutrality of mathematics, even of applied mathematics, this suggestion was ignored until very recently. However, Hannah Fry, a mathematician and popular media presenter on the subject, recently called for this very thing (Sample 2019). She goes on to assert that mathematicians should be taught ethics from day 1 (UCL 2019). Fry is an applied mathematician so she is not handicapped by the purist ideology widespread among pure mathematicians, discussed below.

A Hippocratic Oath on behalf of financial modelers, also applied mathematicians, was proposed over a decade ago (Derman and Wilmott 2009). This oath includes acknowledging that no equations can ever truly describe the social and physical worlds, explicitly committing the analysts to not giving the people who use the models any false ideas about their accuracy, and acknowledging that they may have enormous effects on society and the economy, many of them unanticipated. This position recognizes that the mathematical equations and models used by quants (quantitative researchers in finance) and financial modelers and analysts have a very great impact on financial markets. It is these mathematicians' responsibility to apprise decision makers in finance about the limited and provisional nature of all models and predictive tools, and their potential impacts.

12 Ethics in Mathematics

Courses on ethics and professional issues in undergraduate mathematics course remain uncommon, but one of the first was organized by James Franklin at the University of New South Wales, Sydney, around 2004 (Franklin 2005). After this early foray into the area, few further developments in this area can be found. But since 2016, a number of mathematicians under the leadership of Maurice Chiodo and Piers Bursill-Hall (2018) have instituted the Ethics in Mathematics Project at Cambridge University, UK. The project began with an undergraduate lecture course entitled "Ethics for the working mathematician," taught annually up to and including 2020. It includes case studies of activities that raise ethical questions including:

1. Financial mathematics and modeling
2. Cryptography, surveillance, and privacy
3. Fairness and impartiality in algorithms and artificial intelligence

Further lectures look beyond case studies and examine external forces and influences that shape how mathematicians behave including both ethical and professional issues.

The rationale for the project is as follows:

> [T]he majority of students who study mathematics as undergraduates do not continue in academia, but instead move into other industries. In the early 21st century it is surely a commonplace that mathematics and mathematicians play a fundamental role in the economy and in society, impacting sectors ranging from engineering and biotechnology to finance, information technology, data science, and public policy. Thus, it is important for them to have an understanding the ethical issues they may face as part of their work. (Chiodo and Vyas 2018, p. 1)

Overall, the course has all the ingredients of an excellent introduction to ethics for mathematical practitioners. In particular, it offers preparation for applied mathematical practices as well as for the practicalities of professional life for beginning mathematicians.

Beyond this course the project organizers held international Ethics in Mathematics conferences in 2018 and 2019 for mathematicians, historians, philosophers, and educationists, to explore and share conceptions of the ethics of mathematics (EiM 1 2018; EiM 2 2019). Many of the papers and talks presented are a valuable resource available online, together with an archive of publications supporting the project (CUEiM 2020).

The project is based on a common-sense model of increasing awareness of ethical issues and the mathematician's responses to them. The starting point is the proposition that generally mathematicians regard ethics as irrelevant to mathematics. The model proposes four stages of increasing involvement with the ethics of mathematics, comprising both awareness and action responses. A summary of the model is shown in Table 1.

The model serves both as a descriptive tool for classifying mathematicians' positions and as a prescriptive instrument specifying the desirable progress as a student moves up a hierarchy of increasing ethical awareness and action as a career mathematician.

Overall, this project can be seen as a valuable and exemplary first attempt to plug the hole left by the widespread neglect of ethics for mathematicians. It is primarily practice-driven and does not include any elements of theoretical ethics. This means that good and bad, vice and virtue are not analyzed. It is assumed that bad or harmful

Table 1 Levels of awareness and action concerning the ethics of mathematics (from Chiodo and Bursill-Hall 2018)

Level 0	Believing there is no ethics in mathematics
Level 1	Realizing there are ethical issues inherent in mathematics
Level 2	Doing something: speaking out to other mathematicians
Level 3	Taking a seat at the tables of power
Level 4	Calling out the bad mathematics of others (a) Calling out non-mathematicians using maths unethically (b) Calling out mathematicians using maths unethically

applications can be identified as such through everyday ethical common-sense. The organizers are probably right in making this judgment call with regard to developing an undergraduate course. That is, to focus on the ethics of problematic applications and the workaday practicalities of the beginning professional mathematician, as opposed to looking at ethics in a more philosophical manner. Students could choose to pursue additional studies in ethics if that interests them, but most will probably not take this step. It is very likely that most students will be interested in ethics only insofar as it impacts directly on the mathematics they are studying, including its applications and their own immediate professional practices.

This awareness raising course is relevant for mathematicians entering into both pure and applied practices in which the mathematics is explicit or high-level application practices where the necessary mathematics is subsumed behind the foregrounded goals of the application itself. It represents an important step forward.

12.1 Mathematics and Purity

It has been noted in the ethics in mathematics project and elsewhere including at the start of this chapter that many mathematicians believe there is no ethics in mathematics (Chiodo and Bursill-Hall 2018). This not simply due to a lack of awareness of ethical considerations, nor simply to an uneducated belief in the value-free nature of mathematics, but to adherence to a philosophy, the ideology of purity, often termed "purism" (Restivo 1985).

There are two meanings to the term "purity." First, there is its descriptive sense in which purity applies to something that is unmixed and undiluted or is in its basic or primal state, be it a substance or practice conducted solely for its own sake. Second, there is the normative, prescriptive, or evaluative sense of purity which applies to something that is unadulterated, unpolluted, or unbesmirched. In this sense to describe something as impure is to say that it is tainted or degraded either aesthetically (less beautiful, more ugly) or morally (less good, more bad). Even when purity is used in the descriptive sense, the ambiguity of the term risks smuggling in the connotation of impurity as a negative. Often the term "purity" is used by purists in its full, double-barreled sense, both descriptively and normatively.

Although the adjective "pure" in the term pure mathematics is descriptive, purism in mathematics is sometimes based on the normative or evaluative sense of purity and as such is a position concerned to keep out what are perceived as impurities and taint. Thus, from this position, any signs of human presence, interests, or values are excluded as detracting from the objectivism and absolutism of mathematics. Any attempt to attribute human interests or values to pure mathematics itself, not just to the practices and human foibles of mathematicians, is seen to be antithetical to the pristine purity of the subject. Values including those of ethics are repudiated by purists whose concern is to keep out the taint of ulterior motives such as utility and applicability and to defend pure mathematics as intrinsically valuable and self-driven; knowledge pursued and derived purely for its own sake.

Kline (1980) notes the tendency to purism in modern mathematics, and the mathematician Hardy (1940) celebrates the lack of utility of pure mathematics and

its ethical neutrality. Implicit in his praise is derogation of applied or impure mathematics. Part of the ideology of purism is that the pure is beautiful, the impure ugly: "Beauty is the first test: there is no permanent place in the world for ugly mathematics" (Hardy 1940, p. 14). My interpretation of Hardy is that he subscribes to both the positive and negative tenets of purism in mathematics.

1. *Positive tenet of purism*: Pure mathematics is the superior form of mathematics: it is virtuous, beautiful, and intrinsically valuable, standing in no need of justification. It is the product and expression of the virtuosity of the excellent mathematician.
2. *Negative tenet of purism*: Impure or applied mathematics may be a necessary evil for practical purposes, but it is an inferior form of mathematics driven by extrinsic and ulterior motivations.

Purity remains an important value within mathematics. Ancient Greek thinkers, including Plato, were the first to distinguish pure and applied mathematics and to exhibit purist values. Pure mathematics was said to concern "true being," the realm of pure thought concerning ideal objects and relationships, and thus was seen to be of supreme value (Plato 1941). Applications of mathematics were regarded as lowly activities performed by lesser beings for mundane practical purposes. In ancient Greek society, mathematics and philosophy were the preserve of the leisure class of free citizens, whereas applications of mathematics were the domain of tradesmen and slaves.

Purist values are reflected in the valuation of proof as a higher form of reasoning, and calculation as a lower form, from Plato onward (Ernest 2009). "Oriental mathematics may be an interesting curiosity, but Greek mathematics is the real thing" (Hardy 1940, p. 12). Purism values pure proof-based mathematics as being significant epistemologically, and pertaining to truth, wisdom, high-mindedness, and the transcendent dimensions of being. Equally, this ideology denigrates applied mathematics and calculation as technical and mechanical, pertaining to the utilitarian, practical, applied, and mundane – understood as the lowly dimensions of existence. Pure mathematics was the domain of philosophers and free thinkers. Applied mathematics (termed logistic) was the domain of slaves and tradespersons.

However, purity has only been a dominant value for a fraction of the whole history of mathematics. It was powerful in ancient Greek times and again in modern times, from the nineteenth century onward. Purism was not seen as significant for Galileo, Descartes, Newton, Leibniz, and others in the seventeenth century. At that time, according to the Neo-Platonist outlook, all of nature (the book of nature) was written in mathematics, the language of the divine, and pure and applied mathematics were not distinguished.

So why does purism come to dominate during these eras? In Ernest (2020a), I offer a number of reasons, including the following:

1. Hacking (2014) argues that the resurgence of purism in early nineteenth-century Germany can be traced directly back to the influence of Kant and his imposition of the philosophical categories of pure and applied reason. Following this fundamental distinction, the professionalization of university teaching and research

in the early to mid-nineteenth century, at first in Germany, led to boundary maintenance between professional mathematicians and outsiders alongside others holding an interest in mathematics. It furthered the demarcation of knowledge into disciplines reflecting university departments, helping to reinforce purism (Ferreirós 2016).

2. The dominant absolutist or Platonist philosophies of mathematics of modern times promote an idealized version of mathematical knowledge that is pure, superhuman, and values free. This philosophy supports purism (Erdős in Wikipedia 2020a; Hardy 1929; Penrose 1989; Balaguer 1998).
3. The standard presentation of pure mathematics in the modern era follows the Euclidean model and sequence, including, orders, definitions, axioms, lemmas, and theorems. Lakatos (1976) argues that this represents an ideological purification of proofs that serves to smooth out and eradicate marks of active human choices and labor in construction of mathematics, thus reinforcing purism.
4. The growth of interest in the foundations of mathematics with major work by Cauchy, Weierstrass, Cantor, Dedekind, Frege, Peano, Russell, Whitehead, and others turned the focus of many leading mathematicians inward, or reflected their already inward gaze, into the depths of pure mathematics and away from the world and applied mathematics.
5. During the years of the British Empire, Ancient Greece was "talked up" as the starting point of modern European thought, and the "Afroasiatic roots of Classical Civilisation" were denied and rejected (Bernal 1987). Such Eurocentrism promoted purism, but there is now a widespread literature repudiating the Eurocentric misrepresentation of mathematics, including Almeida and Joseph (2004), Joseph (2000), Pearce (n.d.), and Powell and Frankenstein (1997).
6. British and anglophone education until the nineteenth century was dominated by the classics. Many mathematicians would have been well versed in the Greek classics including Plato and Euclid and influenced by their idealist and purist tendencies. For example, graduated rules and measuring devices were disallowed in school geometry and were viewed as the inferior and imprecise tools of the engineer.
7. Mathematicians are taught and shaped as professionals by working with an older generation of established mathematicians, whose culture, including values and ideologies as well as knowledge and methods, is passed on from generation to generation (Kitcher 1984). Since the preparation of high school mathematics teachers is normally conducted at least in part by mathematicians, the purist values of the past are transmitted forward and sustained among many modern mathematicians and teachers.

For reasons such as these, purism remains a prominent value for many mathematicians up to and including the present day. Purism rejects any human features or influences on pure mathematics. Purism actively protects the disciplinary boundaries against any breaches from the taint of traces of human activity or values. Thus, from this perspective, ethics is perceived not only to have no bearing on pure mathematics, but any suggestion that it might have is repudiated as a threat to its purity.

Of course, purism also plays a valuable role because it maintains the purity of the disciplines and serves to defend the pursuit of knowledge for its own sake from outside interests and pressures (Restivo 1985). This can be useful in protecting the interests of a discipline such as mathematics from political interests that might seek to bend it toward more immediately useful applications, as was witnessed in Soviet Russia under Stalin (Grossman 1980).

Thus, a problem for relating ethics to mathematics is that from the perspective of purism mathematics is regarded as neutral and value free. Ethics is regarded as the set of values most irrelevant to mathematics. Any attempts to raise ethical issues with regard to pure mathematics are seen as possibly tainting or lowering the subject from its elevated state of purity. Purism strenuously rejects any suggestion of the relevance of ethics to pure mathematics and usually does so without serious consideration of ethics. On the face of it, to say that one mathematical concept is more vicious or virtuous than another seems absurd.

However, in Ernest (2016, 2018), I argue that even pure mathematics is value-laden and is imbued with ethical values. Similarly, Johnson (2012, 2017) argues that the formulation of probabilistic concepts and market equations has important and different ethical consequences for society, and MacKenzie (1981) shows how different statistical concepts by Pearson and Yule had profound effects on eugenics programs. So the ethical evaluation of mathematical concepts is not, in fact, absurd.

12.1.1 Values and Applied Mathematics

Like that of pure mathematics, the social practice of applied mathematics is widely regarded as neutral and free from social responsibility, although this is beginning to change. It is acknowledged to be value-laden, but the values identified are typically those of relevance, utility, efficiency, and so on. Applied mathematics is widely seen as neutral technical knowledge, brought in to solve scientific or real-world problems that originate outside of mathematics. Like a bag of tools, mathematics is used in the service of externally posed problems, and applied mathematicians are responsible for the means of solving the problems, not the ends, that is, the nature and significance of the problems themselves. Thus, in mathematics viewed as a tool "Control replaces explanation, and validation is accomplished by use" (Lenhard and Carrier 2015, p. 18). Within applied mathematics applications are generally evaluated in terms of their efficacy and utility in the narrow context of the problem posed, and any issues concerning the problem's wider social significance are not only ignored but viewed as beyond the business of mathematicians. Their role is simply to provide technical support. The research of Chiodo and Vyas (2018, p. 2) uncovered a widespread view that "while there are ethical issues in applied mathematics, these are imported from the disciplines that the mathematics in question is being applied to, and thus do not require a separate mention."

Although there are a growing number of exceptions, many applied mathematicians do not see themselves as having any social or ethical responsibility for their mathematical work. Chiodo and Bursill-Hall (2018, p. 5) summarize the beliefs of both pure and applied mathematicians as "[b]elieving there is no ethics in mathematics – This is where most mathematicians are today." If an applied mathematician

declines to work on developing a missile guidance system or an App that invades people's privacy on ethical grounds, it is seen as a personal choice. Likewise, a vegetarian might object to working in a slaughterhouse or meat packing plant on ethical grounds, but that is currently seen as a personal choice based on personal values rather than a society-wide ethical imperative.

Until recently, few voices have been raised calling for an ethic of social responsibility of mathematics, from within the field. In science, technology, and other areas of use across society, applied mathematics is seen as the servant, the under laborer whose job is to do the work, not to question the task. Thus, perceptions of applied mathematics do not challenge the denial of ethical responsibility associated with pure mathematics. For different reasons, applied mathematics is also regarded as neutral and free from social responsibility, merely a set of tools used by others. From this perspective, it is a technical activity, judged solely on its utility and effectiveness. Of course, as I have indicated above, this view is changing. Typically, it is applied mathematicians, and those involved with applied mathematics that are calling for ethics in mathematics.

13 Virtue Theory and Mathematics

Given the widespread views of the ethical neutrality of mathematics, the questions what is good mathematics and what is a good mathematician remain without satisfactory answers. There is a fundamental ambiguity at the heart of the question of what constitutes good mathematics. From an ethical perspective, good pure mathematics is that mathematics which benefits humankind and contributes to human flourishing. From an epistemic perspective, good mathematics is that pure mathematics which is clearly expressed, which is well justified, normally by means of mathematical proofs, and which generally conforms well to the epistemic standards of the social practice of mathematics and of the community of mathematicians. In the case of applied mathematics, ethically good applications are those that are beneficial to humankind and cause little or no harm. Applications that are good from an epistemic perspective are those that are correctly and rigorously formulated and that accurately predict outcomes or provide good explanatory models for their target domains.

On the face of it, ethical goodness and epistemic goodness are disjoint perspectives from which to consider mathematics. One draws on ethics and moral philosophy, while the other is epistemological. However, virtue theory, and in particular Alasdair MacIntyre's (2007) version of virtue theory, accommodates both of these perspectives. MacIntyre's theory rests on the concept of social practice and the first part of his theory concerns the goods of a social practice. The internal goods of a social practice are the things that are achieved in the course of pursuing the goals within the practice. They can only be achieved through the practice and relate to the particular intrinsic goals of that practice. In contrast, external goods are achieved or obtained in a variety of ways beyond the specific and particular social practice. External goods include fame, fortune, and other things that might extrinsically motivate us.

According to MacIntyre, mathematics is a social practice, or it might possibly be seen as a family of several overlapping practices. The virtues of a mathematician include those character traits that enable him or her to pursue the goods internal to the practice of mathematics, that is, to be a good mathematician. This is to seek to develop skill and ability to advance mathematical knowledge, in order to pursue the inner goods of mathematics, in other words, to develop the virtues of mathematical practice. Possessing such character traits is called virtuosity within that social practice. To be a good mathematician from MacIntyre's perspective is to do good work within the social practice of mathematics. This is to work well and effectively to achieve the goals of this social practice. These goals concern what is valued because it is useful, well formulated, original, powerful, beautiful, or otherwise desirable and acceptable within the social practice of mathematics.

Beyond this, MacIntyre's theory has two more layers or dimensions concerning the virtues that constitute the virtuous life. On the second level, MacIntyre argues that a virtuous person should also possess those traits of character that lead to and sustain a unified narrative of self and the overall good life. Third and lastly, MacIntyre claims that as social beings we humans all live within a cultural, moral, and historical tradition and that our virtues are also manifested in acknowledging, sustaining, and contributing to the development of our tradition in a way consistent with and conducive to our virtuous practices and unified virtuous lives (Ernest 2020a).

Applied to mathematics, MacIntyre's theory entails that every mathematician, every participant in the practice of mathematics, should not only cultivate their own individual virtues, be the best mathematician possible, but also take ethical responsibility for this practice and their overall lives. It is necessary but not sufficient to attain the goods internal to the practice of mathematics, that is, to develop worthwhile mathematical knowledge or applications. Our virtues must include taking responsibility for the practice as a whole and for its social and other outcomes. The humanistic moral tradition, of which I and most mathematicians and mathematics educators are a part, at least in the West, includes such virtues and values as rationality, truth, democracy, justice, fairness, autonomy, and freedom, as well as care for fellow humans, for living things, and for the environment. Thus, it is not enough to focus solely on the goods internal to the practices of mathematics research and teaching. We must also be concerned with the intended and unintended outcomes of these practices on other humans, on all living things, and on the planet as a whole.

According to MacIntyre's virtue theory, a good mathematician is one that addresses the goods internal to the practice of mathematics. That is, being conscientiously devoted to research, working on new proofs, problem solutions, and presentations of mathematics: being good as a mathematician. A good mathematics teacher is one devoted to the goods internal to the practice of teaching, namely working for student understanding manifested in their success at mathematical tasks and their ability to communicate mathematical ideas and reasoning (known within the practice as relational understanding, after Skemp 1976). In both types of mathematical practices, mathematics teachers (and most research mathematicians also teach) should also attend to the flourishing of students as developing human beings.

In any practice "human powers to achieve excellence, and human conceptions of the ends and goods involved, are systematically extended" (MacIntyre 2007, p. 279). The good mathematician will seek to improve his mathematical skills and creative products and contribute to the growth of the practice of research mathematics, just as a good teacher will seek to grow and learn as a teacher and contribute to the practice of mathematics teaching.

Overall, MacIntyre's virtue ethics provides a partial way of respecting the ideology of mathematical purism and even the neutrality of developing applications. According to his theory, the social practice of mathematics should focus exclusively on the internal goods of the practice. A virtuous pure mathematician will strive for these internal goods and eschew the external goods of pure mathematics, including uses, applications, personal rewards, and fame. Thus, MacIntyre's theory accommodates mathematical purism, as well as other ideologies of pure mathematics, by focusing on the internal goods of the social practice. A strength of this approach is that turning away from the purely internal goals within a mathematical practice could lead to a decline in the practice itself. What counts as good in mathematics is the mathematician's virtuosity, the virtues that give rise to their excellence as professional mathematicians working toward the inner goods of mathematical practices. Furthermore, I believe that the best judgments of what constitutes excellent advances in mathematics come from mathematicians themselves. Constraining them from pursuing the most intellectually exciting problems and most significant results in mathematics, as judged by themselves, seriously risks stultifying their activities and the growth of the discipline (Ernest 2020a). Harris (2015) offers a persuasive analysis and justification for this position.

14 Responsibility for Applications of Mathematics

The fact that a good mathematician focuses primarily on the internal goods of her social practice is not an excuse for ignoring the ethics of mathematical applications. As we have seen, MacIntyre's theory also requires mathematicians to take responsibility for each mathematical practice as a whole, for its social and ethical outcomes, as well as for our shared humanistic (or other) moral tradition. Above I distinguished four main areas of ethical concern for mathematicians: institutional and personal ethics for mathematicians, already discussed. I also distinguished the overt and visible ethics of mathematical products, pure or applied, and the implicit, hidden, and possibly unforeseen, ethical outcomes of applications of mathematics. Here I will consider these two areas. I divide them into three types of application: mathematics in public communications, ethically problematic applications of mathematics, and the performativity of mathematical applications. These are all part of the external ethical responsibilities of the mathematician.

14.1 Mathematics in Public Communications

It is widespread for governments and corporations to use mathematical signs or representations to lend support and an air of authority and certainty to

communications and pronouncements. Evans et al. (2014) conducted an investigation into the use of mathematical images in newspaper advertising in the UK. They found that this increased from under 2% in the period 1994–2003 to almost 5% in 2006–2008. They showed that advertisements use mathematics to lend the advertised products valued characteristics of mathematics including precision, rationality, and authority, rather than employing such characteristics to construct reasoned arguments. Mathematics is used in the public media as a rhetorical device to enhance persuasion, without necessarily using mathematically valid arguments.

Seife (2010) quotes the statistic published in a newspaper that only 0.027% of US felony convictions are wrongful. He points out that despite this assertion being false, for it was based on an incorrect back-of-the-envelope calculation, it was nevertheless used in a fallacious argument by the prosecution in a court case that ended with a prisoner being sent to his death.

A further example comes from the May 2020 broadcast by the UK Prime Minister on British national television about the Covid-19 virus threat and the UK Government response (Johnson 2020). In it the Prime Minister claimed that there is a central equation representing the danger from the Covid-19 virus and determining the UK government responses. The equation is: CAL = R + N, relating the *Covid Alert Level* (CAL), the *Rate of infection* spread (R), and the *Number* of infected cases (N). In Ernest (2020b), I analyze the equation and show that is it at best meaningless and at worst deliberately deceptive. The misleading use of mathematics to back up the presentation of the Government's Covid strategy was termed "number theatre" by David Spiegelhalter (Ahuja 2020). My conclusion is that this piece of number theatre is smokescreen designed to "blind the public with science," by giving a spurious sense of mathematical precision and scientific authority. The government chose to follow a politically expedient path in its policies. This led to the highest death toll in Europe at that time, in both absolute and comparative terms. Johnson wished to make it look as if the policy merely followed the route determined by science.

These examples illustrate the widespread use of mathematical signs or representations in communications in order to persuade and sometimes deceive (see also Hauge et al. 2019). Mathematics is used as a rhetorical tool intended to lend precision and force to presentations, that is to persuade without making any rational or mathematically buttressed arguments.

The term "proofiness" has been coined for the art of using bogus mathematical arguments to "prove" true something that is false. According to its coiner, "[o]ur society is now awash in proofiness. Using a few powerful techniques, thousands of people are crafting mathematical falsehoods to get you to swallow untruths" (Seife 2010: p. 8).

This is deeply problematic. In order to combat such deception and unethical manipulations of opinion and protect democracy, at a minimum two defenses are necessary. The first is a well-educated and numerate citizenry able to critically examine and evaluate published claims that rely on mathematical arguments. Secondly, we need mathematics-related professionals at all levels, from researchers to teachers that are willing and able to call out such misuses and who to see this as part of their public duty.

14.2 Problematic Applications of Mathematics

In the past half century, and particularly in the new Millennium, mathematics and mathematical applications have permeated Western society and probably most countries around the world. This is most notable in the universal and accelerating spread of information and communication technologies in governance, public services, and commerce. Such applications are often potentially benign, but there are an increasing number of problematic applications of mathematics, as are documented in O'Neil (2016), Skovsmose (2019), and elsewhere.

Many examples could be cited as ethically questionable. For example, early on Google found "detailed stories about each user – thoughts, feelings, interests – could be constructed from the wake of unstructured signals that trailed every online action" (Zuboff 2019, p. 53). Thus, covert profiles were constructed for millions of users and their friends without permission. This is a deliberate and unethical breach of data privacy principles. Furthermore, Google enables advertisers to target ads to people who search for racist terms, and Facebook enabled advertisers to direct their pitches to the news feeds of almost 2300 people who expressed interest in anti-Semitic topics (Zuboff 2019). Even search results were slanted by the Google search algorithm in ways that reinforced racist and other stereotypes. Noble (2018) found in searching online for resources for her daughter, the first hit for the keywords "black girls" was a pornography site, and that variant searches also turned up disturbing racial stereotypes and other distorted associations and links. Noble's first search took place in September 2011, and after publishing an article about it, the search algorithm was modified by Google. Nevertheless, many unwelcome and unethical misdirections remain in place based on commercial pressures. Thus, Google search results have been modified in "response to *pressure from businesses, outside interest groups and governments around the world*" (Grind et al. 2019, p. 1; original emphasis).

Another new and deeply problematic issue is the widespread circulation of "fake news" stories. Allcott and Gentzkow (2017) define "fake news" as distorted signals uncorrelated with the truth that impose private and social costs by making it more difficult to infer the true state of the world. They found that in the lead-up to the 2016 US election, there were 760 million instances of a user reading these intentionally orchestrated lies online or about three such stories for each adult American. This was part of huge personal data capture and exploitation affair surrounding Facebook and Cambridge Analytica (Cadwalladr 2017). Data of Facebook account holders' "friends" was captured and in combination with other data culled from Internet applications was used to build up a huge database characterizing millions of persons in terms of their social location, political leanings, commercial behavior, and preferences, by Google and others. This data was exploited in organized political disinformation campaigns and profit-driven fake news stories during the 2016 UK Brexit vote and US presidential election. It was partly done by means of individually shaped and targeted stories and posts designed to push a viewer's "hot button," an emotional and usually controversial issue or concern that triggers immediate intense reaction (Merriam-Webster 2020). Triggering a hot button causes the targeted person

to become emotional and irrational, blocking critical reflection and evaluation, and reinforcing strong attachments to particular social or political positions. This often strengthens commitments to radical social or political positions and elicits strong negative reactions to any contrary position. In consequence, through the use of false information and fabricated images, there is increased electoral support for polarized and populist leaders and causes. Woolley and Howard (2018) term this "computational propaganda" and argue that the large-scale automation of messaging and social media platform manipulation amounts to a new political communications mechanism of unprecedented power and threat. Not only is this deeply unethical, it also erodes the very fabric of a free and democratic society.

A further problematic application of mathematics is the building of AI software to help identify targets for lethal drone strikes. The Pentagon has been engaging in these developments with sub-contractors such as Google. However, many Google employees were unhappy with providing support for what they perceived to be an unethical application of mathematics and programming. A number of Google employees resigned and thousands of others signed a protest petition against taking part in the Pentagon project known as Maven. The outcome was that Google announced that it would not renew its contract to do this artificial intelligence work for the Pentagon (BBC 2018).

There are many other examples of applications of mathematics that have been attributed with negative, unethical, and sometimes even disastrous outcomes. For example, the Gaussian copula formula (a multivariate cumulative distribution function) was called "the formula that killed Wall Street" because its overextended use to price derivatives helped to trigger the Global Financial Crisis of 2008 (Salmon 2009).

So who is responsible for these ethically problematic applications? In my view, responsibility should be shared among all those involved, including applied mathematicians, information and communication technology professionals, computing specialists, and authors of algorithms and Apps, as well as those who fund, instigate, and control these applications across society at great social costs, for political and economic gain.

How can we avoid or reduce the harm or potential harm done by applications of mathematics in society like in these examples? Obviously, part of the answer must lie in requiring accountability from the tech and business corporations, as well as the political parties and pressure groups. We need national legislation and international concords to penalize cases of abuse involving from apps and applications. In addition, we need to better educate the persons involved, especially mathematicians, in the ethics of potentially harmful applications of mathematics.

14.3 The Performativity of Mathematics

In addition to the explicitly unethical outcomes that can come from certain mathematical applications and algorithms, there is the issue of performativity. Many mathematical models and algorithms go beyond describing and automating their target areas, but actively modify and transform their domains of application

(Skovsmose 2019, 2020; Skovsmose and Ravn 2019). Such transformation may be intentional and can even be perceived as benign, or they may be unanticipated outcomes.

An early example of this is the Victorian Payment by Results for teachers in British schools. An apparently sensible measure was to tie the annual salaries of teachers to the numbers of pupils in their classes and to their performance at particular exams. But the outcome was that once the inspector's visit was imminent, teachers drilled their pupils mercilessly on test items. Some falsified enrollment registers to keep numbers artificially high. Sick children were dragged along to school to satisfy attendance requirements (Hyndman 1978). Cramming, rather than teaching, became the means to ensure a teacher's livelihood – weakening pupils, teachers, and pedagogy (Welch 2009). This lesson of history has not yet been learned for English; schools are still graded and rewarded on the basis of student assessment scores. This results in many teachers "teaching to the test," distorting the curriculum and reducing the overall quality of students' learning experience.

In Ernest (2019a), I explore more widely the performativity of the mathematization of society as an ethical issue. For example, the widespread official and social identification of intelligence with IQ score not only limits the recognition of human capabilities but also demonstrably impacts on policies, lives, and human identities. Other measures such as evaluative scores in education, as remarked above, can change individuals, schools, and national and regional education systems (Gorur 2016). Warnings about this are not new; Campbell's law says, "The more any quantitative social indicator is used for social decision making, the more subject it will be to corruption pressures and the more apt it will be to distort and corrupt the social processes it is intended to monitor" (Goldstein 2014, p. 209).

There are many troubling but often hidden applications of mathematics needing ethical scrutiny and oversight right across the worlds of governance, banking, and financial markets. These are performative in shaping and driving policies and markets, and go well beyond being simply neutral tools (Johnson 2017). MacKenzie (2006) characterizes the mathematical models underpinning financial markets as engines, not cameras, because financial models shape and change markets performatively. Rather than just speeding up existing practices and making improvements in efficiency, such changes bring in whole new levels of risk and ethical jeopardy.

There is widespread use of programs and algorithms to ascertain if persons are worthy of loans or credit, or are likely to commit crimes. These can change those persons' lives without their knowledge or right of challenge. O'Neill (2016) documents case studies of how algorithms can distort the justice provided to minorities and provide artificial barriers to employment, credit worthiness, home ownership, and gaining insurance. They can even determine who are good employees through automated time on task efficiency measures. These and many more hidden control systems are currently at work, used by corporations and government bodies with virtually no oversight as to their efficiency and correctness let alone their ethicality. But "many of these models encode human prejudice, misunderstanding, and bias into the software systems that increasingly manage our lives" (O'Neil 2016, p. 3).

Marjanovic et al. (2018) term the many negative consequences of this "algorithmic pollution," but I think a more appropriate term is "algorithmic injustice."

As indicated, the mathematization of society is performative. Metrics and measures do far more than capture the concepts and qualities they are supposed to represent. They noticeably alter the social processes that they are implicated in, often with significant impacts on, peoples' overall lives. These changes can have major negative ethical effects, enacting discrimination and stereotyping and reducing opportunities and life chances. When measures are imposed by institutions and policies to manage, shape, and evaluate social practices, the measures become instruments of power to change the practice; they redirect it (Power 1999). Thus, for example, a hospital, prison, or school managed solely by the attainment of target measures of performance is at risk of compromising and dispensing with the care and professionalism traditionally provided by the key staff involved in the service.

In the UK, the reduction of professional competence and satisfaction to targets and measures of performance is often associated with "marketization" – the privatization of public services or the replacement of the professional ethos by a market orientation. The changed measures of satisfaction mean that a cheaper and less-skilled workforce can be brought in to deliver the service. The argument in favor is that this means that there are valuable cost savings to the public purse. However, in practice, the savings are often not realized, and furthermore, a reduced and degraded level of service is provided, directed solely at meeting the targets. Commissioning groups no longer monitor the quality of the social goods provided through professional expertise, but simply check whether the targets are met (Power 1999).

Where is the ethical scrutiny in this process? It is squeezed out, either by inattention or by design. The construction of a measure of some concept or of a model of an aspect of social practice is an epistemological or methodological project. (As an aside, I would like to conjecture a rule that "no domain of professional expertise and practice can be adequately represented by a finite set of measurable targets." Meeting such targets may be necessary but can never be sufficient for capturing the professional expertise, for two reasons. First, professional expertise and mastery can never be reduced to a set of rules. Expert practitioners and professionals always draw on tacit knowledge and intuition developed from their experiences during their path to expert status (Dreyfus and Dreyfus 1986). Second, any application of professional expertise involving other persons requires empathy and an ethic of care, and this cannot be legislated through targets to be fulfilled (Larson and Yao 2005; Slote 2007).) Technical skill, accuracy, and precision are the overarching values. At this point, in measure and model fabrication, there can be deliberate attempts to slant or even mislead, when measures are used for overtly political purposes (e.g., some government measures of unemployment or poverty, corporate designed Apps to conceal car pollution, such as the VW fraud). But even when done without intentional distortion, through their performativity, the forces of measurement and mathematics are radically reshaping and restructuring human practices and social reality, and even the futures and possibilities we can imagine (Skovsmose 2014). Beer (2016: p. 6, original italics) describes this process of performativity and its outcomes succinctly as the "relations that exist between

measurement, circulation, and *possibility*." Where the intensification of these changes will take us is hard to predict, but it is clearly toward a more totalitarian and less-free society. It is a society where there is less respect for the individual and their rights and where governments and corporations alike exercise increasing power and control over our lives. Without exaggeration, it is a future that looks like a blend of Orwell's *1984* and Kafka's *The Trial*.

Mathematics specialists are only one part of the surveillance state, surveillance capitalism, and the performatively reshaped social world, alongside actors from business, corporations, the state, and government. But specialist mathematicians play an essential role in these developments. Because of their privileged access, as well as their implication in the development of these measures, mathematicians have a special duty to acknowledge and identify these applications of their discipline, to scrutinize them ethically, and to call them out where ill-considered or harmful. More generally, as democratic citizens, we share with all other citizens the duty to take responsibility for the direction that social policy is taking and be cognizant of its social justice and ethical implications. There is a direct and inescapable line of responsibility for the mathematization of society that implicates mathematicians and leads to the necessity for political engagement and action. This might sound like an extreme demand of the normally quiet and neutral mathematical expert, but we are not only on the edge of a new world, we, above all others, are helping to construct it.

15 Conclusion

There is a long tradition of ethical neutrality and the purity of mathematics. This is deeply embedded in the culture of mathematics for both historical and philosophical reasons. Many mathematicians and others resist the idea that we need to consider the ethics of both pure and applied mathematics. However, the foundation of this resistance is analyzed above and located in background philosophies of mathematics and the ideologies of purism and neutrality. We are becoming increasingly aware of the powerful impact of mathematical applications on every aspect of modern life. Largely, this is due to the near universal take-up of information, communication, and control technologies across all aspects of modern society. These developments, including some well-publicized abuses, are causing a growing number of mathematical practitioners to wake up to the ethical responsibilities of the mathematician. Nevertheless, a belief in the ethical neutrality of mathematics is still widespread. It is argued above that virtuous mathematicians can legitimately pursue mathematics for its own sake, but as citizens, they also have a responsibility to care about the social impacts of mathematics.

A review of the literature on the social responsibility of science and mathematics reveals that concerns about the ethics of mathematics are starting to emerge in publications and training practices. Given the great power and concomitant risk of harm from the near universal applications of mathematics, a widespread teaching of the ethics of mathematics is called for among beginning mathematicians, just as is

done in science and medicine. This is needed both to question and call out questionable practices and applications, but also to raise mathematicians' awareness of their own responsibilities in developing these applications. Some of the more ethically sensitive areas are distinguished and examples from three problematic categories are explored. These include the use of mathematics in public communications, overt applications of mathematics that have powerful social impacts, and the hidden performativity of mathematics in restructuring society, institutions, and social practices. As I have shown, some applications threaten the very foundations of democracy as well as many of the rights and freedoms we enjoy. Because of the specialist expertise and their involvement in these developments, we mathematicians have a vital role to play in keeping governments and corporations ethical and honest.

To end on a more positive note, I should point out that mathematics is also being widely applied both to indicate the problems facing humankind and the Earth and to propose solutions. Without mathematical data and models, we would not understand the powerful impact we are having in degrading our environment, how pandemics spread and are checked, and the ways in which we can develop green technologies to counter global warming. Through mathematics we come understand, at least in part, for numerical knowledge can never equal the lived experience of discrimination and deprivation, such issues as racial injustice, gender imbalances in society, and the widening gap between the rich and poor. Once again, education in the ethics of mathematical applications should better sensitize mathematicians toward these problems and mobilize their efforts toward finding solutions.

Abstract

We present a short survey of Grothendieck's "known" work (1949–1991), before his seclusion in the Pyrenees (1991–2014). Three main periods are distinguishable: (1) 1949–1957, with his work in functional analysis, homological algebra, categories, sheaves, and *K*-theory; (2) 1958–1970, with the foundations of algebraic geometry, schemes, toposes, and motives; and (3) 1981–1991, with topological algebra, anabelian geometry, stacks, derivators, on the one hand, and long philosophical reflections, on the other hand.

Keywords

Grothendieck · Functional analysis · Category theory · Algebraic geometry · Topological algebra

1 Introduction

The immensity and depth of Grothendieck's work has prevented the community from obtaining a fair appraisal of his contributions. This is somewhat surprising, considering that Grothendieck himself often insisted in the "childish" flavor of his principal ideas. In this survey, organized in chronological order, we will emphasize those "simple" conceptual forces inscribed in his many mathematical creations, leaving some detailed technicalities for a wider monograph (see **Zal20**). Contrary to other approaches of Grothendieck's work, this survey will emphasize *(i)* the coherence and *continuity* of the entire *opus*; *(ii)* the *multilayered* levels of Grothendieck's thought, as it moves between abstraction and concretion, universality and particularity, archetypes and types, unity and multiplicity, structure and calculation, transits and obstructions; *(iii)* a permanent search for *smoothness* in Grothendieck's mathematical practice; *(iv)* an *equilibrium* of inventive power in the three main periods, 1949–1957, 1958–1970, and 1981–1991, against the usual reception, where the IHES period (1958–1970) is unduly overemphasized.

2 First Period: 1949–1957

Grothendieck's first period positions him as a mathematical *genius* (a term to be used sparingly in a century), with an incredible power of concentration, capable to navigate both the higher abstractions and the most concrete calculations, and to transit between widely different fields (functional analysis, homological algebra, categories, complex variables). After becoming the world's greatest specialist in topological vector spaces, Grothendieck turns away to algebraic geometry and introduces sheaves at the very heart of his mathematical practice. In the space of just a few years, Grothendieck opens up entire new perspectives of research and begins to deploy a *grand vision* and a *free inventiveness*, unheard of in his generation.

2.1 Produits Tensoriels Topologiques et Espaces nucléaires (1949–1953)

The *Ph.D. Thesis* [**g**1949–1953] situates Grothendieck among the most brilliant mathematicians of his generation. (The references of the form [**year(s)**, page] send to the bibliography of "Grothendieck Works," at the end of this article. These years mark the *periods of creation* of the works, sometimes before publication.) The story according to which the rebellious young man who had spent the year 1948–1949 in the *Séminaire Cartan* is sent by an annoyed Cartan in 1949 to Nancy, where his mentors Schwartz and Dieudonné assign him 14 open problems to calm his frenzy, is well known. (**Scharlau1** pp. 182–183; **Bringuier** pp. 38–39.) Some months later, he has solved them all, and possesses, according to Schwartz's testimony, many results which would suffice for multiple papers. The *Thesis*, a development of those researches, is defended in 1953 (February 28, doctoral committee consisting of Henri Cartan (*Président*), Laurent Schwartz (*Rapporteur*), and Gustave Choquet (*Examinateur*)), and published in 1955 by the *American Mathematical Society.*

Tensor products and nuclear spaces (introduced by Grothendieck) are studied at the core of the work. In some subsequent accounts of the *Thesis*, Grothendieck emphasizes a characterization of *nuclearity* through a *smooth* coincidence of projectivity $\hat{(\,)}$ and injectivity $\check{(\,)}$ (later denoted $(^{\vee})$), that is, E is nuclear if and only if $E\hat{\otimes}F \approx E\check{\otimes}F$ for all spaces F locally convex (or, alternatively, for all Banach [**g**1952a 100], [**g**1952b 196]). Nuclearity thus corresponds to a stability or *fixed-point* condition, but the *deviations* to the fixed-point situation provide, on the other hand, a very interesting expansion of intermediate variations (an illuminating case will be the 14 natural tensor norms in the case of Banach spaces, intermediate between the projective and the injective norms, see Sect. 5.4 below).

The *combination* of diverse mathematical techniques is exemplary. Topologization, functionalization, algebrization, linearity, ordering, are within the *Thesis*. The technical exuberance is remarkable, if one further takes into account that, a mere couple of years before, Grothendieck did not know anything about modern mathematical structures (in *Récoltes et semailles*, he reckons "ignoring what was a topological space" in 1948, and "not having yet heard uttered, at least in a mathematical context, such strange or barbaric words as group, field, ring, module, complex, homology" [**g1986** 1.18–19]). The entirely novel practice of topological tensor products, the structural behavior of Fredholm's theory, the use of topological projective and injective limits, the original connections with spaces of integrable functions, summable functions, or distributions, the emergence of incisive counter-examples, are all strong expressions of the fascinating *technical struggle* of the young *genius* with his more conventional mathematical surroundings.

The *Thesis* reveals a *multilayered strategy* which will become a trademark of Grothendieck's *style*: a *back-and-forth* between *(i)* definitions, *(ii)* mathematical characterizations, *(iii)* permanence properties, *(iv)* derived theorems, *(v)* examples and counterexamples, *(vi)* specific applications, *(vii)* returns to definitions in ascending or descending levels, etc. In particular, the *art of definition* (of which

Grothendieck will be very proud, having introduced more than a thousand definitions!) stands as one of the central features of a very careful Grothendieckian practice. In a wider context, Grothendieck's *art of language*, an extremely chiseled French sometimes close to Proust's elaborate sentences, is something that will be stressed by Serre and Cartier. The *clearness* of the architectonics depends in fact on the definitional adjustments in the edifice. In that sense, the *Thesis* is paradigmatic, with its long chains of equivalences or with its progressive subdeterminations between concepts, which may wait hundreds of pages before being resolved.

2.2 Résumé de la théorie métrique Des Produits Tensoriels Topologiques (1953)

The *Résumé de la théorie métrique des produits tensoriels topologiques* [**g**1953c] can be seen as a concretion of the *Ph.D. Thesis*, where the general ideas for tensor products of locally convex spaces are specified to the case of Banach spaces. The restriction to the class of Banach spaces produces some outstanding *structural* results on the intermediate norms between the projective and injective norms, described systematically through topological, algebraic, and lattice-theoretic properties. Grothendieck achieves a *characterization* of (the category of) Hilbert spaces inside Banach spaces, through injective and projective properties, solving the Banach-Mazur problem. On the other hand, he inverts correlations between the projective norm and the other intermediate norms (Grothendieck's inequality), thanks to the emergence of a deep constant, still not completely known today. (For a complete presentation of the work, see **DiestelFS**.) The article's inventiveness, mathematical and symbolical, constitutes one of the most accomplished and harmonious texts of Grothendieck's output, and may be recommended as a first entry to his world.

After finishing his *Thesis*, the young apatrid has a difficult time finding a job in France, and Schwartz and Dieudonné help him get a postdoc in São Paulo. (Between the available biographies (Scharlau, Schneps, Bringuier, Douroux, Pradeau), only Schneps investigates with care Grothendieck's stay in Brazil. See **Scharlau1** pp. 185–186, **Schneps2** Chap. 4, pp. 1–7, **Bringuier** p. 41, **Douroux** p. 126, and **Pradeau** p. 74.) In the first year, between March and October 1953, he produces his monograph on topological vector spaces [**g**1953d] and the *Résumé* [**g1953c**], yielding another period of splendor. (The text *Espaces vectoriels topologiques* appears as a "Curso de extensão universitária da Facultade de Filosofia, Ciências e Letras da Universidade de S. Paulo." It would be fully published only in an English translation in 1973: see [**g1953d**].) The *Résumé* is submitted a year later to the *Boletim da Sociedade de Matemática de São Paulo* and published in that journal in 1956. (The reception acknowledgement reads, "Trabalho recibido pela Sociedade de Matemática de São Paulo em Junho de 1954.") The second year in São Paulo will be, instead, a time of crisis (the only one reckoned by Grothendieck in his mathematical life), which will propel him to algebraic geometry (see Sect. 2.3 below). ("At the moment in which I was still doing Functional Analysis, that is around 1954,

it happened to me that I persisted without end on a question that I could not solve, I didn't have ideas and was content with turning around a circle of old ideas which, visibly, did not 'bite'. It was like this for a year, around the "approximation problem" for topological vector spaces, which was going to be solved only twenty years later by methods of a totally different order (...) It was a painful year - the only moment in my life that doing mathematics turned out painful for me! (...) From 1954 on, I took the habit in mathematics to have many irons on the fire at the same time" [**g1986** 1.163].)

A natural continuation of the *Thesis* [**g1949–1953**], the *Résumé* provides a new understanding of classes (not yet called "categories") of Banach and Hilbert spaces, from a triple perspective attentive to inequalities between tensor norms, analytic structures, and algebraic factorizations. Bourbaki's three central *structures-mère* enter simultaneously in play – order, topology, algebra – to solve difficult open problems (Banach-Mazur) and to open unexpected new roads (Grothendieck's inequality). (For an excellent introduction to Grothendieck's inequality and its unexpected uses in quantum mechanics, noncommutative geometry, graph theory, computation theory, etc., see **Pisier**.) The *back-and-forth* between the abstract – Banach and Hilbert spaces *at large* – and the concrete – spaces of type C (continuous functions, including c_0), L (integrable functions, including l^1), λ (L-subspaces), γ (C-quotients) – helps to anchor a general (archetypical) category around the particular spaces (types) which govern it (for precisions on "types" and "archetypes," see Sect. 5.4 below). In these processes, a *harmonious smoothness* prevails, yielding naturally a solution of Banach-Mazur: every Hilbert space can be characterized as being *simultaneously* a subspace of type L and a quotient of type C, that is, simultaneously a λ and γ space.

The methodological strategy of the *Résumé* [**g1953c**] is fascinating: *(i)* describe comparable canonical norms, *(ii)* transform those norms, and *(iii)* cover the full spectrum thanks to a structural hierarchy. Those three general levels possess various sublevels of understanding: (A) following Bourbaki, we have *(i)* order, *(ii)* topology, and *(iii)* algebra; (B) semiotically, we have *(i)* syntax, *(ii)* semantics, and *(iii)* pragmatics; (C) phenomenologically, we have *(i)* separation, *(ii)* continuity, and *(iii) entrelacs*; and (D) musically, we have *(i)* theme, *(ii)* variations, and *(iii)* fugue. (The "entrelacs" in Merleau-Ponty summons the interweaving of multiple perception levels, something also reflected in the "chiasme," interconnection of vision perspectives in the mind. See **Merleau1**; **Merleau2**.) In particular, at level *(i)*, we can recognize one of Grothendieck's major obsessions. In fact, from his *Thesis* until his generalized proof of Riemann-Roch, through the creation of abelian categories, Grothendieck detected ubiquitous appearances of *projectivity* and *injectivity* in many mathematical regions: projective and injective products (*Thesis* [**g1949–1953**]), projective and injective norms (*Résumé* [**g1953c**]), existence of enough injectives in abelian categories with a generator and infinitude axioms in order to reconstruct homology from derived functors (*Tôhoku* [**g**1955–1956]), inductive subspecializations (= "spatializations") of the generalized Riemann-Roch proof in the projective and injective cases (*Rapport Riemann-Roch* [**g1957**]).

2.3 Sur Quelques Points d'algèbre Homologique (1955–1956)

Sur quelques points d'algèbre homologique (nicknamed *Tôhoku* for its place of publication) [**g**1955–1956] insures the *takeoff* of category theory, with a new arsenal of ideas, techniques, examples, and theorems, which go well beyond the initial emergence of the theory in Mac Lane and Eilenberg (1945–1948). Grothendieck introduces central categorical concepts (subobjects, representable functors, equivalences, adjunctions), defines additive and abelian categories, uses many examples of categories of sheaves, axiomatizes infinitary processes, elucidates a common frame for cohomology and derived functors, provides representation and exactness theorems, proves (using Cantor's transfinite recursion!) the existence of enough injectives in abelian categories with a generator and suitable infinitary axioms. (A (topological) sheaf is the simplest and deepest mathematical object to study the *transits* and *obstructions* between the *local* and the *global*. A *sheaf* is formed by two topological spaces E and S, and a projection $p : E \to S$ which is a local homeomorphism (i.e., for each point $e \in E$, there exists a neighborhood $V \ni e$ such that p is a homeomorphism from V into its image). In essence, the space E is then deployed as a series of "layers" locally similar to fragments of S: S is a sort of "basis" which *unfolds* along E, and E is a "multiple" space which is *folded* over a "unitary" space S. The unfolding of a point $s \in S\ (= p^{-1}(s))$ is by definition the *fiber* over s. We have then an image of a space E *"étalé"* (in the terminology of Cartan's Seminary in the 1950s), that is, a deployed space over its basis S. One should not confuse here *étalé* with *étale*, basically opposed concepts, distinguished by only a final accent (see Sect. 5.2 below). The local inverses of p (over neighborhoods in S) are the *local sections*; the global inverses of p (over all S) are the *global sections*. The fundamental objective of *sheaf theory* consists in finding gluing conditions (or proving their impossibility) for local sections, in order to produce global sections (or not). Sheaves emerge from Riemann's ideas on *analytical continuation* in complex variables, and the paradigm of a sheaf is given by the germs of holomorphic functions (for other crucial examples, see notes 18 and 22 below).) An *imaginative richness* and an extremely *precise technique* go hand in hand along a never-ending "article" (102 pp.), where the *invention* of a language (categorization, abelianization) and the *discovery* of deep mathematical structures (sheaves, monoid/group actions, injective objects, derived functors) reveal *natural* connections between algebraic geometry, topology, (co)homology, and complex variables. Still today, the *Tôhoku* article may be recommended as an enlightening (and mostly readable) introduction to the richness of Category Theory. Only *patience* is needed, as always with Grothendieck, while he explains *everything*, in painstakingly humble and accurate detail.

A postdoc in Kansas, in 1955, will be the occasion for Grothendieck's immersion in algebraic geometry. ("The year 1955 marks a crucial turn in my mathematical work: the shift from 'analysis' to 'geometry'. I still recall that strong impression, as if I were leaving arid and aloof steppes, to find suddenly myself in some sort of 'promised Paradise' with luxurious richnesses, multiplied to the infinite (...) There is something in mathematics that (forever without doubt) fascinates me beyond any

other thing, not 'number', nor 'magnitude', but always form. And between the thousand and one faces that form chooses to be revealed to us, the one that has fascinated me most, is the hidden structure of mathematical things" [**g1986** P.26–27].) In that *crucial turn*, the role of Jean-Pierre Serre is fundamental. The correspondence with Serre [**g**1955–1987] presents the progressive emergence of the *Tôhoku* [**g1955–1956**]: (1) February 25, 1955, Grothendieck writes that he is exploring an analogy between the theory of derived functors and the cohomology with coefficients in a sheaf, without knowing yet "if it works well in the case of a non separated space (*Non-separation*, linked to general forms of *smoothness*, will become one of the pillars of Grothendieck's work. In particular, the need to consider non-separated sheaves will be one of the roads that will lead naturally to the appearance of the *topos étale of a scheme*, key in the resolution of Weil's conjectures. See Sects. 3.1, 3.4 below.)" [**g1955–1987** 13–14]; (2) July 13, 1955, Serre informs that "your article on homological algebra was read with care [in Bourbaki's congress] and converted everyone (even Dieudonné, who seems completely functorialized!)" [**g1955–1987** 17]; (3) a year later, September 191,956, Grothendieck indicates that he "has passed the best of last month redacting my *multiplodocus* of homological algebra (...) more than 100 pages (80 already drawn up) in big format" [**g1955–1987** 43]; (4) November 13, 1956, Grothendieck announces that he is going to propose the manuscript to Tannaka's *Tôhoku*, where "it seems that the river-flowing articles do not discourage them" [**g1955–1987** 49]. (The "multiplodocus" (*multiplodoque*), a Bourbaki joke, evokes a gigantic treaty, worthy of the size of a diplodocus, long held to be the longest of the dinosaurs.) *Sur quelques points d'algèbre homologique* is finally received March 1, 1957, in the *Tôhoku Mathematical Journal*, and published in Japan in that same year. We are here in presence of new *global and extended mathematical practices*, which overcome strong local obstructions and guarded traditions (in France and the USA). (For a precise description of the intermediate events related to the publication, in particular some difficulties with Eilenberg and the American journals (*American Journal of Mathematics, Transactions of the AMS*), see **Kromer2** pp. 120–128.)

Tôhoku's technical inventiveness pushes out into many levels of mathematical complexity: *(i)* the first construction, *ex nihilo*, of a general axiomatic categorical environment (abelian categories with additional axioms) where sophisticated mathematics could be achieved (See the following judgments (taken from Krömer, **Kromer2** p. 158): Mac Lane (1981): "The first papers on categories had no immediate sequels, because for this period they provided just a language. The notion of category theory as a subject of study in its own right appears only in the third phase of the abstract algebra movement (...) [*i.e.* the period 1957–1974 under Grothendieck's influence]"; Barr & Wells (1985): "[The *Tôhoku*] demonstrated that categories could be a tool for actually *doing* mathematics and from then on the development was rapid."); *(ii)* the elevation and axiomatic proof (via AB5 + generator) of the existence of enough injectives in a universal frame, a result which would allow a reconstruction of cohomology as a particular case of an even more *plastic, smooth, flexible* technique (derived functors); *(iii)* the use of a *multiplicity of functors* (representable, exact, sheaf-like, derived, resolvent) to establish a precise

architectonics of *transits and obstructions* between mathematical regions (topologies, algebras, differential varieties, arithmetical fragments); and *(iv)* the beginning of a *new vision* of algebraic geometry (connections with Serre's work [**g1955–1956** 120, 137, 171], intuition of new perspectives on Riemann and "arithmetical varieties" [**g1955–1956** 165–166, 199]).

The *definitions* are clean and simple, the *examples* are new and multifaceted, the *theorems and corollaries* are finely hierarchized and phased, and the *proofs* are economical and perfectly fitted in. The *genius is at work*, and a (non-exhaustive) list of the definitions introduced by Grothendieck is really bewildering: subobjects [123], (Numbers between brackets refer here to pages in [**g1955–1956**].) equivalence (and implicitly adjunction) [125], kernels and cokernels [126], additive and abelian categories [126–127], infinitary axioms (AB3-AB6) [128–129], categories of diagrams [130], categories of actions [132], (co)generators [134], injective and projective objects [135], quotient categories [137], (co)bording functors [139], derived functors [143], filtrations [145], presheaves and sheaves (functorial characterizations) [153], spectral sequences (functorially) [148, 171], representable functors [185], *G*-sheaves [195]... As mentioned by Barr and Wells, an *actual practice of mathematics inside Category Theory* became a reality with the *Tôhoku*.

2.4 Classes de Faisceaux et théorème de Riemann Roch (1955–1957)

Continuing with Grothendieck's amazing creativity in his first decade, his generalization of the Riemann-Roch theorem introduces another *deep projection from the archetypical to the spectra of types*. (Riemann-Roch (1857) unifies two very different approaches to obtain a natural invariant for a complex surface. On one hand, the genus g of the surface is obtained by counting the number of holes of the surface, or, equivalently, the number of cuts (minus one) with which the surface becomes disconnected (e.g., the genus of the sphere is 0, the genus of the torus is 1, etc.). On the other hand, one can think about the "good" functions (holomorphic) and the "bad" functions (meromorphic) definable on the surface. If we fix n points on the surface, consider the (vector) space *Hol* of holomorphic functions with zeroes on those points, and the (vector) space *Mer* of holomorphic functions with poles on those points. The Riemann-Roch theorem says that $n - g + 1 = dim\,(Mer) - dim\,(Hol)$. In this way, an intrinsic geometric invariant (the genus) is related to an extrinsic complex variable invariant (harmonic difference between *Mer* and *Hol*). At the very heart of profound connections between geometry, topology, complex variables, differential geometry, and algebra, Riemann-Roch marks the beginning of modern algebraic geometry.) In this case, the *K*-theory group invented by Grothendieck ($K(X)$ = free group of coherent sheaves over a variety X) [**g1957**] is projected onto the cohomology groups, providing a new, higher understanding of *forms*.

(Given a sheaf of rings over a topological space X (that is, where the fibers are rings, and where we denote the total space of those fibers by $\mathcal{O}_X$), one can then take $\mathcal{O}_X$ as a basis for a new sheaf, whose fibers are modules over each $R \in \mathcal{O}_X$. The resulting object (with due initial topologies) is a *sheaf of modules over a sheaf of rings*. If good properties of finite type moreover hold in the vertical transitions (modules of finite type) and in the horizontal transitions (kernels of finite type), we have the notion of *coherent sheaf* (Serre, FAC 1955). The article **Serre2** had a strong influence in Grothendieck. A fundamental example of coherent sheaf is the sheaf of germs of holomorphic functions (everything becomes thus connected around the complex variables, see Sect. 3.2 below).) Using previous tools by Serre (sheafification of Riemann-Roch's statement) and Hirzebruch (topologization of the proof), Grothendieck profits from a quantization (Todd) along the *functorial transit* (Chern) between K-theory and cohomology, from which the classical Riemann-Roch can be derived. The *geometrization* of holomorphic and meromorphic functions in complex variable, the *topologization* present in Riemann surfaces and sheaves, the *arithmetization* of the associated algebraic curves, the *linearization* obtained through group theory, the *categorization* of the structural objects and processes in play, are intertwined in a powerful *unitary vision*.

Even if Grothendieck's interest in Riemann-Roch goes back to Nancy (the "Themes for Bourbaki's Seminar 1951–1952" mention a "Kodaira proof of Riemann-Roch" that Grothendieck was to expose; see *Tribu* 25 (1951), p. 6), the deep new abstract conception is developed between 1955, in Kansas, and 1957, in Paris. The correspondence with Serre shows (1) the initial intuition, February 18, 1955 [**g1955–1987** 5], (2) the final proof, November 1, 1957: "Adjoined a very simple proof of Riemann-Roch, independent of the characteristic" – "I point out to you that 'morally' the new method rests on the determination of $K(X)$ and $A(X)$" [**g1955–1987** 57], underscoring thus the emergence of the group $K(X)$, foundation of K-theory, (3) the corrections and expansions, November 12, 1957: "Following your rectifications (...)" – "With the definition of Chern classes for sheaves (...) Riemann-Roch's theorem can also be stated in the case of non projective varieties (...)" [**g1955–1987** 59].

Grothendieck's main contributions in the generalization of Riemann-Roch occur in the elucidation and *natural understanding* of what seemed before a mysterious "*coup de génie*" by Riemann: *(i)* profound *linearization* of the environment (algebraic geometry, complex variable, arithmetic), thanks to the emergence of the fundamental structures of K-theory (group $K(X)$, ring $A(X)$); *(ii) relativization* of Serre's and Hirzebruch's results (sheaves, cohomology, topology, done for a fixed variety) to the case of a morphism $f : X \to Y$ (*variation of the basis*); *(iii)* ensuing *naturalization* of the Chern transformation between K (K-theory groups) and H^* (cohomologies), adjusted (*quantized* we would say today) through Todd's classes. If f_*^K denotes the image of $f : X \to Y$ under the functor K, and $f_*^H : H^*(X) \to H^*(Y)$ denotes the image of $f : X \to Y$ under the cohomological functors, (We follow here the excellent account **Karoubi2**.) we have that the diagram

$$\begin{array}{ccc} K(X) & \xrightarrow{f_*^K} & K(Y) \\ {\scriptstyle ch_X}\downarrow & & \downarrow{\scriptstyle ch_Y} \\ H^*(X) & \xrightarrow[f_*^H]{} & H^*(Y) \end{array}$$

is *not* commutative, and the Chern morphisms do not work *directly* as a natural transformation between K and H^*. Instead, *indirectly*, through Todd's classes in a generalized Riemann-Roch formula, we do obtain commutativity: $f_*(ch_X(x)T(X)) = ch_Y(f_!(x))T(Y)$ [**g1957** 54–68]. In the particular case in which *Y is reduced to a point*, Grothendieck's formula yields a previous formula by Hirzebruch, $f_*^H(ch_X(x)T(X)) = \sum(-1)^k dim\left(H^k(X,x)\right)$ (where x is fibered over X), which, in turn, yields Serre's formula, (The left side of equality provides the Euler characteristic of the fibration x, that is, the expression $m - gen(f) + 1$ if x is the fibration of f over its Riemann surface, while the right side, restricted to $k = 0, 1$, provides the harmonic cohomological difference between the meromorphic and holomorphic functions definable over the surface of f.) a direct expression of the classical Riemann-Roch in cohomological terms. In this way, the *elevation* of a concrete problematic (original Riemann-Roch), through new mediations (Serre's sheafification and cohomologization, Hirzebruch's topologization), leads to a superior abstract environment (sheaves, K-theory) where one can find the *structural archetypical keys* of the transformations which relate number (differential algebraic dimension) and space (topological genus). *Beyond the fundamental concrete types of mathematical knowledge (number, space), some abstract archetypes (sheaves) govern the situation*: a trademark of Grothendieck's *back-and-forth* understanding of mathematical practice, along the *penduli* universal-particular, abstract-concrete, and global-local.

3 Second Period: 1958–1970

Grothendieck's second period is the epoch of conformation of a strong school, which converts the IHES in the *mecca* of mathematical research in the 1960s. Dieudonné, with his proverbial generosity, already Bourbaki's official writer, disposes himself to the orders of the young *genius* (at only 30 years of age), who becomes surrounded with some of the best colleagues and students of his generation (Serre, M. Artin, Deligne, Gabriel, Verdier, Giraud, Illusie, etc.). The gigantic results (EGA) and (SGA), covering close to 7500 pages in a decade (!), set completely new foundations for algebraic geometry, introduce Grothendieck's main generalizations of number (schemes) and space (toposes), and open the way to solve the Weil conjectures.

3.1 The Cohomology Theory of Abstract Algebraic Varieties (1958)

The Edinburgh lecture, *The cohomology theory of abstract algebraic varieties* [**g**1958], at the International Congress of Mathematicians, constitutes another

major turn in Grothendieck's vision. (Grothendieck presents one of the plenary lectures at the Congress, already a sign of distinction and recognition (for the moment, mainly for the Riemann-Roch achievement). The Fields medals are delivered in Edinburgh to Roth and Thom; Grothendieck will receive it 8 years later, in Moscow, a meeting that he will not attend in objection to the Soviet violations of human rights (Dieudonné will obtain the medal for him): in fact, his anarchist and fearless mind will always be on the side of the oppressed, regardless of any political dogma.)It is the place where *schemes* emerge, allowing the extension and smoothening of many rigid techniques of algebraic varieties. The movements of schemes *over their basis* turn out to be fundamental, as well as the appearance of *nilpotent* elements, related to smooth differential calculations. In an extremely synthetic *pair of lines* (see below), already in the second page of the conference, Grothendieck offers an amazing view of the *étale* world, a deep weaving of Galois and Riemann, which will be extensively developed along schemes (EGA [**g1959–1964**]) and toposes (SGA [**g**1960–1969]). Under the construction of the *étale topos of a scheme*, it will offer the cohomological key to solve Weil's conjectures, 16 years later than the Edinburgh lecture and thousands of pages ahead!

The *heart* of the lecture is directed to one of the central kernels of mathematical thought: the dialectics between the discrete and the continuous. Weil's conjectures (1949) constituted a precise expression of that dialectics, using (after Artin, Hasse, Hecke) a generalized Riemann ζ function along curves over Galois finite fields, and proposing three main properties on the behavior of ζ: rationality, functional equation, and zeroes distribution. After the first emergence of schemes (Serre, Chevalley, Nagata, 1955–1956), where affine spaces were glued, the notion of abstract scheme proposed by Grothendieck glues local rings over the spectrum of *prime* ideals of an *arbitrary* commutative unitary ring (unifying thus the *Riemann trend*, on rings of holomorphic and meromorphic functions, and the *Galois-Dedekind trend*, on rings of algebraic integers). The generalization, a profound enlargement of the notions related to algebraic-topological spaces, turns out to be the needed instrument to study algebraic varieties over a field of characteristic p (discrete environment of the first schemes by Serre-Chevalley-Nagata) through adequate cohomology groups with coefficients in a field of characteristic 0 (continuous environment where one can use Lefschetz techniques to count points). Beyond this, Grothendieck's *genius* appears: the *deep intuition* that *étale* morphisms between schemes form the basis for a (Grothendieck) topology, (An *affine scheme* is the representation sheaf of a (commutative unitary) ring, that is, the sheaf $\pi : E \to X$ formed on the lower space X by the spectrum of prime ideals P of the ring A, with the Zariski topology (closed sets are algebraic sets), and on the upper space E by local ring fibers $\pi^{-1}(P) = A(A - P)^{-1}$. *Schemes* are sheaves which locally behave as affine Schemes. A morphism between schemes is *étale* if its fibers are of finite type (Galois flavor) and non-ramified (Riemann flavor). A formal definition of *étale* appears only much later, see [**g1960–1969** 1.4]) which will allow precisely the construction of the cohomological tools to solve Weil's conjectures. (The rationality will be proved by Dwork (1960, independently of Grothendieck), the functional equation by Grothendieck (1966), and the zeroes distribution by Deligne (1974). Deligne's very hard and ingenious

proof, worthy of a Fields medal (1978), even if using all of Grothendieck's machinery, will depart from the main road designed by the master (see Sect. 3.5 below), something that Grothendieck will never accept. It will be the main mathematical reason for the diatribes against his disciple in *Récoltes et semailles* [**g1986**].)

In the second page of the lecture, Grothendieck writes: "(...) it seems certain now that the Weil cohomology has to be defined by a completely different approach. Such an approach was recently suggested to me by the *connections between sheaf-theoretic cohomology and cohomology of Galois groups on the one hand, and the classification of unramified coverings of a variety on the other* (as explained quite unsystematically in Serre's tentative Mexico paper) (...)" [**g1958** 104, Grothendieck's emphasis]. If the *systematization* of that "revelation" would take many years and many many pages, in the *two underlined lines* one catches the essential kernel of the connections between Galois and Riemann, number and space, algebra and geometry, schemes and toposes. It is a *combined control*, both on the *internal* aspect of the structures given on the fibers of the scheme ("Galois groups": witnesses of finitude and separability) and on the *external* aspect of superposition ("unramified coverings") on the fibers. That *double process of smoothening* on sheaves, internal and external, allows to transfer to the cohomology of new abstract constructs, the counting Lefschetz formulas. If the statement of Weil's conjectures (1949) can be understood as a culmination of *modern* mathematics (tools from abstract algebra and set-theoretic topology to *approach* number theory), its progressive resolution under Grothendieck's school (1958–1974) can be seen as the beginning of *contemporary* mathematics (tools from homological algebra and categorical topology to *deepen* number theory). A complete methodological and mathematical revolution is thus under way in the higher realms of mathematical practice.

3.2 Techniques de Construction en géométrie analytique (1961)

Grothendieck's interest in complex variables was present all along his First Period: spaces of holomorphic and entire functions [**g1949–1953**] [g1953a] [g1953b], Riemann sphere [g1955a], and coherent complex sheaves [**g1955–1956**] [**g1957**]. His understanding of the holomorphic/meromorphic realm is taken further in his lectures for the *Séminaire Cartan* (December 19, 1960–May 8, 1961), *Techniques de construction en géométrie analytique* [**g1961**], where a thorough exploration of the Teichmüller tower is advanced. (Following Henri Cartan, *analytic geometry* referred now to the geometry of analytic (holomorphic) functions. This was very close to Serre's *GAGA*, **Serre1** which was a major influence on Grothendieck.)

The *container* of the lessons seems to reflect its mathematical *content*. Teichmüller's space T_g is first approached axiomatically, then it is described categorically through categories of analytic spaces, then differential local techniques are applied, and, finally, everything becomes integrated thanks to linearizations, coverings, and quotients. (A good introduction to Teichmüller spaces (1937–1939) can be found in **ImaTan**. The *Teichmüller space* over a given surface provides a

parameterization of *all* the complex structures over that surface (it is thus a *holistic, universal, natural* object, of immediate fascination to Grothendieck). If M_g is the *moduli* space of genus g (that is, the set of isomorphism classes of the closed Riemann surfaces of genus g), M_0 is reduced to a point (class of the Riemann sphere), M_1 is reduced to the complex plane (through elliptic curves) and M_g ($g \geq 2$) can be parameterized through $3g - 3$ complex parameters (Riemann 1857). The *Teichmüller space* T_g of genus g is constructed as an adequate covering of M_g, with ramifications associated to the fundamental group of some (= any) closed Riemann surface of genus g. Then T_g acquires globally a *canonical structure* of complex variety, produced from the local fragments of the action of the fundamental group over M_g. The *structure of all* T_g ($g \geq 0$) constitutes what Grothendieck will call later the *Teichmüller Tower* [**g1981**].) The very *text* of the lectures takes on a structural quality – an architectonic *maniera* – with many levels stratified in towers of definitions, lemmas, observations, examples, that reveal the hidden *contrapuntal harmony* of the complex variables environment.

Some of the strategies adopted at the *Séminaire Cartan* highlight the *smoothness* of complex variable spaces: *(i)* release ("*dégager*") functorial mechanisms for the use of coherent sheaves, applied in particular to complex variables, *(ii)* formulate *moduli* space problems in terms of representability of functors, *(iii)* weave *projectivity* properties with existence theorems, and *(iv)* bring closer schemes (algebraic geometry) and holomorphic varieties (analytic geometry), in an extended *GAGA* program which profits from the infinitesimal properties of *nilpotent elements in local rings*. On the other hand, the implicit *dialectics* taking place in complex variables act with all their strength: *(v) ascent* (functoriality, globality) and *descent* (projectivity, modularity, locality, nilpotency), *(vi) back-and-forth* between the One (categorical universality) and the Many (concrete categories of schemes and analytic spaces), *and (vii)* hierarchical stratification of mathematical knowledge along *circulating levels* (differential combinatorics). A highly interesting feature, both mathematical and methodological, of the *Techniques de construction en géométrie analytique* [**g1961**], turns out to be the revelation of *multiple concrete mathematical forms of smoothness ((i)–(iv))* thanks to a *unity of abstract methodological dialectics ((v)–(vii))*.

3.3 Éléments de Géométrie Algébrique (EGA) (1959–1964)

EGA [**g1959–1964**] can be regarded as one of the major treatises of twentieth century mathematics. Grothendieck's tireless inventivity and Dieudonné's not less inexhaustible writing produce in a few years a huge architectonics which offers, around schemes, new foundations for algebraic geometry. The manuscripts of EGA are written between 1959 and 1964, and published between 1960 and 1966. (EGA is divided into IV volumes (and 7 parts): *volume I* (228 pp., finished October 17, 1959, published 1960); *volume II* (222 pp., finished July 22, 1960, published 1961); *volume III.1* (167 pp., finished June 28, 1961, published 1961), *volume III.2* (91 pp., finished December 15, 1962, published 1963); and *volume IV.1* (259 pp.,

finished March 15, 1963, published 1964), *volume IV.2* (231 pp., finished December 15, 1963, published 1965), *volume IV.3* (255 pp., finished November 15, 1964, published 1966). It constitutes an amazing *tour de force* (deepness, discipline, effectiveness) which sums up around 1500 pages and can only be understood under the literal meaning of the *monumental*. We are here in presence of an *ideal of mathematical practice* which has seldom been carried out, in such immensity and concreteness, in the history of mathematics.) The environment of work is the *Institut des Hautes Études Scientifiques* (IHES), created specifically for Dieudonné and Grothendieck. (As Grothendieck recalls, "During the heroic years of the IHES, Dieudonné and me were its only members, and the only ones also to give it credibility and audience in the scientific world, Dieudonné editing the "Publications Mathématiques" (whose first volume appeared already in 1959, the following year of the foundation of the IHES by Léon Motchane), and me directing the "Seminars of Algebraic Geometry" [**g1986** 1.169].) Around them, a School gradually emerges, with brilliant young doctoral students under Grothendieck (some ten students, among which Deligne, Demazure, Giraud, Illusie, the Raynauds, and Verdier). A *community of mathematical practice* propels then the IHES to the forefront of research.

Some of the strategies present in EGA [**g1959–1964**] (and further extrapolated to SGA [**g1960–1969**], see Sect. 3.4 below) include: *(i)* an extension of the notion of *spectrum*, which allows the development of *smoothness and freeness* along structures and sheaves, and opens the way to a natural "algebraic differentiability" thanks to nilpotent elements; *(ii)* the construction of a *new path* for the understanding of number theory, which, in a parallel way to the classical reading (numbers → points → space → separation → discrete geometry), proposes a new reading (numbers → prime ideals → spectrum → non-separation → continuous geometry), and studies a *unification* of the discrete and the continuous; *and (iii)* the elaboration of a *conceptual filtering sieve*, in order to pass from algebraic varieties of characteristic p (environment of the Weil conjectures) to differential forms in a characteristic 0 environment, thanks to finer topologies on sheaves, schemes, and cohomologies. Then, many of the main *smoother* structures in EGA occur (regular rings, flat modules, smooth algebras, ringed spaces, (pre)schemes, coherent sheaves), and a *free* calculus on them is developed (functors, adjunctions, representation theorems, noetherianity, constructibility).

One of the central objectives of schemes consists in exploring worlds where the *indiscernibles* may become *discerned* (one of the many Galois "Resurrections" in Grothendieck's output). This happens, for example, when new infinitesimals are introduced to capture differences. Three main techniques enter into play (see **Dieud2** vol. 2, VIII, §§ 27–47): *(a) relativization*: given a scheme S, study of the *comma category* Sch/S of morphisms $X \to S$, *(b) basification*: study of $X \to S$ through $S' \to S$, which produces (via pullbacks) $X \times_S S' \to S'$, *and (c) representation*: study of $X \to S$ through the representable functor $h_X : Sch/S \to Set$. The techniques help to elucidate – beyond our "blind eyes," as Tarkovsky would later say – some of the

transits between the discrete and the continuous, between the finite and the infinite. Given a morphism between schemes $f: X \to S$, and given $s \in S$, if $\chi(s) = \mathcal{O}_s/\mathfrak{M}_s$ is the residual field over s (quotient of the local ring by its unique maximal ideal) and if one considers the basis change $Spec(\chi(s)) \to S$, the fiber $f^{-1}(s)$ can be seen as the underlying space of $X_s = X \times_S Spec(\chi(s))$ (see **Dieud2** pp. 198–200). Thus, X appears parameterized by the X_s, and a *smoothness* strategy consists in determining f from the properties of the X_s. How much does the punctual basis $Spec(\chi(s))$ determine in fact the general basis S? The *limits* in the category Sch/S can solve the question: the properties of schemes over arbitrary extensions may be reduced to properties over finite type extensions, and the properties of schemes over arbitrary rings can then be understood through properties of finite type algebras over $\mathbb{Z}$. (Dieudonné calls this the "realization of Kronecker's old dream," **Dieud2**, p. 200.)

Lefschetz's formula (valid in characteristic 0) is the fundamental (co)homological tool to count points in varieties (one of the objectives of the Weil conjectures in characteristic p), and thus the *controlled transit* between cohomologies in characteristic p and cohomologies in characteristic 0 becomes central in Grothendieck's program. (If $f : X \to X$ is a continuous function over a triangulable compact topological space X, Lefschetz's formula *counts* the number of fixed points of f thanks to some traces over the homology groups: $\sum_{x \in FIX(f)} i(f, x) = \sum_{k \geq 0} (-1)^k Tr(f_* \downarrow H_k(X, \mathbb{Q}))$ (where $i(f, x)$ is the index of f in x, intuitively, the number of f windings around x). Through Lefschetz's formula, one can reckon how the counting of points in a variety (left side of the equation) is related to the understanding of its homology (right side).) The construction of that *conceptual filtering sieve* (approaching characteristic 0 through "limits" of prime characteristic) is obtained thanks to the general *étale* environment, where many cohomologies blossom (*étale*, crystalline, l-adic, etc.), more akin to the finer topologies needed to approach the discrete obstructions of number theory. An ample *smoothness/softness theory to capture discrete structures*, or, which is the same, a far-reaching *topologization of algebra*, is at the very heart of the program. We can discover here many of the seeds of Grothendieck's works in his Third Period ("topological algebra," see Sect. 4 below).

It is interesting to compare the two extended decades 1958–1970 and 1981–1991: while the first *ascends* to general forms of smoothness (schemes, toposes) which then descend to the particular (Weil's conjectures), the second *grows* from particular expressions of smoothness (*moduli* spaces, Teichmüller tower, *dessins d'enfants*) which then produce general frames of unification (n-categories, stacks, derivators, looking for a deep entangling of homology and homotopy). With some perspective, one can thus observe that *all Grothendieck* is looking for a very deep *back-and-forth* between universal-general-archetypical forms and concrete-particular-typical forms, with many *zigzag* movements in the middle of its creative spectrum: vertical (EGA [**g1959–1964**], SGA [**g1960–1969**]), horizontal (*Longue marche* [**g1981**], *Esquisse* [**g**1984], see Sects. 4.1, 4.3 below), or diagonal (*Stacks* [**g**1983], *Dérivateurs* [**g**1991], see Sects. 4.2, 4.4 below).

3.4 Séminaire de Géométrie Algébrique (SGA) (1960–1969)

The *Séminaire de Géométrie Algébrique* (SGA) [**g1960–1969**] is one of the greatest *collaborative* efforts in the history of mathematical thought. (SGA is divided into 7 volumes (and 12 parts): *SGA1. Revêtements étales et groupe fondamental* – "Un séminaire dirigé par A. Grothendieck, augmenté de deux exposés de Mme. M. Raynaud" (447 pp., 1960–1961). *SGA2. Cohomologie locale des faisceaux cohérents et théorèmes de Lefschetz locaux et globaux* – "Alexander Grothendieck (rédigé par un groupe d'auditeurs), augmenté d'un exposé par Mme. Michèle Raynaud" (287 pp., 1962). *SGA3. Schémas en groupes* – "Un séminaire dirigé par M. Demazure et A. Grothendieck, avec la collaboration de M. Artin, J.E. Bertin, P. Gabriel, M. Raynaud, J.P. Serre." *Tome 1: Propriétés générales des schémas en groupes*; *Tome 2: Groupes de type multiplicatif et structure des schémas en groupes généraux*; *Tome 3: Structure des schémas en groupes réductifs* (564 + 654 + 529 pp., 1962–1964). *SGA4. Théorie des topos et cohomologie étale des schémas* – "Un séminaire dirigé par M. Artin, A. Grothendieck, J.L. Verdier, avec la collaboration de N. Bourbaki, P. Deligne, B. Saint-Donat." *Tome 1: Théorie des topos (Exposés I à IV)*. *Tome 2: (Exposés V à VIII)*. *Tome 3: (Exposés IX à XIX)* (525 + 418 + 640 pp., 1963–1964). *SGA5. Cohomologie l-adique et fonctions L* – "Dirigé par A. Grothendieck, avec la collaboration de I. Bucur, C. Houzel, L. Illusie, J.P. Jouanolou, J.P. Serre" (484 pp., 1965–1966). *SGA6. Théorie des intersections et théorème de Riemann-Roch* – "Un séminaire dirigé par P. Berthelot, A. Grothendieck, L. Illusie, avec la collaboration de D. Ferrand, J.P. Jouanolou, O. Jussila, S. Kleiman, M. Raynaud, J.P. Serre" (700 pp., 1966–1967). *SGA7. Groupes de monodromie en géométrie algébrique*. *Tome 1* "Dirigé par A. Grothendieck, avec la collaboration de M. Raynaud, D.S. Rim." *Tome 2* "Par P. Deligne et N. Katz" (523 + 438 pp., 1967–1969). From the point of view of *mathematical practice*, some remarks are in order: the continuous presence of Serre, the ever growing diversity of collaborators, and the funny appearance of Bourbaki (Borgesian autoreference, mention of a collective inside a collective). Just looking at the network of authors, one can sense the driving impulse of Grothendieck and the mystic of the Group. Compared with EGA [**g1959–1964**], SGA constitutes another *monumental* work which sums up nearly 6000 (!) pages.) In his *Esquisse* [**g**1972], Grothendieck underlines that, among his topological ideas, "The most fundamental seems to me the extension of general topology, in the spirit of sheaf theory (developed initially by Jean Leray), contained in the topos point of view. I introduced these toposes from 1958 on, for the necessity of defining an *l*-adic cohomology for algebraic varieties (more generally, for schemes), which would agree with a cohomological interpretation of the celebrated Weil conjectures. (For a corroboration of that early date, see [**g1986** P.24]. On the other hand, in the *Archives Grothendieck* at Montpellier, one doesn't find another temporal register associated with the beginnings of topos theory. For good histories of topos theory, see **Belanger** and **Kromer2**.) In fact, the traditional notion of topological space is not sufficient to treat the case of algebraic varieties over a field different of the complex numbers, since the Zariski topology does not provide reasonable 'discrete' cohomological invariants" [**g1972** 3–4]. (Again, and always in Grothendieck, the search to *understand the*

discrete through new continuous tools will propel many of his most revolutionary points of view. I thank here Alexander Cruz for many conversations around the dialectics (continuous ↔ discrete) in Grothendieck, and, particularly, around Grothendieck's very original inversion (continuous → discrete) expressed along the search for general forms of varieties, and universal topological algebra constructs.)

SGA [**g1960–1969**] provides a multilayered architectonics where many deep perspectives are brought together: a systematic work on foundations (schemes, sites, toposes), (Given a category C, a *Grothendieck topology* J on C is the synthetic analogue of an analytic (set-theoretic) topology: for each object X of the category, a collection $J(X)$ of morphisms over X is given ("coverings") such that the identity is a covering, coverings of coverings are coverings, and pullbacks of coverings are coverings [**g1960–1969** 4.1.219]. A *site* is a pair (C, J), with a category and a Grothendieck topology on it [**g1960–1969** 4.1.221]. A *sheaf* over a site is the synthetic analogue of an analytic sheaf over a topological space (through some appropriate categorical characterization [**g1960–1969** 4.1.223]). A *Grothendieck topos* (or just "topos" in this context) is a category equivalent to the category of *all sheaves over a site* [**g1960–1969** 4.1.302]. Grothendieck toposes were characterized by exactness properties (Giraud [**g1960–1969** 4.1.303]). A simplification of those exactness properties (limits, exponentials, subobject classifier) gives rise to Lawvere's *elementary topos* (1970), axiomatized over a first-order language. Any Grothendieck topos is an elementary topos, but not viceversa (e.g., topos of finite sets). Examples of toposes abound [**g1960–1969** 4.1.311–322]: topos of sets, topos of presheaves, topos of sheaves, topos associated to a topological space, topos associated to a space of operators, topos of actions, classifier topos of a group, initial and final topos, etc. The *étale topos of a scheme* (Grothendieck) is obtained by considering the *étale* morphisms over a given scheme X, which form a Grothendieck topology E (" *étale* topology"), and taking the topos of sheaves over the site $(Sch/X, E)$. The *étale topos* will turn out to be the central key in solving the Weil conjectures (Grothendieck-Deligne). On the other hand, the *arithmetic topos may* be a key to solve the Riemann hypothesis (**Connes**). In this way, toposes become deeply submerged into some of the most formidable mathematical conjectures of the last two centuries. For a good account of all the logical, *model-theoretic force* of Grothendieck toposes (beyond elementary toposes), see **Caramello**.) a new opening to abstract topological algebra (fundamental algebraic group), a construction of diverse cohomological theories (coherent, *étale*, l-adic, De Rham, crystalline... leading to the emergence of motives, see Sect. 3.5 below), a wide program of ramifications around the Weil conjectures (Lefschetz local and global theorems, Picard groups, study of homological and homotopical invariants of an algebraic variety [**g1972** 15]), and, more generally, an understanding of the archetypical connections between number and space. (Beyond Einstein's *space-time*, Grothendieck's *space-number* should offer new orientations for the mathematics of the twenty-first century. Time, just a *linear* dimension of number, should be enlarged to *ramified* magnitudes which may explain many of the intricacies of both arithmetical geometry and the cosmos.)

Grothendieck and the IHES school enter then in a new realm which serves as a "synthesis between two worlds, until then contiguous and tightly solidary, but nevertheless separated: the *'arithmetical' world*, in which reside the so called 'spaces' without principle of continuity, and the *world of continuous magnitudes*, in which reside the 'spaces' in the proper sense of the term (...) *In the new vision, those worlds separated before, form only one*" [**g1986** P.30]. Thus, *beyond separation*, thanks to the abstraction (*freeness, projectivity*) provided by sheaves, a new mathematical *smoothness* governs the interrelations between arithmetic and geometry. Grothendieck's revolutionary shift is as *simple* as deep: instead of *(i)* a topological space X, consider *(ii)* all sheaves over X, and study *(iii)* the topos T_X of all those sheaves; then *the understanding of the structure T_X turns out to be the true understanding of X*. A double differential and integral process (see Sect. 5.3 below) governs the situation: exploring *multiplicity* along all sheaves, and threading *unity* along the exactness properties of the topos.

3.5 Standard Conjectures on Algebraic Cycles (1968)

Around the mid 1960s, (From a semiotical and philosophical perspective, the general method is fascinating: to understand something, consider all possible points of view, and search for a *structural connection* between them. Only then you will be approaching *true knowledge*. A systematic use of the *liberty and multiplicity* of topos theory in our ordinary life would have huge consequences on tolerance, ethics, politics, and social action: an example of how *high mathematical practice* would transform our *everyday practice*.) Grothendieck imagines a "daydreaming" [**g1972** 17] where a *common form* hopes to unify the diverse cohomologies that have emerged until then. A *motif* (unity) is thought as a conceptual basis (or "heart of the heart" [**g1986** P.45]) over which many cohomologies can be represented (multiplicity). Contrary to his previous practices, Grothendieck publishes little on motives, but one of his best renderings is the article *Standard conjectures on algebraic cycles* [**g1968**]: "We state two conjectures on algebraic cycles, (An *algebraic cycle* over a variety X is a formal linear combination $\sum_i(n_i \cdot V_i)$ (coefficients n_i in $\mathbb{Z}$ or in $\mathbb{Q}$) of subvarieties V_i in X. The cycles, as *decomposition* processes of sophisticated mathematical objects, become central in the emergence of *motives*. In the Riemann-Roch strategy, the *equivalence classes* of cycles are obtained through *rational equivalence* (difference between cycles parameterized through rational functions) [**g1957** 38].) which arose from an attempt at understanding the conjectures of Weil on the ζ-functions of algebraic varieties. (...) The first is an existence assertion for algebraic cycles (considerably weaker that the Tate conjectures), and is inspired by and formally analogous to Lefschetz's structure theorem on the cohomology of a smooth projective variety over the complex field. The second is a statement of positivity, generalising Weil's well-known positivity theorem in the theory of abelian varieties. It is formally analogous to the famous Hodge inequalities, and is in fact a consequence of these in characteristic zero" [**g1968** 193].

Grothendieck delineates the consequences of the two conjectures (for their precise statements, see below), in order to obtain an eventual resolution of Weil's conjectures. The first step consists in recalling the rationality (obtained by Artin and Grothendieck in the SGA [**g1960–1969**]) that governs the Zeta function Z of a variety X with good *smoothness* properties (smooth, projective, irreducible) of dimension n over a finite field $\mathbb{F}_q$:

$$Z(t) = \frac{L'(t)}{L(t)},\ L(t) = \frac{\prod_{i=0}^{n} L_{2i}(t)}{\prod_{i=1}^{n} L_{2i-1}(t)},\ L_i(t) = \frac{1}{P_i(t)},\ P_i(t) = t^{dimH^i(\overline{X})} Q_i\left(t^{-1}\right)$$

where Q_i is the characteristic polynomial of the action of the Frobenius endomorphism of X over $H^i\left(\overline{X}\right)$, H^i denotes the i-th group of l-adic cohomology (l prime different of q), and $\overline{X}$ denotes the extension of X to the algebraic closure of $\mathbb{F}_q$ [**g1968** 193–194]. The second step consists in signaling that the first conjecture forces the P_i to have entire coefficients (independently of $l \neq q$), and in observing ("thanks to an idea essentially due to Serre" [**g1968** 194]) that the two conjectures *at the same time* force the eigenvalues of the Frobenius (that is, the reciprocals of the roots of the P_i) to have an absolute value $q^{\frac{i}{2}}$, which proves Weil's conjectures [**g1968** 194]. (Instead, the path followed by Deligne to prove Weil's conjectures is *completely different*. Grothendieck never really accepted that proof, in his view extremely ingenious but *artificial*, estranged from the *natural path* offered by the standard conjectures (and, in depth, by motives). That *mathematical discontent* is one of the many reasons, in a complex thread of disillusions, that alienated him from Deligne and the mathematical community in general.) Concisely and limpidly, in one page and a half, a vast panorama is drawn, still open today (2020) in many senses.

"The conjecture 1 (of Lefschetz type)" [**g1968** 195–197], states two equivalent forms ($A(X)$, $B(X)$) of the conjecture. If $C^i(X)$ denotes the set of i-th cohomology classes of algebraic cycles, Grothendieck indicates that one gets (through hyperplane projections: Lefschetz's operator) an homomorphism (*) $H^i(X) \to H^{2n-i}(X)$ ($i \leq n$) subject to the commutative diagram

$$\begin{array}{ccc} C^j(X) & \longrightarrow & C^{n-j}(X) \\ \downarrow & & \downarrow \\ H^{2j}(X) & \longrightarrow & H^{2n-2j}(X). \end{array}$$

Conjecture $A(X)$ postulates that (*) is always an isomorphism, and that, if $i = 2j$, (*) induces also an isomorphism (through the commutative square) at the level of algebraic cycles $C^j(X) \to C^{n-j}(X)$ [**g1968** 196].

"Conjecture 2 (of Hodge type)" [**g1968** 197–198], proposes to handle the good behavior of a bilinear form on "primitive cycles." In detail, if $\xi \in H^2(X)$ is the class of an hyperplane section, if $P^i(X)$ ($i \leq n$) is the "primitive part" of $H^i(X)$ (that is, the kernel of Lefschetz's morphism induced by ξ^{n-i+1}), and if one defines the set of (classes of) primitive cycles by $C^j_{Pr} = P^{2j} \cap C^j(X)$, one obtains then a bilinear symmetric form $C^j_{Pr} \to \mathbb{Q} : (x, y) \mapsto (-1)^j K\left(x \cdot y \cdot \xi^{n-2j}\right)$, where K is the

isomorphism $H^{2n}(X) \approx \mathbb{Q}_l$. The conjecture $Hdg(X)$ postulates that the form is positive-definite [**g1968** 197]. (If V is a real vector space, a bilinear symmetric form $B : V \times V \to \mathbb{R}$ is *positive-definite* if $B(x, x) \geq 0$ for all x. The positive-definite forms correspond to quadratic forms, basic instruments for arithmetical (Gauss) or metrical (Riemann) mediations, and are associated to central problems in representation and optimization. The emergence of a positive-definite form in algebraic geometry, close to Weil's conjectures, serves thus as a weaving between arithmetic, algebra, topology, and geometry: a *natural* mediating tool, very attractive to Grothendieck.)

Grothendieck underlines that, in characteristic zero, $Hdg(X)$ is obtained immediately from Hodge theory, and explains the great technical interest of having *simultaneously* the two conjectures in arbitrary characteristic: "$B(X)$ and $Hdg(X \times X)$ imply, by certain arguments of Weil and Serre, the following: if f is an endomorphism of X such that $f^*(\xi) = q \cdot \xi$ for some $q \in \mathbb{Q}$ (which is necessarily > 0), then the eigenvalues of $f_{H^i(X)}$ are algebraic integers of absolute value $q^{\frac{i}{2}}$. Thus, this implies all of Weil's conjectures" [**g1968** 197]. On the other hand, Grothendieck points out that the conjunction $Hdg(X)$ and $B(X)$ forces Hodge's Λ operator to arise from an algebraic cycle with rational coefficients, *independently of l* [**g1968** 198]. In this way, plumbing the depths, emerges the vision of some *global universal archetypes* (independent motives), which may then be projected over *local arithmetic strata* (l-cohomologies).

4 Third Period: 1981–1991

Grothendieck's third period escapes from the stringent exigences of architectural perfection (EGA, SGA), and allows the exploration of conjectural and error-prone wanderings around number and space. *The genius is set entirely free.* Inverting Poincaré's algebraic topology program, Grothendieck invents *topological algebra*, introducing new topological invariants for algebraic objects and new forms of *smooth* topology (tame topology). The emergence of *anabelian geometry* studies varieties through the action of their fundamental algebraic group. On the other hand, proceeding from low level geometrical objects, Grothendieck offers combinatorial descriptions for Riemann surfaces ("*dessins d'enfants*") and for their classification, level by level, along actions of the Grothendieck-Teichmüller group. Beyond this, in a powerful *back-and-forth* between concrete examples and universal theories, he introduces stacks and derivators, in order to study homotopy types and their homological counterparts from a categorical perspective. The 1980s become also the time of his very deep philosophical reflections on *mathematical creativity*, and, particularly, on his own work.

4.1 La Longue Marche à Travers la théorie de Galois (1981)

Grothendieck's retirement from the IHES in 1970 is due to a diversity of factors, not reducible to a single perspective: technical exhaustion (after 20 years of extremely

hard work, a point underlined by Cartier and Serre), individual liberation [**g1986** 1.65], social conscience [**g1986** 1.159], academic turmoil after May 1968 [**g1986** 1.156], disappointment with the mathematical community [**g1986** 1.65], rejection of the military support given to the IHES (the "standard" argument [**g1986** L.3, 1.169]). One often hears, with no reason, that Grothendieck abandons the world of mathematics. Nothing could be farther from the truth. He dedicates a great effort to the radical ecologist movement *Survivre et vivre* (1970–1975), but continues steadily to give lessons (*Collège de France* (1970–1972), *Université de Paris-Orsay* (1972–1973), long series of conferences in Romania, Canada, Germany, France, Switzerland, USA), and to foster the mathematical research of his students (*Université de Montpellier* (1973–1984), with even more Ph.D. students there than at the IHES). What seems to be true is that between 1970 and 1980 his own mathematical research is somewhat "muted." Its huge reemergence in the decade 1981–1991 appears then as a kind of "miracle," and one encounters again the inexhaustible Grothendieck at work.

The first expression of Grothendieck's "resurrection" is the unending (and unpublished) manuscript *La longue marche à travers la théorie de Galois* [**g1981**]. Written between January and June 1981, it covers close to 1600 pages in the principal text and close to 1000 pages in notes and addenda. Some sections of the manuscript have been transcribed (Malgoire, Schneps), but they are difficult to read. They will become integrated later in the synthetic *Esquisse d'un programme* [**g1984**] (see Sect. 4.3 below). Open to the careful observation of concrete examples, *La longue marche* [**g1981**] combines holistic perspectives (categorical treatments, towers) and case studies (*moduli* spaces, modular curves, *dessins d'enfants*). The study of *algebraic variation* through topological tools and the unveiling of *universal structures* (fundamental algebraic group, Grothendieck-Teichmüller group), behind Galois, Riemann, and Poincaré, become the foundations of Grothendieck's *topological algebra* in the 1980s.

The two central themes of *La longue marche* [**g1981**] are *(i) anabelian geometry* and *(ii) Grothendieck-Teichmüller theory.* Around *(i)*, the central point is to study a variety (algebra – number theory – Galois), or a scheme (Grothendieck), through its fundamental topological group (topology – geometry – Poincaré), or through its fundamental *algebraic* group (Grothendieck). Given a scheme X (automatically a topological space), one considers the fundamental homotopy group $\pi_1^{top}(X,x)$ (Poincaré) for some point $x \in X$ (if X is arcwise-connected, one can forget the base point x), and the *profinite completion* of $\pi_1^{top}(X)$ is by definition the *fundamental algebraic group* $\pi_1^{alg}(X)$ of X (Grothendieck). This group classifies the *étale*, since its finite continuous orbits are precisely the *étale* coverings of the Scheme. A fundamental example is the projective plane P except three points: in that case, the absolute Galois group $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right)$ acts over $\pi_1^{alg}(P)$ and hides deep arithmetical combinatorial structures (*dessins d'enfants*). The central problem of *topological algebra* becomes how to detect or describe those varieties X completely characterized by $\pi_1^{alg}(X)$. By definition, those are the *anabelian varieties*, whose geometry (space) and arithmetic (number) are codified in their (non-abelian) fundamental

algebraic groups. Grothendieck's main conjecture states that the *moduli* spaces M_g (see note 25 above) constitute the anabelian varieties over $\mathbb{Q}$, and, as a special case, that the hyperbolic curves over algebraic number fields are anabelian. Mochizuki solves in 1996 the particular conjecture (**Mochizuki1**) and launches then his ambitious program of new foundations for *arithmetic geometry* (**Mochizuki2**).

Around *(ii)*, the central object of study becomes the absolute Galois group $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right)$ (algebra – number theory – Galois) through its *actions over geometrical objects* (complex variable – geometry – Riemann). In that sense, as its very name shows, the "absolute" Galois group becomes an *archetype* which hopes to be understood through its actions over diverse *types*: curves, *moduli* spaces, fundamental groups (homotopic, algebraic), *dessins d'enfants*, and combinatorial towers. Given a variety $M \in M_{g,\,\nu}$ (g holes, ν selected points) and given its fundamental homotopy group $\pi_1^{top}(M)$, Grothendieck considers its profinite completion $\widehat{\pi_1^{top}(M)}$ and studies the profinite groups of loops, through automorphisms, interior automorphisms, quotients ($C_1(g, \nu)$), discretizations (basis of the group), and characters ($C_2(g, \nu)$). An strategy to understand the absolute Galois group $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right)$ consists then in presenting it as a quotient $C_1(g, \nu)/C_2(g, \nu)$ [**g1981** 26–28], *uniformly* over all (g, ν) with $(2g + \nu \geq 3)$. (Schneps indicates that this approximation fails at least when $(g, \nu) = (0, 3)$, due to a later result of Drinfeld. See **Schneps3** p. 62.) Nevertheless, Grothendieck himself observes that this seems to be a "very brutal" strategy [**g1981** 163], and that one should "proceed in a more inductive manner, from the presence of $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right)$ [in the Teichmüller tower] (for arithmetico-geometrical reasons), in order to clear up strong properties, and provide finally a purely algebraic characterization" [**g1981** 165]. (The program will be later developed by Drinfeld (1991), through what he will call the *Grothendieck-Teichmüller group* $\widehat{GT}$. A delicate description of $\widehat{GT}$ can be done through subgroups and products of $\widehat{F_2}$ (completion of the free group with two generators), $\widehat{K_5}$ (completion of Artin's braid group), and $\widehat{\mathbb{Z}}$ (completion of the integers). Drinfeld conjectures that $\widehat{GT}$ is also the *automorphism group of the Teichmüller tower*. An injective homomorphism $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right) \hookrightarrow \widehat{GT}$ holds (Drinfeld, Ihara, Belyi). A proof of the open conjecture $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right) \approx \widehat{GT}$ would provide the "purely algebraic characterization" dreamed by Grothendieck. See **Schneps3** pp. 64–66.) In all of this, we can see how Grothendieck *zigzags*, looking for a deep harmonization between vital polarities: visible/invisible, exterior/interior, discrete/continuous, local/global, layers/completion. A new form of *mathematical practice* emerges along a *new, open, free, tentative, plastic*, style. The conjectural, the inventive strata, the elastic heart, even if imprecise, *command* the theorematical, the solid architectonics, the strict reason. A myriad of questions are then opened for generations to come.

4.2 Pursuing Stacks (1983)

Between 1981 and 1991, Grothendieck will follow concentrated *impulses*, along *continuously flowing* manuscripts, either purely mathematical (*Longue marche*

[**g1981**], *Stacks* [**g1983**], *Esquisse* [**g1984**], *Dérivateurs* [**g1991**]), either methodological, philosophical, and mystical (*Récoltes* [**g1986**], *Songes* [**g**1987]). One can sense in the 1980s his strongly burgeoning spirit, never at rest. *Pursuing stacks* [**g1983**] is the longest Grothendieck manuscript written in English. Proceeding from an *epistolary mood*, that once initiated never stops, it includes three letters to Larry Breen (1975, 58 pp.), a letter to Daniel Quillen (1983, 23 pp.), a table of contents (1983, 10 pp.), and a deep *journal of discovery* (February 27, 1983 – November 4, 1983, 593 pp.) Around higher forms of sheaves and category theory, Grothendieck explores a "*vast synthesis* of homotopical algebra, (co)homological algebra, and topos theory," in a "*non precise and provocatively fragmentary*" manner (*Archives Grothendieck*, Montpellier, cote 109).

Stacks appear in different ways in [**g1983**] – as coefficients in noncommutative homological algebra, as strata in categorical towers, as unifier bridges between homology and homotopy – but Grothendieck never offers a precise definition of the concept. (A *stack* is considered today as a *generalization of a sheaf* in the context of 2-categories (or bicategories). In an iterated fashion, a n *– stack* is understood as a $(n+1)$ *– sheaf*. In some cases, *stacks* may be characterized through categorical *fibrations*. In a more precise approach, a *stack* over a site S is a pseudofunctor (preserves identity and composition with respect to isomorphisms) $S^{op} \rightarrow Cat$ (2-category) which satisfies an effective descent for coverings. A *stack of groupoids* takes values in the category of groupoids. A *stack of moduli* takes into account not only equivalence classes in *moduli* spaces but also the *automorphism groups* of those structures. In this way, the development of *stacks* is closely related to Galois' *ambiguity theory* applied to arithmetic. For a thorough guide of an ever growing panorama, see the many entries in the webpages *nLab* and *Stacks Project*.) This is due in part to the *work in progress maniera*, where the *vanishing lines* of the building become primordial, in detriment of its foundations. (The importance of the *style*, or *maniera*, in *Pursuing stacks* [**g1983**] is essential: "I sometimes find it difficult to find a proper balance in these notes between the need of working on reasonably firm ground, and working out suggestive terminology and notations for what is coming up, and on the other hand my resolve not to get caught again by the EGA style of work, when it was understood that everything had to be worked out in complete detail and in the greatest generality" [**g1983** 445].) Nevertheless, Grothendieck's *vision* may be broken down along some well defined steps: *(i)* acknowledgment of the existence of nontrivial automorphism groups (interest of Galois' ambiguity theory), in order to *structure certain structures* (first essential hierarchical iteration); *(ii)* classification of those structures (e.g., *moduli* spaces) thanks to continuous variations (interest of Riemann's representation theory), in order to *differentiate certain differences* (second essential hierarchical iteration); *(iii)* consciousness of the ubiquitous role of groupoids (algebraic or topologic) in the preceding themes (structuration, representation, differentiation); and *(iv)* integration, in higher sheaves, of all previous informations (variation, gluing, ascent/injection, descent/projection). The *coherence* of the program is solidified when one comes to see it as some sort of *methodological sheaf* applied to the very richness of mathematics.

Passages between diverse types of *stacks* become then entirely *natural*, in a *back-and-forth* between (1) *algebraic stacks* (algebraic varieties, schemes, toposes), (2) *differential and topological stacks* (differential varieties, topological spaces, toposes), and (3) $n-stacks$ ($0-stacks$ = sheaves, $1-stacks = stacks$, etc., leading to n-categories and n-groupoids). All these paths offer new horizons: (1) the fine theory of *moduli* spaces, oriented towards arithmetic (Langlands' program), (2) the classification theories in noncommutative algebra, oriented to anabelian geometry (Grothendieck-Teichmüller's program [**g1981**] [**g1984**]), (A central example of a *stack* is the (pseudo)functor $S^{op} \to M_{g,\nu}$ where S is the category of affine schemes over a fixed scheme with the *étale* topology and $M_{g,\nu}$ is the *moduli* space of Riemann surfaces of genus g with ν points. The particular case $(g, \nu) = (1, 1)$ (corresponding to elliptic curves) was first treated by Mumford (1965, introduction of the term "*stack*" in 1969), before Grothendieck considered the general case (g, ν).) and (3) the homotopical theories of types and categories, oriented towards an alternative foundation of mathematics in higher geometrical orders (Voevodsky's program, HoTT). (*Homotopy Type Theory* (HoTT) looks for a *fourth foundation* of mathematics (after set theory, intuitionistic species, and category theory). A strong geometric intuition (homotopy types) is postulated, *before* considering the combinatorial (sets), the constructive (species), or the relational (categories). An essential part of the program consists in *debilitating equality* (very restrictive for the natural structures of mathematics), and changing it with isomorphisms ("univalence axiom"). For an introduction to HoTT, see **VoevH**.) We observe here a *continuous thought* expressed through categorical unitary archetypes, *high* enough and *general* enough, to be able to cover the multiplicity of diverse particular types. (A comparison of Hilbert with Grothendieck, easily the two major mathematicians of the twentieth century, may be instructive: while, in Hilbert, each fragment of his production constitutes a well *separated and complete* conglomerate (algebra, number theory, geometry, functional analysis, logic, physics), in Grothendieck all fragments are always intertwined, from the implicit categorical *maniera* of his *Thesis* [**g1949–1953**] until the overarching "functional analysis" panorama of the *Dérivateurs* [**g1991**].)

4.3 Esquisse d'un Programme (1984)

Esquisse d'un programme [**g1984**] constitutes a research project for Grothendieck's admission to the CNRS, after his retirement from Montpellier University (1984). The *Esquisse* (dated January 1984 [**g1984** 51]) retrieves some of the central ideas of the *Longue marche* [**g1981**], and extends them to two new paths in *topological algebra*: on one side, *dessins d'enfants*, (A *dessin d'enfants* may be presented as a graph D finite, connected, bicolored, embedded in an oriented compact topological surface X, such that $X \backslash D$ is a finite union of disks (see **GirondoGonzalez**, p. 207). Some examples (posterior to Grothendieck) are striking: the (topological) sphere S^2, with an inscribed *dessin* formed by a black vertex, a white one, and another black, corresponds to the Riemann surface associated to z^2; the sphere with a *dessin* formed

by vertices black-white-black-white-black corresponds to the Riemann surface associated to $z^2(z-1)^2$, etc. On the other hand, proto-ideas around the *dessins* can be traced back to the nineteenth century (Hamilton, Klein, etc.)) through which Grothendieck combinatorially captures compact Riemann surfaces and studies their behavior under the actions of the absolute Galois group $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right)$, and, on the other side, "tame topology" (*topologie modérée*), which hopes to eliminate wild phenomena and artificial counterexamples in classical set-theoretic topology. An "ascent" to higher concepts is provided, in order to "descend" after to lower constructs. In this case, a systematic study of "high" algebraic actions (fundamental algebraic group, anabelian geometry, Grothendieck-Teichmüller group) is explored, in order to understand topological surfaces of "lower" dimension (compact Riemann surfaces, *moduli* spaces).

The *Esquisse d'un programme* [**g1984**] covers three main subjects: *(i)* Teichmüller's tower and the absolute Galois group (*Sect. 2* of the typescript), *(ii) dessins d'enfants* (*Sect. 3*), and *(iii)* tame topology (*Sects. 5, 6*). Two secondary topics are considered: regular polyhedra and two-dimensional geometry (*Sects. 4, 8*), *stacks* (*Sect. 7*). Finally, some considerations about the personal circumstances of the author are included: balance of research and teaching experience (*Sects. 1, 9, 10*). From *higher* perspectives, Grothendieck looks for a general theory of *dévissage* ("unscrewing"), in order to understand the architectonics of stratified mathematical architectures. This leads naturally to the iterative construction of *stacks* and to tame topology, hoping to capture *smooth combinatorial forms* along hierarchical transits. From *lower* perspectives, surfaces, complex algebraic curves over number fields, elliptic curves, modular subgroups, and regular polyhedra, offer many illuminating examples which help to adjust the architectonics. In the *middle ground*, modular multiplicities and their associated groupoids, general varieties over number fields and their associated fundamental groups, Riemann surfaces and their associated *dessins d'enfants*, stratified actions of the absolute Galois group and their invariants, *connect continuous and algebraic variations*, and become ciphered in the fundamental anabelian conjecture about the multiplicities $M_{g,\nu}$ (*stacks*, not varieties). The *Esquisse* [**g1984**] offers thus a typical Grothendieckian *vision*, conjugating abstraction and concretion, theory and examples, unity and multiplicity, universality and contingency, continuity and discreteness, globalization and localization. A *yin* drive (see Sects. 4.5, 4.6 below) towards particular forms of smoothness is complemented with a *yang* drive towards general forms of *dévissage*.

The *arithmetical heart* of the researches collected in the *Esquisse* [**g1984**] glues together (in a sort of methodological sheaf) the *continuous variations* present in the *moduli* spaces $M_{g,\nu}$ and the *algebraic variations* of $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right)$ acting on the Teichmüller tower. In particular, the appearance of the space of elliptic curves $M_{1,1}$ on the first floor of the tower, and its associated modular group $SL(2, \mathbb{Z})$, underlines the arithmetical richness of the environment. On the other side, the *natural* emergence of algebraic curves over number fields along compact Riemann surfaces (Belyi 1979), strikes Grothendieck very deeply. (Belyi's theorem characterizes the compact Riemann surfaces associated to complex algebraic curves

defined over number fields. More precisely, if S is a compact Riemann surface, the following are equivalent: *(i)* S is defined over $\overline{\mathbb{Q}}$, *(ii)* there exists a meromorphic function $f: S \to \mathbb{P}^1$ with at most three ramification points. Belyi's discovery, "that technically is reduced to such a small thing, exerted in me a very strong impression, and represented a decisive turn in my reflections, a shift of the center of my mathematical interests (...) I do not recall that another mathematical fact had striken me so strongly (...)" [**g1984** 12]. Thus, in Grothendieck's own words, the *decisive turn* towards algebraic geometry (Kansas 1955) and the *decisive turn* towards combinatorial topological algebra (Mormoiron 1984) seem to be two major illuminations. It is interesting to observe that the two circumstances occur far away from the official academic centers of mathematical thought, and after some important psychological crisis. *Mathematical practice*, through immense manuscripts (*Tôhoku* [**g1955–1956**], *Longue marche* [**g1981**]), well beyond just mathematical learning, will always be for Grothendieck a way to stabilize his soul.) Beyond this, thanks to Grothendieck's equivalence between compact Riemann surfaces and oriented topological surfaces with *dessins d'enfants* inscribed on them, the known action of $Gal\left(\overline{\mathbb{Q}} : \mathbb{Q}\right)$ over compact Riemann surfaces becomes transferred to a *new combinatorial action* over *dessins d'enfants*, and one can hope to obtain a *smooth combinatorial* description of the absolute Galois group. (This will lead to Drinfeld's *definition* of the Grothendieck-Teichmüller group $\widehat{GT}$ (see *Note 45* above).) Finally, the main goal of anabelian geometry, that is, to control curves over number fields through their fundamental algebraic groups (extending homotopy to the new configurations of topological algebra), achieves the architectonics of the *Esquisse* [**g1984**]. In this way, once more, Galois, Riemann, and Poincaré, become connected along the depths of Grothendieck's thought, but now under an arithmetic-algebraic-complex-geometric weaving to which are added an elementary combinatorics (*dessins d'enfants*) and a smooth universal understanding of topological forms (*topologie modérée*).

4.4 Les dérivateurs (1991)

Les dérivateurs [**g1991**] is Grothendieck's last known manuscript. (Between 1991 and 2014, the year of his death, Grothendieck wrote extensively on many subjects, embracing mathematics, physics, philosophy, mysticism, history, sociology, including a long history of evil in mankind which tracks in particular the monstruosities of concentration camps. Summing up to more than 50,000 pages (20 years is a very long time for a restless mind!), Grothendieck bequeathed his last writings (extremely well organized in careful arranged boxes, as reported by Georges Maltsiniotis) to the *Bibliothèque Nationale de France*. Nevertheless, his heirs have acted differently, and his heritage is being appraised for an eventual sale to a highest bidder (a hideous contradiction with Grothendieck's anarchist and free spirit). When those 50,000 pages will be made available to the public, our understanding of Grothendieck will acquire a new dimension, complementing his extremely complex intellectual portrait

through a *Fourth Period* (1991–2014), which should be full of surprises.) The gigantic text (around 2000 pages) was distributed to friends and colleagues, like the other texts of the decade, (In total, the output was immense, summing up circa 8000 pages (!): *mathematical*: *Longue marche* [**g1981**] ∼ 2500 pages; *Pursuing stacks* [**g1983**] ∼ 700 pages; *Dérivateurs* [**g1991**] ∼ 2000 pages; *philosophical*: *Récoltes et semailles* [**g1986**] ∼ 1400 pages; *La clef des songes* [**g1987**] ∼ 1000 pages. The *flow* of Grothendieck's writings, in solitary confinement, is almost equal in this *Third Period* to the production in the previous *First and Second Periods combined*, even if we count there the help of his multiple IHES collaborators!) and opens new roads for the eclosion of higher category theory. Grothendieck tries to axiomatize *at large*, at a universal global level in the category *Cat* of all categories, some canonical notions in topological algebra. Through a general axiomatics applied to adjunctions, localizations, and actions (oriented by the category *Hot*: *CW*-complexes with homotopy classes as morphisms [**g1983**]), Grothendieck seeks to recover *both homological algebra* (coefficients, abelian and derived categories) and *homotopical algebra* (limits, *n*-categories, topos constructs), as complementary *slopes* of a unitary whole ("prederivators," sort of localizations of Yoneda's Lemma, independently of basis changes). Beyond isolated efforts (Maltsiniotis, Cisinski, Groth), many of the ideas and techniques of *Les dérivateurs* remain yet to be assimilated and developed by the mathematical community.

Les dérivateurs [**g1991**] provides many topological techniques and perspectives to capture algebraic notions, through *smooth abstract coverings*: *(i) Hot* covered by *Cat*, *(ii)* types of homological algebra (coefficients) and types of homotopical algebra (limits) covered by general categorical archetypes, *(iii)* homotopical formalisms and (co)homological adjunctions covered by an axiomatics of (pre)derivators, (Fundamental examples of (pre)derivators are: *(i)* presheaves $A \to Hom(A^{op}, M)$ (A, M categories), *(ii)* localizations $A \to W_A^{-1}Hom(A^{op}, M)$ (W_A subset of arrows – weak equivalences" – in Yoneda's image of $A \subseteq M^{A^{op}}$), and *(iii)* a natural functor HOT: $Cat \to Cat$ associated to a localization of simplices in the category *Hot*. For precise definitions and developments, see **Cisinski**.) *(iv)* variations (functorialization of derivation processes) and invariants (intrinsic stability, independence of basis changes) covered by universal procedures in the category of all categories, and *(v)* resolutions to obstructions to non-canonicity in abelian and derived categories covered by *localizations*. (Grothendieck's problematic begins with observing some *canonicity failures* in the construction of the derived category of an abelian category [**g1955–1956**]. If A is an abelian category, $C(A)$ is the category of complexes over A, and W is the set of quasi-isomorphisms of $C(A)$ (morphisms $f : X \to Y$ such that $H_n(X) \approx H_n(Y)$ for all n), the derived category is defined by the (formal) localization $Der(A) = C(A)[W^{-1}]$. Then, many functoriality and adjunction problems emerge, in order to capture the original information of A. For an introduction, see **Maltsiniotis3**.)

In a letter to Thomason (Les Aumettes, 2.4.1991), (Available at www.grothendieckcircle.org, under a folder on derivators.) Grothendieck explains some of the essential points of *Les dérivateurs* [**g1991**]: universality of abstract axiomatizations in *Cat*, localizations *at large* in *Cat* and comparison with Quillen's model

categories, understanding of the additional structure of a derivator with respect to its underlying derived category, correlative study of adjunctions associated to a derivator. The *axiomatic* investigations (See [**g1991** I.23–25] (derivator axioms), *Archives Grothendieck*, cote 157–4, pp. 268–350 (localization axioms).) in the ever-evolving document (Again, as happens all along the 1980s, a *diary of invention* is proposed, and one can follow the many ideas, errata, changes, new elaborations, through the evolving manuscript. A detailed study of such *mathematical practice* in a great mathematician, with all its *residues of stratified invention*, is yet to be undertaken. It would provide a magnificent witness of *creativity at large*.) are witnesses of Grothendieck's practice to clear up ("*dégager*") the universal mechanisms that govern many regions of mathematics. As a consequence, Grothendieck obtains a sort of *general methodology of smoothening singularities* (strong conceptual connections with Hironaka's "resolution of singularities," 1964), where the *tameness* of the topology, the *n*-elevation of *stacks*, the unification at large of *derivators*, respond to the desired smoothness. The possibility of *transiting* in higher categories helps to overcome the many *obstructions* in lower regions. Grothendieck's work acquires thus a strong solidarity, going from his very *Thesis* [**g1949–1953**] until the *Dérivateurs* [**g1991**]. For developments on this *unity, continuity, and coherence*, see Sect. 5 below.

4.5 Récoltes et Semailles (1983–1986)

Récoltes et semailles [**g1986**] is perhaps the major analysis ever written on higher mathematical creativity. Beyond Poincaré's *L'invention mathématique* (1908) and Hadamard's *The Psychology of Invention in the Mathematical Field* (1945), (**Poincare Hadamard**.) Grothendieck's reflections surpass its predecessors both in extent (1500 pages), and in depth (detailed study of the emergence of Grothendieck's main mathematical ideas, a refined approach to one of the two greatest mathematicians of the twentieth century) (see *Note 50* above). The subtitle of the work, "Reflections and testimonies on a mathematical past," indicates its two main watersheds: on one side, reflections on *mathematical practice*, entering in detail inside Grothendieck's practices, and on another side, testimonies on his own life and his *mathematical school*, expressing a disenchantment with how the "seeds" (*semailles*) of his work had not been adequately "harvested" (*récoltes*) in the period 1970–1983. The *style* of the retrospective is typically grothendieckian: passionate, meticulous, exhaustive, irritating, astonishingly beautiful, both in his autoanalysis and in his accountability of the community. The harsh sincerity of the volume struck his mathematical colleagues, and ended up severing the few remaining ties that Grothendieck had with his previous intellectual environment.

Along this survey, we have had the opportunity to quote many times the manuscript. (The manuscript, not yet published in French, is accessible in many sites online. It has been translated in Japanese (Tsuji, also published), Russian (Fridman and Filkenberg), English (Lisker), and Spanish (Navarro). The best study of *Récoltes et semailles* [**g1986**] is **Herreman**.) The text is divided into seven main sections:

Walk Around a Work, or the Boy and the Mother (65 pp.): January–February 1986; *Letter and Introduction* (56 + xxii pp.): March 1984, May–June 1985, February 1986; *First part. Fatuity and Renovation* (171 pp.): June 1983, February–March 1984; *Second part. The Burial I, or the Clothes of China's Emperor* (249 pp.): April–June 1984; *Third Part. The Burial II, or the Key of Yin and Yang* (354 pp.): September 1984–January 1985; *Fourth Part. The Burial III, or the Four Operations* (478 pp.): February–June 1985; *The Doors over the Universe. Appendix to the Key of Yin and Yang* (127 pp.): March–April 1986. Acceleration and multiplication point to a *never-ending outpouring* of words, concepts, images, reminiscences. *Récoltes et semailles* [**g1986**] encompasses the inexhaustible richness of Grothendieck's persona, underappreciated and ill-understood by the mathematical community, in particular by his great peers, a Serre, a Dieudonné, who never accepted the hermit, the mystic, and the anarchist.

The *complexity* of *Récoltes et semailles* [**g1986**] captures the complexity of the Grothendieckian world: (1) disaggregation of mathematical thought, in its eternal fight between substance (e.g., spaces, numbers, structures) and form (e.g., cohomologies, motives, derivators); (2) reflections on the inroads to mathematics, and, in particular, on a naive entrance to creativity (freshness, smoothness, childish perception); (3) considerations on mathematical method, and, in particular, on the demands of constant and persevering work (tasks of the architect and the laborer); (4) systematic study of the yin-yang watersheds in creativity, in general, and in mathematical creativity, in particular; (5) journey around the intellectual biography of the author, his central passions, and his tasks in pursuit of alternative life movements (ecology, austerity, oriental philosophy); (6) detailed analysis of the historical and sociological circumstances where that biography is inserted; (7) strong criticism of the degenerescence processes occurring in the Western world in the 1970s and 1980s; (8) stylistic constructions, multi-spatial and multi-temporal, which mirror an inquisitive and open mind, attentive to contemporary trends.

The metaphor of the *rising sea*, "by immersion, absorption, dissolution" [**g1986** 3.553], acquires a fundamental technical value thanks to Category Theory, when an object ("nut") is submerged in an adequate category which absorbs it ("sea"). This is the case of the central theorem in the theory, Yoneda's Lemma, (In a parallel way to Yoneda (c. 1958), the Lemma also appears independently in EGA [**g1959–1964** III.1.7].) where a *double iteration* of the rising sea appears: *(i)* objects are first immersed in their "auras" (representable functors) and *(ii)* categories of objects are then immersed in presheaf categories. The result provides, for every small category, a *complete* extension through non-representable functors: these can be understood as *phantasmata* which come closer to the invisible. On the other hand, the rising sea occurs also naturally along toposes, when a topological space (or a site) is submerged in the category of *all* sheaves over it. In the topos emerges a powerful "superstructure" (completeness, exponentiation, subobject classifier), invisible from the initial space (or site). In these cases, the *rising sea* reveals a *general* mathematical richness, previously invisible, that can help to solve very difficult *particular* problems (e.g., Weil's conjectures).

The *Appendix* to *Récoltes et semailles* [**g1986**], *The Doors over the Universe* (abbreviated DU), 127 pages written in a month-long euphoria (March 17–April 14, 1986), adopts a sophisticated system of pairings yin/yang to understand human action, in general, and *mathematical practice*, in particular. On the yin side, one finds discovery processes, smoothness, a mother language of intuition. On the yang side, emerge inventive processes, architectonics, the superficial languages of description. Along yang resides reason ("razón" in Spanish), along yin lies the heart ("corazón" in Spanish, *duality* perfectly captured by the prefix "co"). Grothendieck proceeds to construct a *stratified combinatorics* of yin/yang pairs, having in a first level "polygamies" (a yang related to two yins, e.g., sun with moon and earth) and "polyanders" (a yin related to two yangs, e.g., earth with sun and sky) [**g1986** DU.7–8]. The first levels become then iterated along higher growing cycles. One of the major interests of (DU) is the use of Grothendieck's mathematical arsenal (sheaves, schemes, homologies, geometries, combinatorics) to provide an analysis of thought. In this way, *mathematical practice* orients our *common material practice*. In fact, many of the tasks assumed in (DU) refer to gluings, inversions, strata, breaks, thresholds: *(i)* variations, degrees, intensities, between warm (*yin*) and cold (*yang*) [**g1986** DU.16–17]; *(ii)* inversions, through subgroups, between continent and content, abstraction (*yang*) and concretion (*yin*) [**g1986** DU.19–20]; *(iii)* dialectics multiplicity/unity ("I feel myself as a multiple in search for unity") [**g1986** DU.23]; *(iv)* diagrams (hexagons, icosahedrons, trees) to capture tonalities yin/yang [**g1986** DU.28–32]; *(v)* dynamics between ideal (*yang*) and real (*yin*) [**g1986** DU.36–37]; *(vi)* zigzag iterations and homologies between unity/mystery (*yin*) and order/simplicity (*yang*) [**g1986** DU.37–40]; *(vii)* tension between discovery of structures (*yin*) and invention of languages (*yang*) [**g1986** DU.47–51]; and *(viii)* "accordion" between exterior (surface, light, *yang*) and interior (deepness, shadow, *yin*) [**g1986** DU.51–55], etc. In this way, there appear many implicit inversions and symmetries (Galois connections), and multiplications and unfoldings (Riemann ramifications). As an "Ahab after the White Whale" [**g1986** DU.66], Grothendieck immerses himself in the never-ending complexities of the world.

4.6 La Clef Des Songes (1987–1988)

La clef des songes, ou dialogue avec le Bon Dieu [**g1987**] studies the spiritual wanderings of the author, in an ever meticulous, extremely detailed manner, the Grothendieckian Way. After a precise register of his dreams in previous years (more than a "thousand" [**g1987** 6], Grothendieck's numbers always amaze), the author proceeds to a *dévissage* of the oniric realm, along extremely diverse strata and thresholds. The emergence of multiple types of spirituality (breath, faith, heart), intellectuality (eyes, language, reason), and sensibility (hands, passion, eros) offers a fascinating immersion in Grothendieck's mind. This leads him to the "revelation" of an archetype – a Dreamer, a Hand, an Eye, forms of the *Bon Dieu* – which is *projected* into his own dreams, writings, and visions. *Iterating* this self-reflexive mood, there emerges, naturally, a key (*clef*) to understand both Grothendieck's Self

and the World. (As in *The Doors over the Universe* (see above), it is enthralling to see how Grothendieck uses, beyond mathematics, the very central methodologies of his mathematical thought: *dévissage*, multiplication, projection, iteration, etc.) The central text of *La clef des songes* [**g1987**] (315 pages) is complemented with many notes (691 pages), which contain a long final development (circa 500 pages), *Les mutants*, where Grothendieck proposes a sort of genealogy of his spiritual Masters, and their influence on his own libertarian thought.

The manuscript is divided into six parts and many notes, summarized in what follows. *I. All the dreams are creation of the Dreamer* [**g1987** 1–46]: the dream and the knowledge of the self, discovery of the Dreamer, childhood, dreams proceed from the Dreamer, instants of truth, the key of the big dream, the voice of reason and the other voice, acts of knowledge and acts of faith, the spark and the flame, work and conception, the rhythm of creativity, cycles of Eros, emotion and thought. *II. God is the Dreamer* [**g1987** 47–79]: God is the Dreamer, lost knowledge, the incredible Good News, brothers in starvation, meeting the Dreamer, prohibited questions, reunion with God, only one Dreamer exists, the Creator and the Web, God is not defined nor proven, a new multiplication Table. *III. Voyage to Memphis (1): wandering* [**g1987** 80–136]: my parents, God's splendor, Rudi, a fall of wonders, God by sound reason, lost encounters, the calling, the turn, faith and mission, death, God speaks in low voice. *IV. Aspects of a mission (1): a freedom song* [**g1987** 137–182]: unthinkable convergence, testimony as a call for the discovery of one's self, Eros or power, Eye or sense, vision as testimony, soul and labor, man as a creator, creativity and repression, free creativity and interior work. *V. Aspects of a mission (2): spiritual knowledge* [**g1987** 183–268]: inclusive knowledge, beauty and contemplation, pain and shadows, the soul of things and the man without soul, the mentality of the flock, the use of Times, creativity and interior voice, creativity and listening, the tree of good and evil, archaic spirituality, law, ignorance, truth and creativity, resistance and suffering. *VI. Voyage to Memphis (2): seeds for a mission* [**g1987** 269–315]: acting, separation, beginning without end, hope, Tempest, the new man, surface and deepness, the call of silence, the messenger, crossing of the desert and revelation, seeds and harvest, tasks and gestation. *Notes* (notes numbered 1–57) [**g1987** N1-N176]: Eros, the One and the Infinite, wisdom of the body and action of God, the role of dreams, archetypes and God's manifestations, dream and free will, mystic experience and self-knowledge, miracles and reason, truth and knowledge, mathematics and imponderables, belief and faith, the boy and the mystic, my friend the "*Bon Dieu*," mission and creativity, Hell and Providence, eros and spirit, the great innovators, the creative boy, "unthinkable May 68," creativity and maturity, error and ignorance, doubts and security, work and desire. *The mutants* (notes numbered 58–145) [**g1987** N177-N691]: register and study of spiritual guides and freedom thinkers, Fujii Guruji, Gandhi, Walt Whitman, the mutants (1: spirit, justice, freedom), the place of Riemann, A. S. Neill, Edward Carpenter, Félix Carrasquer, the mutants (2: power, diversity, sex), Solvic (sic = Slovik), Steiner, Krishnamurti, the mutants (3: self-knowledge, reconciliation, crisis of civilization, hope), Darwin, Freud.

Through this list, one can see how Grothendieck is mainly concerned with *creativity*, and how the different layers of creativity *expand* from his own

experiences and dreams, towards a superior archetype (God), passing through many intermediate Masters (*mutants*: the visionary leaders of a "Great Mutation" needed for a redemption of mankind, a chronological list of Grothendieck's 18 *mutants* appears in [**g1987** N480-N482]). The *multiplicative richness* of Grothendieck's ideas covers history, phenomenology, metaphysics, psychoanalysis, sociology, religion, and mystic thought. As if it were a *universal sheaf* in action, Grothendieck looks for a common blowing, a unitary life, a universal harmonics ("global sections"), beyond the most particular concretions, blades of grass, daily dreams, sensible perceptions ("local sections"). *Content and form* are combined in a uniquely *smooth* state of grace in *La clef des songes* [**g1987**]: on one hand (content), the search for a common stem in the Tree of Life, found with passion in Whitman and Darwin, and reflected along Grothendieck's main mathematical unitary archetypes (nuclear spaces [**g1949–1953**], projective norms [**g1953c**], *K*-theory group [**g1957**], schemes [**g1959–1964**], toposes [**g1960–1969**], motives [**g1967**], anabelian varieties [**g1981**], derivators [**g1991**]); on the other hand (form), the development of a *free language*, disentangled from bonds and prejudices (types), and plastically open to "listen to things" (archetypes) which transcend language itself.

5 A Synthetic Account of Grothendieck's Work

Grothendieck's mathematical work shows a strong equilibrium between (1) high conceptualizations and (2) concrete examples. In the first trend, the use of Category Theory is ubiquitous; we will call *categorical reason* this tendency to the global and the general. In the second trend, the uses of complex variables, algebraic structures and topological forms pervade the work; we will call *mathematical heart* this support on the local and the particular. Grothendieck's work can then be understood as an *adjunction* between reason and heart, in Spanish, between *razón* and *corazón*. Since *corazón* = *co-razón*, we can sense a full *duality* ("co") between intelligibility and sensibility, something clearly stated in *Récoltes et semailles* and *La clef des songes*. The duality extends to a deep understanding of the polarities *étalé and étale* (all Grothendieck may be ciphered in an accent!), *relativity and universality*, *types and archetypes*.

5.1 Mathematical Heart and Categorical Reason

The *back-and-forth* between the particular and the universal, the concrete and the abstract, the typical and the archetypical, the Many and the One, the local and the global, the examples and the theories – paradigm of a *pendular mathematical practice* – pervades Grothendieck's work. We will call *mathematical heart* the environment of his local technical strengths (functional analysis, topology, complex variables, sheaves, co/homology, algebraic geometry, etc.), and we will call *categorical reason* the environment of his global conceptual visions (schemes, topos, motives, *stacks*, *n*-categories, derivators, etc.) Following a pendular movement

between "mathematical heart" and "categorical reason," a full dialectics ("co") is established between *co-razón* (= corazón = heart) and *razón* (= reason).

In Grothendieck's *First Period 1949–1957*, the mathematical heart appears in *topology* (A: topological vector spaces, B: sheaves, C: non-separation problems), *functional analysis* (D: Hilbert and Banach spaces, E: nuclear spaces, F: approximation problems), *complex variables* (G: Riemann-Roch, H: spaces of holomorphic functions, I: Riemann sphere), *abstract algebra* (J: tensor products, K: stability properties, L: co/homology). The twelve forces (A-L) support Grothendieck's originary intuitions and secure the *concrete richness* of his mathematics. A *calibration* of forces along the main productions of the decade ([**g1949–1953**], [**g1953c**], [**g1955–1956**], [**g1957**]) shows that themes (C) and (K) are ubiquitous, and that themes (B) and (J) reveal some of the favorite *universal* constructions of the young mathematician.

Along Grothendieck's *Second Period 1958–1970*, three new forces occur in the *mediation* between mathematical heart and categorical reason (X: schemes, Y: topos, Z: topos *étale* of a scheme). Emerging from the Edinburgh lecture [**g1958**], they propagate through the main IHES writings ([**g1961**], [**g1959–1964**], [**g1960–1969**]), converging finally in the standard conjectures [**g1968**]. A calibration of themes (A-L) and (X-Z) inside those texts shows how Grothendieck in this "communitary" period passes to work at high levels of abstraction ("categorical reason," X-Z), to the detriment of the initial concrete seeds ("mathematical heart," A-L) that fostered first his imagination.

Finally, Grothendieck's *Third Period 1981–1991* shows a strong return to classical themes at the heart of mathematics (α: *moduli* spaces of Riemann surfaces, β: absolute Galois group, δ: fundamental groups / groupoids, γ: homotopy types). A fascinating back-and-forth is constructed between the very concrete in arithmetic (anabelian varieties [**g1981**]) and the very abstract in homology and homotopy (derivators [**g1991**]), going through unexpected combinatorial mediations (*stacks* and *n*-categories [**g1983**], *dessins d'enfants* and tame topology [**g1984**]). In these years, a calibration of the themes (A-L), (X-Z), and (α-γ) shows how "corazón" and "razón" become tightly entangled, producing an extremely powerful integrative *co-reason* (= "co-razón").

The *continuity* of Grothendieck's thought becomes evident when one ponders his reflections on "gluing" *space-number*. In a *First Period*, *varieties of space* (topological vector spaces, spaces of holomorphic functions, Riemann surfaces) *resonate* with *varieties of number* (tensor products, rings, co/homologies), before becoming fully integrated at *two unification levels*, first as singular sheaves, then as plural sheaf categories. In this second level (*Second Period*), emerge (1) sheaf categories with *abelian fibers* (fibers are abelian groups, the case of *abelian categories*), (2) sheaf categories with *local fibers* (fibers are local rings, the case of *scheme categories*), (3) sheaf categories with *set-theoretic fibers* (fibers are sets, the case of *toposes*), and (4) sheaf categories with *arithmetic fibers* (fibers are finite and separable residuated fields, the case of *étale toposes*). In this last environment, the fine techniques of entangling space and number provide the adequate "rising sea" ("categorical reason") to solve Weil's conjectures ("mathematical heart"). On the other hand, those algebraic

topology or algebraic geometry forces become *inverted* in the *Third Period*, where the new constructs of topological algebra (fundamental algebraic group, anabelian varieties, Grothendieck-Teichmüller group, etc.) complement Grothendieck's deep explorations of the extremely complex and stratified *space-number* realm.

5.2 Étalé and étale

An *extreme synthesis* allows to condense a fair amount of Grothendieck's work in the *behavior of an accent*! In fact, the wide difference between the terms *étalé and étale* (very often confused, even between Grothendieck scholars) captures two of the main watersheds of Grothendieck's thought. On one side, (1) *étalé* summons the "*espace étalé*" of Cartan's school [**g1955–1956**], that is, a *sheaf* as an unfolded space. On the other side, (2) *étale* calls for the "*topologie étale*" of Grothendieck's school, that is, the smooth, folded category-theoretic topology used in the resolution of Weil's conjectures [**g1960–1969**]. The opposition is extreme: (1) the *étalé* alludes to multiplicity, ramification, unfolding of a given sheaf, while (2) *étale* alludes to unity, smoothness, folding in a category of schemes. The *pendular movement between the Many and the One* is double: in (1), over the particular (one sheaf), one studies the variation of topological sections, while in (2), over the general (multiple schemes in a category), one observes the stability of arithmetical fibers – (1) reveals the transit from the One to the Many (*étalé*) while (2) detects, inversely, the passage from the Many to the One (*étale*).

The *étalé* strategy (1) governs Grothendieck's world, traversed in all directions by sheaves. The main problem, understanding the *mixture space-number*, is explored through universal sheaf constructions (*K*-theory, topos), which explain the *types* of space and number as projections of sheaf-like *archetypes*. On the other hand, the *étale* vision (2) enters in harmonic conjugacy with the *flat or rising sea* (Victor Hugo's " *mer étale*"), (Grothendieck acknowledges that "in my work I am as yin, as sea and movement, as one can be" [**g1986** 3.595]. The " *étale* sea" appears in Victor Hugo's *Les travailleurs de la mer* (1865–1866): " *Le niveau uniforme du varech sur toutes les roches marquait la ligne de flottaison de la marée pleine et de la mer étale*," **Hugo1** p. 678.) where general categorical settings (abelian categories, topos, derivators) literally flood our understanding. The architectonic tensions between (1) *étalé* and (2) *étale* help to situate Grothendieck's major inventions. In the universal, abstract environment of the (1) *étalé*, live the main *strata and hierarchizations*, the staggered flats of the building: tensor norms in Banach spaces [**g1953c**], iterated sheaves [**g1959–1964**], Teichmüller's tower [**g1961**] [**g1981**], homotopy types and *n*-categories [**g1983**], etc. On the other side, in the universal, abstract environment of the (2) *étale*, live the main *coverings*, the high perspectives from the building's top: nuclear spaces [**g1949–1953**], abelian categories [**g1955–1956**], *K*-theory [**g1957**], toposes [**g1960–1969**], motives [**g1967**] [**g1968**], tame topology [**g1984**], derivators [**g1991**], etc.

Two strong varieties of *mathematical practice* are then combined in Grothendieck's work: (1) unfolding, unscrewing ("*dévisser*"), and towering (close

to a "mathematical heart"), complemented with (2) folding, screwing, and covering (closer to "categorical reason"). The *back-and-forth* methodology between (1) and (2) allows to explore a multitude of *apparently* wild and unlike situations, and to find *natural universal invariants* beyond the variable multitudes of mathematics and the World. A new *(1) differential* and *(2) integral calculus* is thus proposed at a very high conceptualization level.

5.3 Relativity and Universality

The detailed *practice* of "relative mathematics" is a permanent feature of Grothendieck's "doing." (We use the term "doing" ("hacer" in Spanish) in the sense of Javier de Lorenzo, who, since his *Introducción al estilo matemático* (1971), insisted in the importance of constructing a mathematical philosophy attentive to the advances of the discipline, and carefully oriented towards *mathematical practice*. See **Lorenzo1 Lorenzo2** De Lorenzo anticipated thus by 40 years (!) the present-day movement (fashion?) of the " *philosophy of mathematical practice.*" For a complete vision of De Lorenzo's work until the year 2000, see **Zal10**.) In fact, the *localization* and *variation* of the objects occur early in comma categories [**g1955–1956**], in local rings along coherent sheaves and in local projections of the *K*-theory group over (co)homology [**g1957**], or in local schemes over a given basis [**g1959–1964**]. These methods become then extended to any form of construction which may be deemed "Grothendieckian." *Relativity* constitutes one of the sine qua non forces of his thought. But on the other hand, its natural counterpart – to look for invariants beyond variation, universals beyond relativization, globals beyond localization – is what really defines his enterprise. His *systematic finding of archetypes beyond types* (see Sect. 5.4 below) distinguishes him from many previous great mathematicians.

The finding is not accidental and is due to the *systematic use of sheaves and categories* in Grothendieck's thought. Both an *epoch* (when sheaves and categories were emerging) and an exceptional *character* (vision, courage, solitude, discipline) were required to provide a deep new notion, a true revolution both in mathematics and philosophy: the ingenuous glimpse and the strenuous practice of the concept of a *relative universal*.

The notion immediately seems a contradiction in terms (how can something universal be relative and vice versa?), but it acquires a sense as simple as profound when one conjugates the dialectics *abstract-concrete* in Category Theory. The essential obstruction to overcome is to be able to imagine the idea of *the Universal without the Absolute*, something that can be obtained when universality is linked to a *practice of dynamical abstraction*. On one hand, *concrete categories* (classes of structured sets, e.g., groups, rings, ordered sets, topological spaces, differential varieties, etc.) provide very diverse distinctions, and capture the *relativity of mathematical practice*. But on the other hand, *abstract categories* (classes of morphisms with associative composition and identities) offer integral paths, and capture the *universality* of mathematical thought, thanks to simple and general definitions that can be provided through the extremely powerful quantifier "exists unique" (∃!). (For

example, an "initial object" 0 (defined by the property $\forall X \ \exists\ !\ 0 \to X$) is a relative universal in abstract categories, which incarnates in many ways in concrete categories: in the empty set 0/ in the category of sets, in the trivial group with one element $\{e\}$ in the category of groups, in the ring of integers $\mathbb{Z}$ in the category of (commutative unitary) rings, in a minimum *m* in the category associated to a partially ordered set, etc. On the other hand, 0 *does not* incarnate in the category of infinite sets (due to the infinitude, and thus non-unicity, of morphisms from ω, the only plausible candidate for an initial object). The *unifying structure* (A) of the abstract universal is thus *distributed* along the *variegated multiplicity* (B) of its very diverse concrete relativizations. We are here again in presence of a high conceptual *integral (A) and differential (B) calculus*. In a certain sense, our "blind eyes" (Tarkovsky) become then disposed to see: *beyond types emerge archetypes, beyond appearances we can grasp a "universal breath.").*

The *relative universals* are the *clef de voûte* of Grothendieck's cathedral. Thanks to them, a *cohesion* of multiple elements is obtained, and the cathedral's arches are well adjusted, without collapsing. The *topos* notion [**g1960–1969**] constitutes perhaps the richer relative universal of Grothendieck's opus. Its construction mixes many levels along the adjunctions between the pairs relativization/universalization and localization/globalization: *(i)* in an arbitrary category *C* with pullbacks, a Grothendieck topology *J* uses localization and variation techniques, giving way to a site (C, J); *(ii)* a sheaf on a site combines localizations over the base and a search for global sections in the unfolded (*étalé*) space; *(iii)* the collection of all sheaves on the site (Grothendieck topos) universalizes in a new unitary structure all possible types of relativizations. The result offers a generalization of space (topological space → site → topos), whose *relative universal* (topos) is extended well beyond the initial source (topological space). In the *ascending* injection to the universal, and, further, in the *descending* projection to the relative, many technical tools are invented (e.g., *étale* cohomology) which help to understand the very concrete (Weil's conjectures) thanks to the very abstract (topos of a scheme). In particular, in this example, the *conjunction of the étalé and étale visions* can be seen as a strong partial weaving between the universal (topological sheaf – *étalé* world) and the relative (arithmetical scheme – *étale* world).

5.4 Types and Archetypes

The *Tôhoku* [**g1955–1956**] introduced sheaves and categories into the landscape of "real" mathematics. (Along with **Corfield** we understand by "real" mathematics, the corpus of the hard-working mathematicians along their *mathematical practice*: combinatorics, number theory, abstract algebra, algebraic geometry, topology, complex variables, functional analysis, differential geometry, etc., well beyond just sets and logic (the reduced, impoverished, realm of analytical philosophy). Sheaves were invented in 1942 by Leray, and categories were invented in 1945 by Mac Lane and Eilenberg. Nevertheless, their actual use in "real" mathematics, as signaled by the very Mac Lane (see **Kromer2** p. 158), is due to Grothendieck.) Grothendieck's

contributions to Category Theory in this paper are impressive on their own (introduction of subobjects, adjoint functors, equivalences, representable functors, additive and abelian categories, generators, infinitary axioms), but the central points of the *Tôhoku* deal with two kinds of *archetypes related to mathematical practice*: (1) to prove that in an abelian category with a generator and a suitable infinitary axiom, any object ("type") can be embedded into an injective object ("archetype") and (2) to prove that the cohomology of a space, with coefficients in a sheaf ("types"), can be reconstructed as a projection of a formalism of derived functors ("archetypes"). In that way, "projective" (co)homology, one of the main mathematical investigations in the period 1895–1950, can be regarded as a seed of an even more fundamental theme: a theory of abstract derivators in suitable categories [**g1991**].

Grothendieck's *Tôhoku* strategy is very interesting in terms of the duality *abstraction-concretion*. First, categories abstract universal properties holding in the diversity of mathematical regions, through a series of *axioms*: associativity and identities (all categories), existence of an abelian group structure in the *Hom*-sets (additive categories, e.g., category of holomorphic fibered spaces over a Riemann surface), existence of kernels, cokernels, and adequate factorizations through them (abelian categories, e.g., category of sheaves with fibers abelian groups), etc. In this approach, the *axiomatic abstract definitions* have their expected *concrete models*. Second, in the abstract setting, that is in general categories which satisfy the axioms, not yet "reified" in concrete models, "archetypes" occur in a *natural way* (definitions and properties related to the quantifier "exists only" $\exists!$), and only afterwards they are projected into existential objects along concrete categories. Thus, abstract categories are "doubly archetyped" (*inside* categories, free objects appear; *outside* categories, free objects incarnate in apparently very different disguises), while concrete categories become just partial modelizations of general categorical transits. Third, in the abstract settings, many general theorems occur thanks to a *free machinery* which has escaped from the particularity of the concrete models.

Grothendieck's *La longue marche à travers la théorie de Galois* [**g1981**] sets a new research program, after his works of the First (1949–1957) and Second (1958–1970) Periods. His attention is now turned to "low-level" complexity objects, that is, surfaces in general and Riemann surfaces in particular, modular curves, complex towers, and combinatorial approximations to the absolute Galois group. As we have seen (Sect. 4.1 above), one of his main conjectures states that the anabelian varieties over $\mathbb{Q}$ are essentially the isomorphism classes of Riemann surfaces. In this way, an *archetypal* property (anabelianity) is expected to capture some of the main *types* of modern mathematical thought, the Riemann surfaces. On the other hand, *Pursuing stacks* [**g1983**] sets the stage for a profound connection between homotopy and homology, and a *hierarchy* of concepts, objects and techniques is explored through the many levels of homological and homotopical groups. In that sense, an n-stack can be understood as an n-truncated homotopy type, which in turn can be imagined as a $(n + 1)$-sheaf. The *iteration of types* gives rise to ∞-categories, where all information on n-morphisms (morphisms, functors, natural transformations, etc.) is piled-up. ∞-categories act then as *very large archetypes* which cover huge varieties

of models. Finally, *Les dérivateurs* [**g1991**] proposes several *axiomatic* treatments of the constructions first imagined in *Pursuing stacks*. Axioms are imposed on classes *W* of morphisms in *Cat*, to try to model some properties of weak equivalences in the category *Hot* of *CW*-complexes with homotopies between them. The program consists in trying to *elevate types in Hot to archetypes in Cat*. Axioms *free* the lower level constructions (say, in *Hot*), in order to get *smoothness* properties at higher levels (say, in *Cat*). In an *abstract, free, archetypal* environment, derivators capture some of the main *type constructions* of homotopy (coming from toposes and homotopy groups) and homology (coming from abelian categories and homology groups).

The *archetype/type dialectics* between abstract categorical constructions and structured, concrete models, considerably enriches the panorama of *mathematical practice*. The abstract and the concrete, the universal and the particular, categorical reason and mathematical heart, become all necessary to *nurture mathematical imagination*. Mathematics has to explore all possible worlds, beyond mere actuality, but, on the other hand, many of her greatest achievements occur when a general architecture illuminates an actual conjecture. The *back-and-forth between types and archetypes*, elevated to a method in Grothendieck's work, helps us to understand the irreducible complexity of mathematical thought.

Abstract

In these notes, *my* personal reflections on practice and working philosophy of mathematics are discussed. Some of the reviewed issues definitely have a philosophical sense, or at least flavor. The generality of some of them is suited to similar observations of recognized specialists open-handedly quoted.

1 Introduction

The article by Etnyre (2019) is concluded with the statement

> Good introductions can elevate the community's appreciation to your work and quite possibly you, so make sure to write great ones.

Not throwing even a shadow on this instructive article, one may (half)jokingly ask whether that specific text needs a great introduction. Pronouncing this, we come to one of the borders between mathematical and philosophical paradoxes. In the sense that such a border may appear anywhere, making one hesitate what side of the border is more attractive that very moment.

I am not going to deeply discuss purely philosophical paradigms and their reflections in mathematical ways of thinking in full, so to say, philosophical depth. Instead, I shall try to recall the cases and aspects of my practice as an acting researcher in pure mathematics which, in my opinion, were of general nature common to all humanity, and which I dare, justified or not completely, call philosophical. Recall Littlewood's (1957)

> I asked Prof. Wittgenstein was this not a profound philosophical joke, and he said it was.

On the other hand, it is probably a moment for the first reference to Persson (2021), where not only the one who is interviewed sounds, but the interviewer as well; in particular, the latter said:

> Popper failed really to consider mathematics seriously, probably because like most modern philosophers, and here I very much include Wittgenstein, he did not know much about mathematics and had certainly done no work in mathematics, which is a prerequisite for understanding mathematics.

Arguing neither against nor for this statement itself, I cherish hopes for having the mentioned prerequisite, which may allow me to catch certain appropriateness in a less familiar area. However, I would like to begin with taking a roundabout approach to the subject. There was a famous Russian poet (of Georgian-Armenian origin) Bulat Okudzhava. Some of his rhymes converted to very nice and popular songs. However, he also was a successful and very interesting Prosaist. A part of his novels went back to certain events of Russian nineteenth-century history. Once being interviewed in a written form about how a writer like him works on historical issues, he preferred to present a metaphorical song instead of just writing down more or less standard words. Here is this song in my equi-rhythmical translation (possible to be sang – contrary to a non-rhythmical word for word translation as in Okudzhava [1982]), entitled

I am writing an historical novel
In a bottle, darkly brown,
once full of imported beer,
of a rose the scarlet crown

bloomed with soft and proud cheer.
I was writing of the past,
slowly letting it unravel;
from the first page to the last
one was my uncertain travel.
Refrain:
One's bequeathing as it's easing.
It is easing as one's breathing.
As one's breathing one's bequeathing,
never bothering to please.
This for nature is a withness.
What for — is not our business,
why — is not for us to quiz.
Distances were colored blue,
pure fiction was in plenty,
and from my own fate I drew,
any thread if it was handy.
Helped my heroes' ways to weave,
on the history inquired,
and an officer retired
was sometimes my make-believe.
Refrain:
Fiction is not a deceit;
nor a finish is the matter.
Let me keep on writing it
to the very final letter.
And before the rose-leaves die,
which inside the bottle grow,
let me cry the words that lie
stashed away since long ago.
Refrain:

I am aware of the translation by Evgenia Sarkisyants, some of her phrasing inevitably coincide with mine, but mainly I tried to have the refrain first of all and some other pieces as I see it, either for better (closer to the source) meaning, for better rhythm, or just to my taste. And, of course, keeping in mind the present topic and how this illustration fits it. Back to our subject, mathematical work can be described similarly, in a sense. In fact, once I tried to parody Okudzhava's rhymes as **I am writing a mathematical paper,** but let us skip too much poetry and return to mathematics and philosophy.

2 What Is This About?

However, it is not that easy to switch to purely mathematical impressions because of the social side of mathematical activity. The point is that it is impossible to conceal oneself in the ebony tower, and very often a mathematician faces the need to explain to plain people (of course, here the people who lack certain mathematical education are meant as plain) what such a person is doing (and even gets money for). Unfortunately, an immense majority identify mathematics with numbers and arithmetic calculations (something like accountant) or figures and measurements (say,

land surveyor). No wonder that many people identify mathematicians and computer programmers despite that this is by no means the case and interesting exceptions are just interesting exceptions. On the other hand, getting acquainted, many people immediately start telling how good or bad they are (were) in mathematics.

2.1 Mathematics Versus Music

Some time ago, my former tennis partner, a musician, firmly told me that music is something creative, contrary to mathematics, which is a dry routine work. Laying aside the fact that he had no idea what mathematics is (back to the previous paragraph), that meaningless discussion had brought my attention, and not for the first time, to possible relations between mathematics and music. I am sure that far more advanced minds than mine have been thought on these interrelations. However, my feeling is that only mathematicians have been troubled by such reflections. Well, many mathematicians are fond of music; some of them play music on a professional level. For example, Per Enflo and Louis Rowen used to give concerts, playing piano and violoncello, respectively. Closer to our topic, it seems that research in pure mathematics can justifiably be compared with composing music. Of course, the means are different as well as the ways of perception; however, some similarities are striking. Does a theorem (a theorem is an intentional simplification; the question may concern a new approach, a new notion, or a new theory) exist "somewhere" unless formulated, proved, and presented (published) by a mathematician? By the way, these steps may sometimes be fulfilled (or a more musical word – performed) by different people or groups. In fact, involved mathematicians evoke from "somewhere" a "melody," fixing it by means of "notes" – notations and words. The observation that the number of notes and other musical signs is essentially smaller than the number of notions and notations should not be a serious objection. After all, there is a diversity of musical instruments, performers, etc. Or, which is simpler and maybe more correct, music can be compared with a specific area of mathematics rather than with mathematics as a whole. Combinatorics, for instance. Sound extracted should not be considered as a determining factor. Indeed, there is a notion of inner hearing of music. Or, there are "professional" music lovers who come to a concert and listen to a music with the score in hands. Anticipating possible objections, let us mention that both manifestations can be emotional.

Looking at the matter the other way round, recall that mathematics is frequently identified with language. To my taste, this is almost a perfect definition (at least, to some extent). Maybe it is more precise to say that being a language for various phenomena, mathematics is imprescriptible from the language itself in which the results, proofs, and conclusions are given. But music is not less frequently called a language of soul, feelings, or the like. A different feature of music is a need of its performance, with masterly performance as a characteristic of this phenomenon. However, mathematicians are very often on the stage, even not mentioning their teaching activity. As V.K. Beloshapka wrote in his reminiscences about Vitushkin (posted on https://arzamas.academy/mag/1051-math?fbclid=IwAR04xUpED2FSKfnEOkCkyz7ZZPFV9PWhFgtpK3P8SkzwvvhR13PRuzo8rrQ):

> Life of a mathematician takes its shape as life of seminars. It is something like concerts, where mathematicians gather and tells something to each other.

And there are coryphaei, masters, and apprentices in this activity. We shall return to this issue in the sequel.

2.2 Mathematics Versus Fiction

One more activity which, at a glance, seems having nothing in common with mathematics is fiction. In fact, this is sometimes exactly the same process, or at least the published result of the corresponding process is, concerning maybe crime fiction or detective novels more precisely. Let us analyze this assertion. There is something intriguing and hidden, it is searched all the time, with certain clues found, real or false, and the proof of the "main result" as an apotheosis. One may object that the audience is very different, especially in amount. That's obviously correct, and the reason is similarly obvious: special terms and language in general as well as much or less symbolics. However, special language and symbolics, important and sometimes decisive, can be found in modern fiction. Here are a couple of examples immediately coming to my mind. In the famous "Jurassic Park" by Michael Crichton, the action could not move further without reading and understanding a computer print. In fact, not only the hero must understand the printing but the reader too. In the not less famous "The Flanders Panel" by Arturo Prez-Reverte, the reader must understand chess, including chess notation. Clearly, most of the readers do not understand these issues, just skip them and, to be honest, get the main pleasure in killing the time. The main objection might be that such readers just enjoy pleasant and talented reading. However, along with talented authors, there is an immense of a middle or low level. They more or less successfully publish their writings and find their gratifying readers. But the same is among mathematicians: there are very talented authors (in the sense of writing; not all the authors of great results are such) and many more not great in writing. Therefore, the main difference is the specially prepared audience, but the same is with the mentioned listeners of music with the score or spectators of the so-called "elite" movies.

To be precise, what I have compared with fiction concerned a plot, and research papers were mostly understood. But mathematicians do write books, and quite many authors write pretty many books. The process is discussed, and various recommendations on this subject are given in Silverman (2019). A wish to make one's book a delicious and popular reading, with many demanded copies, is apparently the same for any author, regardless of the topic. To mention a recent successful example, Iosevich (2007) is a very impressive one. However, a personal experience and conclusions should be mentioned in order to be complete and honest. Already publishing three books and having one more in process can be considered as a material for possible generalizations. First of all, a strong wish to present a readable text claims for certain demands, self-demands. There must be a plot, a scenario, and a thread going through the whole text. There must be something beyond a collection of facts and results. My

first book Iosevich and Liflyand (2014) was an attempt to overview the results where the Fourier transform can be characterized by its asymptotic behavior. The second one, Liflyand (2019), appeared when the separated facts on the behavior of the Fourier transform of a function of bounded variation seemed to be united in a comprehensive theory. In other words, when the puzzle was almost completed. The third book, Liflyand (2021), is more a textbook than a research monograph. The idea was to extend the first chapter of Liflyand (2019), given as a necessary brief toolkit to the further material, to a sort of a textbook on harmonic analysis on the real line in full value. In each of these cases, the goal was to present the author's view of a certain topic in a readable way and more or less full generality. In short, each time this is a comprehension of the topic as a whole, with slight abuse of terminology a philosophical comprehension. On the other hand, moving within the classification of mathematicians as theory builders and problem solvers, the one who writes a monograph (not a textbook) switches from the latter to the former, in a sense.

3 Individual Work and Joint Work

The problem of the general and the individual is considered as one of the fundamental problems of philosophy and psychology. I believe that in mathematics, it expresses itself in research. Except a very clear individual manner of thinking on a mathematical problem, there are different models of collaboration. Luckily, the publications authored by 20 or 40 names are really marginal in mathematics and mainly are not of research nature if appear. Two and three authors are the most typical collaborative groups in mathematics; by the way, the Research in Pairs program in Oberwolfach assume from two to four collaborators. I do have an experience with three other coauthors, but it is unique and probably not enough for conclusions. So, let us discuss the events where two or three people struggle with a problem or write a survey text.

The most natural and the most fruitful collaboration seems to be the one of two colleagues. Very often such collaborators are the friends possessing experience in discussing the problems of mutual interest or even in joint work on other problems. On the other hand, very often an accidental collaboration becomes a basis for a long-standing friendship. In each of the cases, this new or renewed collaboration starts with mutual interest in a certain problem and, what is maybe more beneficial, with understanding that they have an idea or ideas and tools for a successful attack on the problem. In fact, in most cases there is no much difference if three people participate. In many situation, two of them could be characterized as a pair described above, while the reasons appeared for the third one to join them are the same reasons as those above for two. To be honest, sometimes such an activity of two or three (or more) is accidental, valid for one occasion only, and does not result in further collaboration. It sometimes turns out that the participants or some of them are incompatible, sometimes they just fail to find more problems and tools of really mutual interest. In all of these situations, successful or not, the issues of psychology or social philosophy turn out to be more important than those professional.

Last but not least, what collaboration may protect better than individual work is the novelty. The possibility of working on something already discovered might be very bothering. Similarly, there exists an option on elaborating something formally new but trivial in essence. This is well illustrated in the underestimated book Lem (2013) (it was translated into English only in 2013, decades after its appearance):

> Not everything constitutes scientific truth: an ocean of insignificant variables is larger than an ocean of stupidity – and this is already saying something.

Let me describe a case in my practice, where some concrete mathematics is in order. There is a well-known theorem of Hardy and Littlewood. It asserts that if both a periodic function and its conjugate are of bounded variation, then the Fourier series of each converges absolutely. One day a desire appeared to extend this statement to the non-periodic case. However, the start of this project had been postponed for a distant period. This time was spent in asking far more educated colleagues and looking through the literature for a possible existence of such an extension. There was a feeling of how it can be that nobody had tried it. Finally, the work was done with one of my colleagues and published in Liflyand and Stadtmüller (2013). And only then, in a while I was terrified finding a non-periodic extension in a recognized paper, Hille and Tamarkin (1935), which I looked through many times. Luckily, that story had a happy end: in that paper a quite restrictive additional condition was assumed not needed in our work and in general. The point was that we benefited from using the modified Hilbert transform not known to Hille and Tamarkin (1935). Hence, the only negative feature of Liflyand and Stadtmüller (2013) turned out to be not referring to Hille and Tamarkin (1935); the result however remained safely new. In a different occasion, coming to a conference, I planned to devote free time to a particular problem in harmonic analysis. However, already during the flight, I started thinking on a problem of combinatorial nature and eventually spent all the week in cracking some relevant obstacles. Flying back, I already had a well-composed theory, with results and proof. Luckily, I believed in the novelty of my speculations for not a single moment. Indeed, in a while one of my more experienced and educated colleagues enlightened me in the regard that what I "discovered" were the Stirling numbers (of the second kind). One can read about them in every book on combinatorics. However, I was delighted in the coincidence of my calculations with the corresponding piece of the general theory. Unfortunately, similar troubles used to happen from time to time, and nobody knows when such an event may occur in the future.

The fears of false novelty or trivial novelty are already mentioned. There is one more fear, the one of possible mistakes. The whole third chapter of Littlewood (1957) is devoted to a collection of various misunderstandings and misprints, but mostly of logical or linguistic nature. However, in §13 of this chapter a misprint of wrong sign resulted in the use and application of a wrong statement. This is closer to what is meant as a fear: the use of a false argument, omission of an argument, and the like.

Back to the problem of the general and the individual, probably the most common form of constant generality is seminars. It has already been mentioned in

Beloshapka's saying above. In fact, the complete citation is continued with a funny statement.

> Mathematics is probably transmitted through airborne droplets. Some possess immunity from it since their school-days, while few others are ailing – a sort of a limited epidemics.

There are two roles on seminars that everybody plays, frequently or rarely: the speaker and the listener. I have also experienced a third role of the long-standing organizer of a seminar. It seems that having a continuously working and constantly attended seminar is completely beneficial. Sharing one's own results with colleagues and learning from them new facts and approaches – what can be more fruitful for a mathematician in addition to the main issue of searching new results and solving challenging problems. As of possible mistakes, a good and erudite audience sometimes saves the speaker from certain (not all, alas) mistakes in time, prior to the publication. Of course, there are enough people who avoid constantly playing the mentioned roles. Well, social philosophy will apparently cluster them as a group enjoying equal rights with those mentioned before.

4 Applications: pro et contra

Einstein's observation (Bloch 1995, p. 243)

> Inasmuch as the mathematical theorems are related to reality, they are not sure; inasmuch as they are sure, they are not related to reality.

adds fire to this everlasting contradiction. One moment in my personal experience seems to be very instructive. It concerns the work which finally resulted in Liflyand and Trebels (1998). Here more concrete mathematics comes into play. Considered are radial functions in the n-dimensional Euclidean spaces, that is, the functions depending on the Euclidean norm of the variables. As is well known, their Fourier transform is also radial and can be expressed in a more sophisticated form than the standard Fourier transform via the Bessel functions. The problem is under what conditions on functions (or for what classes of radial functions) the multidimensional Fourier transform can be expressed asymptotically in such a way that the leading term is a purely one-dimensional Fourier transform of a function related to the given one. (By the way, a priori such results have numerous obvious applications in the way that many important one-dimensional results can "for free" be extended to the radial case.) One day my collaborator claimed for examples concerning a certain assertion. I would be happy to construct some but failed. My statement instead was that the Fourier transform is a very important and recognized object that any new result on it sounds by itself and does not need immediate illustration. After a few days of this conflict, none of us was able to deliver an example, and my collaborator had to agree with me (well, the circumstances forced him to do so). This particular situation has, in my opinion, a philosophical side. Not only in the sense of

interrelations of theory and practice. There is one more feature of new results which may justify them regardless of their immediate applicability. What is meant is the aesthetical aspect, of course, a specific mathematical aesthetics is understood. It cannot substitute for the proof but can be a landmark on the road to a possible proof or just to an interest or lack of that in the issue in question. Along with the place of the considered problem, the aesthetical side may give an a priori belief that certain applications will appear in due time.

This is well expressed in (Stewart 1995):

> Mathematics is a harmonious whole: except that the harmony is incomplete, because there are always gaps in our knowledge and vaguely understood hints of new interrelations. In this sense, an application of any mathematics from this central body is an application of the whole. If you insist that mathematics justify its existence by providing applications, then an application of one part will justify the whole. We do not cut off a violinist's feet just because he doesn't use them in playing the violin: in the same way we ought not to dismiss group theory just because it won't pay the rent.

(A remark aside: Does pay as far as I know!)

There is an additional point in this controversial issue: whether a person has a right to do whatever one is interested in, not thinking much on possible applications, or in a wider sense, on possible relations with practice and other areas? Of course, I mean a professional side of this arbitrariness, not a discussion in Dostoyevsky's style. I believe that these problems are related to such social issues as the existence of middle class contrary to the elite group, its weight, and role.

5 Concluding Remarks

Of course, many of the above analogs and comparisons, like those with music and fiction, are relative and serve more for dialogs with strangers. All these similarities and differences are disputable, with numerous pro et contra in each of them. Last but not least, one may ask where philosophy is here. The answer is: everywhere. Even pondering over these problems makes a serious difference and becomes a decisive step toward philosophical reflection. This as well as possible getting down to philosophy in mathematics can be well illustrated by Hersh's explanation in Persson (2021):

> I had gotten hooked on philosophy of math when I volunteered to teach a course that was listed in my department's catalogue as Foundations of Mathematics. No one had ever offered it, before or since. I expected to just do my usual thing when teaching a subject I know nothing about – pick the best textbook I can find, and stay a chapter ahead of the students. Not this time! All the textbooks I found simply presented three viewpoints – logicist, intuitionist, and formalist, and left it plain that all three were inadequate, unsatisfactory, failures. End of course!! As a teacher I found that situation deeply unacceptable. After all, I ought to at least know what was my own personal philosophy of math. But I found that I simply didn't know. So I had to find out where I stood, what was my understanding of the nature of the subject to which I devoted my life. On my part, The Mathematical Experience

> was a stage in my struggle to figure out my own answers. Then also, my career as a mathematician had given me a special kind of experience, which had not been much exploited in a literary way. I was very lucky to find Phil Davis as a collaborator. We never dreamed that the book would make such a splash. It was far short of our original intentions, but we were desperate and submitted what we had. It seemed only a rag-bag at the time, but nevertheless, it worked, after all!

Hoping that the presented notes will also work to a certain extent and mentioning that the topic is inexhaustible, both theoretically and on the level of individual experience, what can be recommended for further reading and thinking (in addition to one's main research work) is to look through the publications that attracted my attention in general and while working on these notes, Bochner (1966), Gromov (2018), Manin (2007), Shapiro (2005), and Stewart (1995), to mention some. And, of course, numerous Hersh's books and articles. I would also like to mention Wigderson (2019): it is not less philosophical than "technological." For sure, these by no means will be boring.

Abstract

Although not typically thought of as useful or relevant to social theory, this chapter proposes that mathematical ideas and tools can be used to generate new spatial imaginaries about the world, that is, new ways of imaging the relations that pertain to existence (who we are, as people, collectives, and societies) and to experience. I will describe some existing spatial imaginaries (for example: that the world is made of distinct parts) and draw on gender and race scholars to show how they function to maintain various forms of oppression. I also consider several examples of mathematical ideas and tools that trouble or transform normative relations in order to produce new ones – in particular, new spatial imaginaries for disrupting systems of oppression.

1 Introduction

In his writing, Martinique poet and philosopher Édouard Glissant insists that in order to reckon with the consequences of colonialism, including the history of violence it has produced, we need new spatial imaginaries – indeed, he calls for an "insurrection of the imaginary faculties" (Glissant 2005, pp. 24–25). His own archipelagic philosophy, which draws inspiration from his Caribbean sensibility, strives to do just this. Whereas continental thought provides a kind of bird's eye view of the world "as a bloc, taken wholesale, all-at-once, as a sort of imposing synthesis" (2009, p. 45) that is fixed and static, archipelagic thought is multiple (one sees many islands) and relational (the islands are entangled in the spread of land and the movement of sea), as well as local "we know the rivers' rocks, without a doubt even the smallest ones" (ibid.). A spatial imaginary is not so much about imagination, and more a way of seeing/thinking/feeling life or, as Drabinski (2010) writes, "that precarious aesthetic sphere of knowing and being that structures a relation to the world" (p. 304). Spatial imaginaries that tend to the particular, the moving, the unpredictable, to the relational, the multiple, the compositional, are tending away from the abstract, fixed, and the defined and divided. Since many of the dynamics of oppression involve enclosing people into separate (abstract) categories and defining them in various modes of (fixed) "otherness," often in (neatly divided) hierarchies, it is evident that images of existence are significantly at play in systems of oppression.

I am interested in the possibility that mathematics can be a generative source for producing new spatial imaginaries, particularly ones that differ from more normative spatial imaginaries – those, like continent thinking, that guide everyday assumptions about who we are and how we relate to each other. This may seem counterintuitive, especially for those who see mathematics as being far removed from human concerns, and who further see it as a rigid, deductive, rule-based discipline that lacks the kind of poetic or speculative creativity that might disrupt existing spatial imaginaries (and the logics they entail). Indeed, few people would assume that the hermetic, symbolic, and predictive world of mathematics could have much to say about the messy, affective social world.[1] But those who do mathematics, I think, know that it is a playground for creating new objects and relations, even if they very rarely have anything to do with the physical or social world, and it is precisely these new

[1] Those who have studied the role of mathematics in the history of thought know that mathematical ideas can be both precursors to and accelerators of ways of worlding that reverberate in philosophy, architecture, art, literature, science, and so on.

objects and relations – which potentially exceed everyday experience – that I'm interested in.

In this chapter, I explore the different ways in which mathematics can participate in the creating of new spatial imaginaries. I won't argue that doing so absolves it from the many negative effects of mathematics in our society (as a gatekeeping discipline that serves to exclude many people from leading good lives, while causing extraordinary anxiety for a silent majority [see Ernest 2020]). Nor do I argue that it's the only way of producing new spatial imaginaries – as Glissant shows, so can poetry and philosophy. But there is something about mathematics – its freedom from the exigencies of the visible, physical world – that I believe makes it a particularly generative source for troubling normative relations and logics. We can use mathematics to imagine our worlds differently – not just as a model of how things *are*, but as a speculative apparatus for producing *new ways of being and becoming*.

In the sections that follow, I document several ways in which mathematics has already been used to produce new spatial imaginaries. I'm particularly interested in ones that disrupt some of the spatial imaginaries that have served to oppress, and which dominate capitalist, extractive, and colonial systems. A spatial imaginary structures ways of seeing/thinking/feeling relations that use some kind of spatial logic. When Deleuze and Guattari implore us to move away from tree-thinking to rhizomes, they are pointing to a spatial imaginary (the tree) that sets out relations as foundational (the trunk), teleological (toward a fixed goal), and hierarchical (always progressing). In contrast, rhizomes are decentralized, nonhierarchical, and non-teleological. Tree-thinking might lead us to assume that societies have evolved over time to be increasingly civilized, moving toward a goal of liberty and equality, based on a foundation of reason, laws, and sensibilities. But, as Graeber and Wengrow (2021) show quite convincingly, this narrative does not match current archeological evidence.

When Latour (2009) asks us to think about space as something that is made through relations rather than something that contains relations, he too is changing the spatial logic because space becomes inextricable from action, time, and objects, rather than being a container for them. Container thinking is a natural extension of set theory, where the only purpose of a set is to circumscribe its elements. What if the insertion of a new element somehow fundamentally changed the set so that it didn't just lasso around its members, but plugged back into a part of itself – so that the set was not just a whole, but a mechanism for making new parts? Space-as-container imagines a province or a state as being a collection of cities or regions and rivers, mountains, forests, people, animals, etc. There is a flatness to the collection, which merely encloses everything that can be named. But space-as-relation allows actual and imaginary space to be made – new spaces created by stories or events, spaces that cannot be captured by longitudinal and latitudinal coordinates. If my language is ripe with mathematics (sets, coordinates, topology, etc.), it is because these ideas – and the spatial relations they invoke – are not confined to the discipline of mathematics.

I am identifying as normative those ways of thinking that are really only named as such by those who want to imagine a different world, a world in which capitalist,

racial, and colonial forms of oppression are not as rampant. There are of course many other nonnormative spatial imaginaries that could be considered – and reading science fiction provides many examples, some of which might actually be more relevant or helpful than we now realize. But in this chapter, I draw primarily on research that offers critiques of persistent normative ways of thinking and, in particular, grapples with the oppressive structure of current ways of imagining the world as being made up of separable entities that operate in determinate and sequential ways.

Before turning to the examples, I take a short detour into the broader question of how mathematics figures into a history of thought in order to point to instances where the imagining in mathematics has already transformed the world.

2 Mathematics in the History of Thought

> I will not go so far as to say that the construct of history of thought without profound study of mathematical ideas of successive epochs is like omitting Hamlet from the play that is named after him. That would be claiming too much. But it is certainly analogous to cutting out the part of Ophelia. The simile is singularly exact. For Ophelia is quite essential to the play, she is charming—and a little mad. (Whitehead 1929, p. 31)

In his essay entitled *Mathematics and the Good*, the mathematician and philosopher Alfred North Whitehead (1941) undertakes the kind of study of the mathematical ideas of successive epochs mentioned in the quote above, ultimately arguing that mathematics is uniquely situated to attune us to the good because it forces us to reckon with the contingency of knowledge (and its relation to assumptions). While being a claim that one could agree with in principle, it is quite evident that current school mathematical practices likely do just the opposite, and that most people end up thinking that mathematics is about certainty more than contingency. But Whitehead's essay pays little attention to how mathematical ideas can provoke new ways of thinking. This is interesting, given that he himself used mathematics to work out a new set of relations that was better suited to this process ontology, which I will return to in the next section.

If we stick to the mathematics ideas that played a part in the history of thought, then Everdell's argument in his book *The First Moderns*, that the mathematical work around the time of Cantor, Dedekind, and Frege, particularly in relation to the question of "what is a number?," heralded – not on its own, but in a significant way – the late nineteenth-century cultural shift toward modernism.[2] Everdell locates the shift both in the turn toward rigour – exemplified in Frege's axiomatic approach

[2] Everdell is mainly interested in what it is that characterizes the twentieth century, to which he affixes the term "modernity." His list of characteristics of modernity though do not necessarily coincide with the way that modernism has been defined in relation to postmodernism. For my purposes, the actual tags and characteristics are less important than the fact that mathematics is part of the story.

to number – and in the turn to the digital, which can be seen in Dedekind's definition of the continuous through the discrete (the Dedekind cut). In fact, mathematics was just catching up with the positivist turn that had already taken hold in the sciences, one in which objectivity prevailed. In the words of Frege (1984):

> I understand objective to mean what is independent of our sensation, intuition and imagination, and of all construction of mental pictures out of memories of earlier sensations, but not what is independent of the reason, for what is independent of the reason? To answer that would be as much as [...] to wash the fur without wetting it. (p. 43)

Everdell (1998) writes: "Modernism began with mathematics, in a pattern closely resembling the way another revolution in thought had begun 250 years before with the profound mathematical meditations of Descartes" (pp. 351–352). What is interesting is the spatial imaginaries involved in the list of features of modernism that Everdell uses, spatial imaginaries that are still dominant today, including the idea of the discrete.

For Steingart (2023), if Frege's work marks a pivotal point in Modernism, it is the turn to axiomatics (or "high modernism") in the 1950s that entrains a whole new way of seeing the world, not only in sciences, but also in the social sciences. Following in the footsteps of mathematics, complex situations could be reimagined as being governed by a small number of axioms, which could be chosen so as to generate a complex phenomenon, not only in mathematics, but also in economics, psychology, and sociology. Even better was the promise that these mathematical systems would be fundamentally apolitical, working as sorts of creative abstractions that were blind to ethical considerations. This axiomatic use of mathematics, which is reductionist and abstract, does indeed entail certain assumptions about how the world is. It is the kind of thinking that is at play in Birkhoff's equation for measuring the aesthetic value of a certain object (the aesthetic measure, $M = O/C$, where O is order, and C is complexity). It reduces the aesthetic experience to a small number of variables that can then be used to produce a numerical quantity that appears to be "independent of reason," to use Frege's parlance.

Before leaving Everdell, it is worth noting that his history of thought takes the ideas and work of Cantor, Dedekind, and Frege to be of the same kind as that of artists, psychoanalysts, poets, architects, and dancers, in terms of contributing to epochal changes, which would have pleased Whitehead. But the ideas of Cantor, Dedekind, and Frege – thrilling as they are/were within mathematics – were more or less following a broader societal trend, though perhaps the perfect embodiment of those trends, thereby allowing mathematics to become a kind of model of (modernist) reason itself. This would not have pleased Whitehead.

Like most histories of thought, however, Everdell's is hopelessly linear. Discretization happened before and will happen again; other mathematical ideas were introduced in the twentieth century that were decidedly more about the continuous than the discrete. Indeed, there are also histories of "minor mathematics," which I will discuss in the next section, that interrupt the narrative of twentieth-century modernism. Nevertheless, more recently, it is physics rather than

mathematics that has provided the more potent new spatial imaginaries for the social sciences and humanities, through the work of feminist philosopher and physicist Karen Barad (2007). Their reading of the interpretations of Niels Bohr, along with the poststructuralist writings of Jacques Derrida, show how quantum concepts such as indeterminacy, entanglement, and nonlocality can give rise to fundamentally new ways of thinking about agency, causality, and time. The uses of quantum physics in the social sciences are many decades old, and have hitherto been mobilized as metaphors (perhaps sometimes fanciful), but Barad's work figures the quantum as an ontological reading of the world and, relevant to my interests, as an ethico-onto-epistemology. The new spatial imaginaries abound. Instead of positing two objects (people and things) as discrete entities and then investigating how they relate, Barad begins with the relation as the ontological primitive. Using graph theory imagery: Instead of two points, which can then be related (and studied for their individual agencies, for example), Barad posits a line, which is the relation, and which therefore is agential. A simple reorientation can have massive consequences for the social sciences: Instead of isolating the bully as the agential force that causes harm, for example, Zabrodska et al. (2011) locate the agency in the network of relations that produce bullying. Similarly, in mathematics education research, instead of positing the student and the tool as two distinct nodes in which the tool is a mediator to mathematical meaning, de Freitas and Sinclair (2014) study what mathematics the student-tool does (instead of what mathematics the students do with the tool or how do tool mediates certain mathematical concepts).

I bring up quantum physics for two reasons. First, it illustrates well what I mean by the production of new spatial imaginaries that are counterintuitive to normative ways of seeing/thinking/feeling the world. And second, Barad's use of quantum physics does not remain at the level of a metaphor, or even a model, and instead aims to rethink philosophical concepts such as ontology, epistemology, and ethics. A metaphor sets up a mapping between two things and it works because they are actually different. A spatial imaginary is more like a verb – it is the knowing and becoming of the world.

3 Mathematics as Charming and Mad

I pick up on Whitehead's description of Ophelia, as charming and mad, as it resonates with the mathematical ideas and practices that Deleuze and Guattari chose to mobilize in their own conceptualizing of political relationships. Indeed, they drew on the paradoxical, the temporal, and the problematic – sometimes unearthing and other times intensifying dangerous ideas or hidden practices. They contrasted the state-sanctioned mathematics, which silences and demotes unwieldy ideas and replaces them with rigor and axiomatics, with the nomadic or minor mathematics such as "becoming, heterogeneity, infinitesimal, passage to the limit, [and] continuous variation" (Deleuze and Guattari 1987, p. 363). Charming and mad, indeed.

Minor mathematics has obvious relevance in the production of new spatial imaginaries, if only because it often expresses the intuitive, eventful indeterminates that state mathematics attempts to control, and therefore forms of relating that might not be as rigorously defined or categorical or static. Of course, what is minor changes over time and, in fact, usually becomes major (or state) mathematics, as in the case of calculus, infinitesimals, and continuity. Indeed, while the infinitesimals were banned by Jesuits in the seventeenth century, though used surreptitiously by many, they became part of state mathematics through the work of Abraham Robinson. The radical and paradoxical nature of these new numbers, as Deleuze and Guattari worked with them, which had given rise to new, fertile ways of calculating, were eventually tamed (at the state level) – however, as they figure in mathematical practice, as they are sensed and transformed, their paradoxical nature never completely disappears.[3] But Deleuze and Guattari also turned to other mathematical concepts such as number and measurement and fractals. They drew particularly on topology (and associated concepts such as manifolds and singularities) as they reworked their political ontologies towards rhizomatic thinking.

In this section, I will discuss five different spatial imaginaries in which mathematics features significantly, and which generate relations that have sociopolitical import in that they deal with knowledge about existence and events. As Ferreira da Silva (2023) writes,[4] normative ontoepistemological (as well as judicial and economic) assumptions feature the following: *separateness*: that what can be known must be distinguishable from everything else (so, spatially separate, like points on a grid); *determinacy*: that knowing involves understanding the causes of observable effects (so, phenomena can be categorized into grids or tables); and *sequentiality*: that existents and events can be separated into discrete temporal units having positions in a sequence or plot points on a line, and often associated with images of progress (development of Homo sapiens from apes, of adults from children, and of civilized societies from primitive ones) (see also Mikulan and Sinclair 2023). Evidently there are spatial and temporal imaginaries at work here.[5]

The first example (*identity and*[6] *difference*), which draws on Deleuze and Guattari's work, concerns both separateness and sequentiality, where the new spatial

[3] We might even say that in all state mathematics, there is minor mathematics to be found, or rather excavated (see de Freitas and Sinclair [2022] for an example of this in relation to measurement).

[4] Ferreira da Silva is primarily concerned with Black racism and its ongoing relation to capitalism. However, as part of her project, she rereads post-enlightenment philosophy to uncover the "images of existence" that they instilled and promoted. Her own reliance on imagery (and diagrams) is part of what makes her analyses and philosophical insights so unique and persuasive. In addition, as the reader will see later in this section, she draws on mathematics in quite specific ways to produce new spatial imaginaries (while also naming the various ways in which mathematics is also co-involved in post-enlightenment thought).

[5] Importantly, for Ferreira da Silva, these three procedures of separateness, determinacy, and sequentiality (which are wrapped up in Blackness as cause and effect at the same time) operate as necessity.

[6] In order to avoid binaries, negations, and sequentiality, I am using "and" here in lieu of "or," or of the hierarchical connotation of "from. . . to. . .."

imaginary attempts to move from a philosophy of identity to a philosophy of difference – and which is interesting mathematically for the ways in which identity is taken as axiomatic, as in Euclid's axioms. The second example (*negation and indeterminacy*) principally concerns determinacy, reworking the classical binary categorization of A and not-A, which presumes to account for everything, in order to make space for opacity, for that which cannot be categorized and therefore treated causally. The third example (*linear and fractal*) chiefly concerns sequentiality, working in resonance with quantum time to rethink images of the mechanical, progressive passage of time, one that functions on a principle of replacement (the now replacing the past, which will then be replaced by the future). The fourth example (*metric and topological*) concerns all three, focused as it is on the move from spaces that can be measured from the outside, in which part-whole relations are stable and ordered, to spaces that produce their own measures, and do so in ways that respect spatiotemporal entanglements that are less prone to ascending lines and more to folds and inflections. The fifth example (*parallel and intersectional*) concerns both separateness and determinacy in that it shifts from multiple independent descriptors to entangled ones – entangled not only among themselves, but in broader sociomaterial processes. This in effect messes with determinacy because grids and tables are no longer adequate ways of accounting for effects. In the final section, I show how geometric inversion can function as an apparatus or device that makes things visible. To the extent that inversion works on relations of proximity and relatedness, inclusion, and exclusion, it becomes an interesting generator of new spatial imaginaries.

3.1 Identify and Difference

I have already mentioned Deleuze's interest in spatial imaginaries, which drew on biology, but also frequently on mathematics. One of his main concerns, as a philosopher, was to work out an alternative to the prevailing philosophy of identity, which he called a philosophy of difference, and which became crucial for his political ontology (de Freitas 2016). Following Leibniz, Deleuze found much inspiration for his philosophical work in calculus, particularly with concepts such as the differential relation, singularities, multiplicities, and the virtual. Of course, there is a long tradition of interaction between mathematics and philosophy in the West, going back to Plato – for whom Euclid's geometry provided a model for ideal forms. As Smith (2007) notes, though, philosophers of the nineteenth and early twentieth centuries, whose interests have primarily been foundations, tended to gravitate toward axiomatic set theory rather than to calculus. But Deleuze and Guattari were interested neither in foundations nor in ideals – they were interested in the conditions of real experience, and in formulating a philosophy of difference adequate to those conditions (see Smith [2007] for more details). Such a philosophy would break with the philosophy of identity, which defines a thing as essence or substance, which in turn has particular predicates or properties. In a philosophy of identity then, difference is secondary – I first define A and B and then compare them according to their

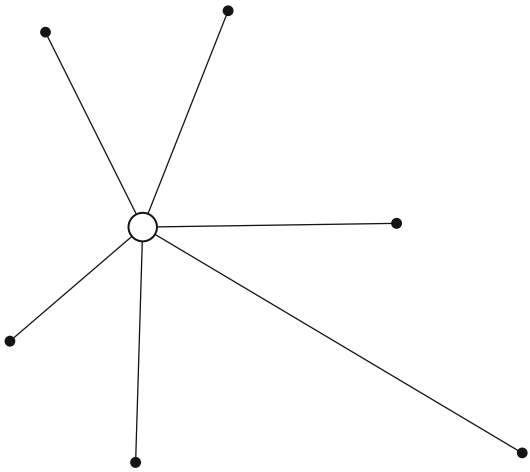

Fig. 1 Substantialist images: a thing and its properties

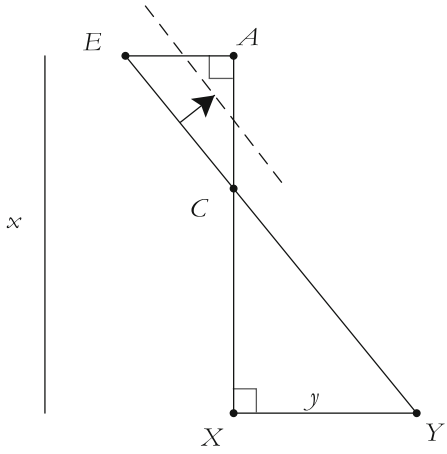
properties, which I have determined in advance.[7] Spatial imaginaries associated with the philosophy of identify include graph theoretical nodes and edges. A node is a thing (chair, human, triangle, and river) and it has edges that represent each of its properties (Fig. 1). With each node being a sovereign thing, equality can be achieved when the properties are the same, while difference arises when they are not. Deleuze's challenge was to think about difference as primary, so that A and B emerge out of pure differing (rather than out of preexisting differences).

Deleuze drew heavily on Leibniz for this work. I will run through the differential triangle example, also provided in Smith (2007), because it exemplifies so powerfully (and spatially) what difference as primary can look like.[8] Take two right-angled triangles CAE and CXY, as in Fig. 2. These two triangles are similar, which means that the ratio EA/AC in the top triangle is equal to XY/CX in the bottom triangle. Now imagine moving EY parallel to itself, toward A, as indicated by the arrow and dotted line. The lengths of EA and AC will decrease, eventually becoming zero, *yet*

[7] The idea of equality – which is so important in mathematics – is also based on identity. Mazur (2007) provides an excellent overview of the complexities of equality, its dependence on separateness (you can only say that two things are the same, if you separate out specific qualities, like white, or prime, or one-holed). Reading Mazur, I get the sense that even mathematicians want to move away from the overbearingness of equality, as evidenced by associated relations such as equivalent, congruent, and isomorphic!

[8] Indeed, it can be difficult to use language to give an adequate sense of Deleuze's philosophy of difference, particularly given the nounified tendencies of English, where things are already separate and distinct, rather than eventful. From a phenomenological point of view, imagine looking out at the ocean. As you look more closely, you begin to make distinctions *which arise from relations* – the water is higher here (on the wave) but not there, the color is a little darker over there, a bird swoops and catches a fish, etc. These are all distinctions that produce difference, where the differences are intrinsic to the eventful world, rather than external, as abstract categories. As Deleuze wrote, the problem with abstract categories is that they let too many fish pass through!

Fig. 2 Leibniz's triangle



their ratio will continue to exist and be a perfectly well-defined finite quantity *x*/*y*. This differential relation (*dx*/*dy*) is "a relation that persists even when its terms disappear" (p. 11). In contrast to differences that are between two things that have an a priori identity (and could therefore not exist without the things), Deleuze's concept of difference-in-itself does not require identity.

Taken as a spatial imaginary, both *motion* (the moving line EY) and *analogy* (that EA:AC as XY:CX) feature strongly. Motion helps move away from a substantialist view of things (static, determined through properties). Analogy suggests whatever EA and AC are at a given period is conditioned by the triangle XYC, so that the conditions of difference are determined with what they condition, and not more abstractly. This is an ontologically significant step in Deleuze's philosophy, but it is also one that offers new ways of thinking about identity and difference, which are crucial terms in gender, sex, class, ability, and race politics. A philosophy of identity takes categories such as Women and Man or White and Black or Rich and Poor, and substantializes them by loading them up with fixed (often stereotypical) properties that are usually determined in relation to a dominant identity (Man) which then subordinately determines the other (Woman). Within identity politics, it becomes difficult to attend to other differences (including ones not coded in the binary) or even to uniqueness, that is, the way in which we each exceed stereotypes. The differences upon which these categories arise are not seen as conditions, but as givens.

In a philosophy of difference, there are no natural categories that give rise to difference, but only differences of differences, which are always contingent. In other words, difference A with respect to condition *a* and difference B with respect to *b* are actualized situationally rather than universally. The conditions themselves must be plastic and mobile, "no less capable of dissolving and destroying individuals than of

constituting them temporarily" (Deleuze 1994, p. 38). Deleuze therefore replaces the traditional concept of substance with that of multiplicity.[9]

While Deleuze finds strong inspiration in calculus, we must recognize that calculus itself has also "[lent] credence to the classical view of determinism, that is, a clockwork universe without any novelty, in which the future was completely determined by the past" (Smith 2007, p. 15) through astronomical predicts and discoveries. Indeed, while the spatial imaginaries may be latent in the ideas of calculus, they also need to be recognized not just as techniques to solve problems (about astronomy), but as ways of understanding existence and events. The importance of the intentions associated with the wielding of new spatial imaginaries will become especially clear in the next example.

3.2 Negation and Indeterminacy

Brazilian and Black feminist scholar Denise Ferreira da Silva (2017) uses mathematics in a more radical way, using only the laws of arithmetic as abstract devices to "explore [the] potential of blackness to unsettle ethics" (p. 8). In her thinking about race, she works against the Hegelian dialectic logic that begins with the Aristotelian positing of A and not-A. The A, defined as what is taken to be the "natural" category, which in Ferreira da Silva writing is White, is the one against which other categories are measured, while not-A is Black, and therefore defined negatively, and only determined in relation to A.[10] She argues that continuing to fix a Black identity – by focusing on how Black lives matter, for example – maintains the category not-A, and will therefore never disrupt the logic in which Blackness is defined with respect to Whiteness (rather than on its own grounds).

A mathematical example might be helpful in exemplifying the unsettling that Ferreira da Silva is undertaking – and not that I am, with caution, following in Ferreira da Silva's footsteps by dangerously associating people with numbers.[11] Her project is like rethinking irrational numbers, which are usually introduced as the not-A of rational numbers, so that they are not fixed, passively, as a mere negation of the normal, natural category of rationals. Working towards making irrational numbers easier to understand or more represented in everyday life will not change the fact that they are ultimately subordinate to the category of rationals. How to think of

[9] Multiplicity here isn't about having multiple perspectives on the same thing, as an epistemological reading; it is about being multiple, ontologically – being different things at once. The image of the electron as *both* wave and particle is one way to think about this multiplicity.

[10] This dialectical habit of Hegel has been criticized by many, including Ferreira da Silva and Deleuze. Rendered visually, as the set A and then everything outside of A, but within the rectangle that is the "whole," there are three spatial assumptions being made about relations: that there is a whole that can be posited; that there is a strict distinction between A and not-A; and that the categories are static, unchanging, and fixed.

[11] And just as dangerously, bringing in language of rational and irrational to do so, much like she works with positive and negative, the racist connotations thus entailed.

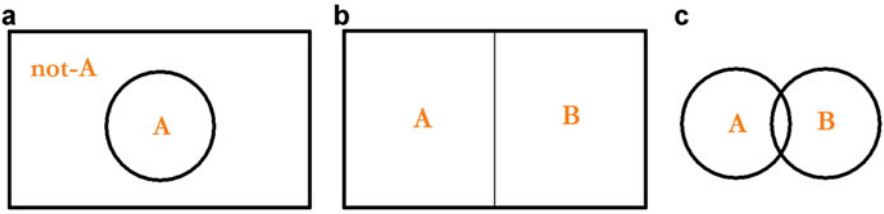


Fig. 3 (**a**) Opposing A and not-A; (**b**) separating A and B; and (**c**) distinguishing A and B without making them exclusive or exhaustive of other differences

irrationals in ways that somehow exceed the restricted, subservient space they have been given?

Ferreira da Silva mobilizes Blackness's capacity to unravel thought as dialectic (where this thought is always a racial dialectic) without reproducing the violence housed in Western concepts of knowledge, and she does this through arithmetic. Setting life (Whiteness) equal to 1 and not-life (Blackness) to 0 – which is, critically, not the Hegelian −1 of not-Whiteness – she proceeds to calculate. And so: 0 added to or subtracted from itself is still 0; 0 multiplied by anything is still 0. Therefore, addition, subtraction, and multiplication reproduce themselves, maintaining the categories. But division turns out to be a generative operation because dividing by 0 is undefined. This is how Ferreira da Silva achieves the indeterminacy that refuses to contain Blackness. She accords to Blackness the power to unsettle the ethical program governed by the determinacy of Aristotelian logic in which there is either A or not-A, a determinacy that captures all (the general, abstract) in one fell swoop.

The logic that Ferreira da Silva is working within and against, which she deploys in relation to Blackness (as a category of modern abstraction), is one that is relevant in many other settings. Feminists have also critiqued the way in which the category of Woman is defined in terms of that of Man; disability is similarly defined in relation to a normative category of ability. Glissant would argue that these habits of thought are not just discursive, but draw – perhaps subconsciously – on spatial imaginaries, by which he means the ways we assume things to be related. The dialectical (and often dualistic) imaginary is well expressed by the image in Fig. 3a. Its entailments may not be so obvious until we consider other ways of relating, as seen in Fig. 3b, c. Figure 3b operates under strict division, but does not function through negation, or through the abstract category that catches everything but A. Figure 3c does not posit the total space of possibility (there is no enclosing rectangle), and admits overlaps between A and B (and could perhaps allow the potential of more overlaps of C, D, etc.).

3.3 Linear and Fractal

Fractal images have been used widely in the popularization of mathematics, featuring on computer screens, in artwork, and in extracurricular or enrichment activities

with students. Few would object to the claim that fractals are more popular outside mathematics than within, where they tend to be seen as belonging to recreational mathematics. Ferreira da Silva (2016) mobilizes what she calls fractal thinking as an intentional way to disrupt the linearity of time. Clockwork time – which orders the past, present, and future, and which flattens temporality into extensive units of hours, days, and years – instills and maintains sequentiality. This sequentiality enables linear thinking in which the past is over, and doesn't intervene in the present or the future; it posits that the future is only yet to come, perhaps causally following from the past, but certainly not affecting it (see also Mikulan and Sinclair 2023). For Ferreira da Silva, fractal thinking is a way to account for how the past operates in the present, a way to reckon with the violence of history, to see similarities across space and time (see Fig. 4). She deploys these similarities in the specific context of violence against Black people, showing not only that these violences repeat, despite changes in law, in the skin colour of the president, in anti-racism education, but also that they repeat because they are the necessity by which capitalist extraction continues to accumulate the total value.

In contrast to linear thinking, which might posit a break – a "now we know, so we can be different" – fractal thinking does not erase the past. As Ferreira da Silva points out, and in resonance with Barad (2007), fractal thinking draws more on quantum rather than classical approaches to physics. In quantum physics, time does not operate linearly: the future can change the past; the past and future are symmetrical.

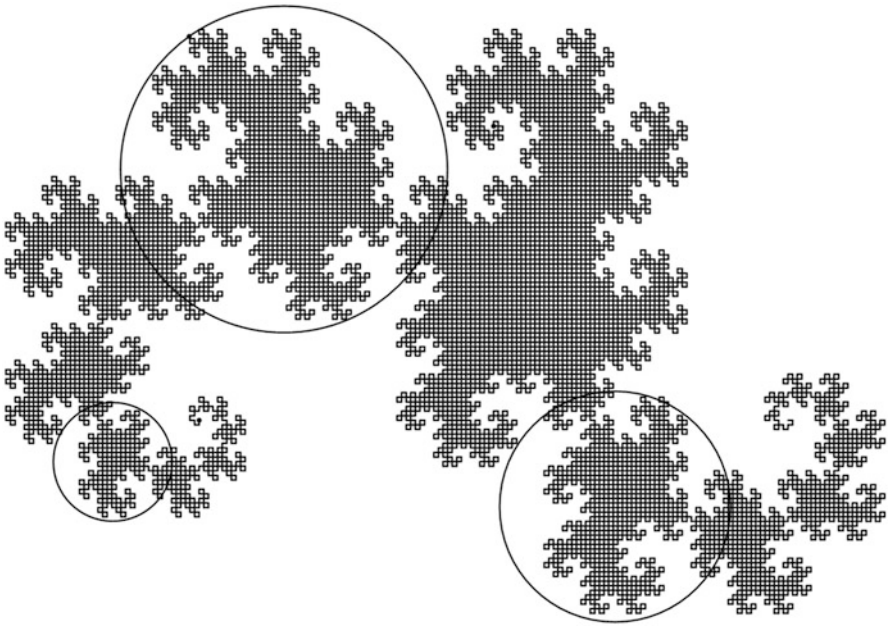

Fig. 4 The dragon curve with three circles to show similarity across different spatiotemporal moments

Without the sequential line, the whole assumption of progress dissipates, as we acknowledge the ways in which things repeat – similarities across scale. The world becomes not just the immediate present, and not even just the historical march toward the present, but also that which was never actualized – or, in the words of Ferreira da Silva, "a composite of so much of what never came to be and what never will be" (p. 265).

Although fractal images have significant spatial appeal, it is less the overall spatiality that interests Ferreira da Silva and more the spatiotemporality involved in the iterative similarity: that even though a particular event occurs in a particular time and place, it is literally present in future events (at other times and places) – that events are stacked in space-time rather than being lined up sequentially. Her injunction is for us to refuse to keep history in the past; to not be surprised when "the same thing" happens again "even though. . ."; and to cultivate different spatial imaginaries that can interrupt the neat, progressive flow of clockwork time. The repercussions are far-reaching. They change how we imagine our responsibility to the past and the future; they change assumptions about equality and liberty by acknowledging that humans cannot be – and never will be – equal across space-time (though certainly unique).

3.4 Metric and Topological

In some senses, Whitehead's interest in process philosophy arose from his own critique of the post-Enlightenment thinking of philosophers such as Kant and Hegel. Like Deleuze, he was interested in the conditions of real experience, and was therefore suspicious of fixed categories and static abstractions. While he did not share Glissant's or Ferreira da Silva's political agenda, there are aspects of his own spatial imaginaries that are consonant with theirs – particularly in relation to his mereotopology. Whitehead relied on a distinctively mathematical approach to generating the new relations that could better align with his process ontology. He found that set theory, the prevailing foundational theory, was inadequate to this philosophy, since it was based on the ideas of an abstract set (which we might say belongs to Glissant's continental thinking) and the relation of inclusion with its members. Whitehead abandoned the linear part – whole relation of set theory – where relations are either about inclusion or exclusion – in favour of an entanglement of superposed parts and whole, where each part *is* a whole *and* a part within that whole. While set theory invites thinking of the abstract collection, the "universe," or the container for the elements (the rectangle of Fig. 3a), Whitehead's mereotopology avoids this unified, abstract whole. It concerns the topological transformation of wholes and parts that do not bow to the fixed, spatial logic of set inclusion.

Mereotopology invites us to think of the complex network of open-ended activities, all in relations of resonance but also differentiated along multiple, spatiotemporal timelines. In other words, while one part–whole relation may hold at one particular time/space, the whole may become the part in another time/space. This is not simply a graph of points related by lines, since the points themselves are not

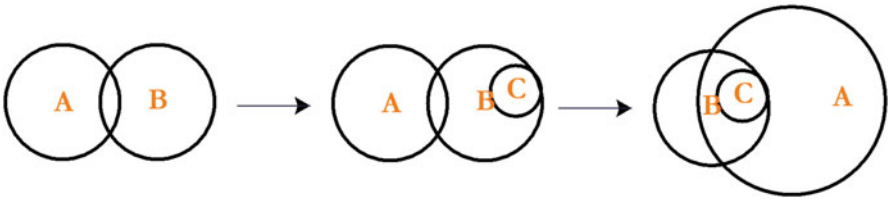

Fig. 5 Mereotopological relations of overlap, touching, partials inclusions, making space as relations change

fixed, and since the two- or even three-dimensional space in which the graph is embedded does not allow for simultaneous spatiotemporal timelines. Mereotopology, when operating as a spatial imaginary, conceives of relations as being overlapping (though still discrete), sometimes contradicting and always changing affiliations in the world – it is about events rather than discrete objects. Diagrammatically, this might involve multiplying the forms of relation (not just inclusion, but crossing, overlapping, tangent, straddling, etc., and iterating over time). These relations seem to invite sensings that are not just ocular – Kant's preferred sense of abstraction – but haptic (touching) and kinetic (moving) as well (Fig. 5).

3.5 Parallel and Intersectional

In his article entitled *Fiber Bundles and Intersectional Feminism*, Dagan Karp (2021) uses a mathematical concept (fiber bundles) as a means of explaining the sociopolitical concept of intersectionality. It is evident that the intended audience is mathematicians since most journal article–reading people would likely find it much easier to understand intersectional feminism than fiber bundles! Indeed, Karp provides a comprehensive, clear, and persuasive overview of gender inequity in mathematics, providing ample evidence of the underrepresentation of women in mathematics, and the even more significant underrepresentation of racialized women in mathematics – highlighting both institutional and personal biases, and therefore both psychological and sociological causes. He also provides an excellent overview of the different waves of feminism, including the more recent move toward intersectionality, coined by Kimberlee Crenshaw, which recognizes the multiple, intersecting identities that individuals have, including race, gender, ethnicity, sexuality, economic class, and ability, and how the dynamics of difference – and of inequity – affect certain people more than others when their multiple differences (female *and* poor, for example) are taken into account. An important insight of intersectional feminism is that "just as aspects of identity in individuals are intersecting and inseparable, so too are the systems of oppression, bias and privilege governing our lives" (p. 5). Given this multidimensional, entangled set of causes and consequences at play, Karp turns to fiber bundles to *model* this complex situation.

It can be instructive to consider other mathematical concepts that would not model intersectional feminism well. For example, while Venn diagrams certainly model the idea that individuals might be in different and sometimes intersecting categories, it fails to show how these multiple identities are shaped by and shape societal norms and histories – and, importantly, that systems of oppression affect some people more than others. On the other hand, the topological concept of fiber bundles enables Karp to make visible how the "fibers" of US society ("ableist cis-heteronormative white-supremacist capitalist patriarchy" (p. 8)) are maps between the base space (society, or the set of people) onto another topological space (certain aspects of identity, which are inseparable, or intersecting). Since these maps preserve the structure of the fiber, so too are systems of oppression preserved. In other words, the intersection of identities cannot be separated from these sociopolitical systems, and therefore both shape and are shaped by them.

By refusing the assumption of separability – both in terms of aspects of identity and in relation between individual and collective manifestations of them – Karp's use of fiber bundles breaks with discrete spatiality. Interestingly, the strength of the preservation of mapping, which highlights the inseparability of individual social forces, may also be its weakness if we are looking for spatial imaginaries that change systems of oppression. As such, this example shows that mathematics is quite good at modeling complex sociopolitical issues – and, as I've said before, it shapes and is shaped by existing spatial imaginaries – but the prior examples differed from this one in that they aimed to create new spatial imaginaries. For example, in the same way that Ferreira da Silva raises concerns about the reifying nature of identity politics, we can also ask how further narrowing down on intersectional identities operates both to highlight invisible forms of inequity *and* render static and abstract a category through a philosophy of identity. Do the structures of the fibers always have to be preserved? Can they be transformed through operations similar to Ferreira da Silva's division by 0?

3.6 Devices for Producing New Relations

Inversion is a geometric transformation that has the effect of turning the plane inside out about a given circle. Points that are infinitely far away curl into the finite middle, whereas points within the circle are mapped outside – with the center corresponding to the infinitely far away. The idea was invented by Jacob Steiner (1796–1863) and led to new branches of mathematics and to new ways of solving previously intractable problems. Inversion transforms any point (Q) inside a circle (center O, radius r) into one outside the circle (P), such that $OP/r = r/OQ$. The circle of inversion can be chosen arbitrarily, thus performing the crucial act of contingency. Figure 6a shows six points (labeled A, B, C, D, E, and F) and a circle of inversion. Once the inversion is performed, the points are mapped to A′, B′, C′, D′, E′, and F′ (Fig. 6b). Two points that were previously close together (A and B) are now extremely far apart, thereby upsetting proximity relations. Points that were previously peripheral (C and D) are not central. Points that were included (A, B, and E) are now excluded, and vice versa.

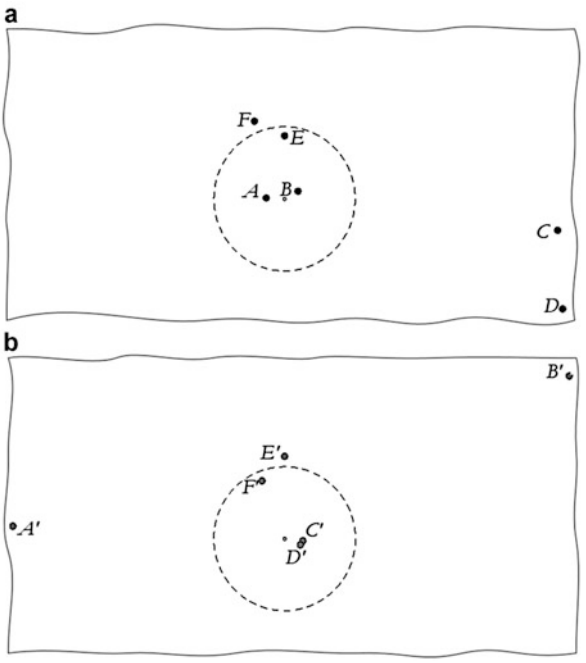

Fig. 6 (**a**) Points on the plane, along with a circle of inversion; (**b**) the inversion of the points

Points that are close to the circumference of the circle of inversion change little, which means that the transformation treats different points differently, depending on location.

de Freitas et al. (2022) use inversion to explore new geographic relations that can be created between cities (in their case, the locations of the different members of an international education project) that might disrupt normative associations. For example, cities that might have been previously related through associations of proximity (Calgary and Edmonton) can become wrenched apart if the circle of inversion is centered around them, scattering former alliances. Relatedly, previously far-flung locations, such as Vancouver and Manchester, can inherit new relations of proximity. With lines becoming circles, the usual bidirectional flows of goods (and historically, slaves) that comprise the trade triangle of the Atlantic Ocean now "devolve into vortexes, dethroned of their power to circulate in the same way" (p. 10). Inversion thus functions as a device for generating new ways of thinking spatial relations (less focused on "natural" categories of proximity and linearity), and speculating about new relations and new future movements. The new map they produce, through inversion, is seen as "folding mathematics into a critical geography," as "refus[ing] the typical tame and clean measures of Euclidean geometry" (ibid.).

Inversion thus functions as a generative device that is not intended to represent phenomena – as doing so would reify their existing relations – but to generate new ones for consideration. Much in the same way that one might perform a vertex

splitting on a graph or alter an axiom or transform a function, what is produced as a new object can then be explored for potential meanings. Inversion is a particularly powerful device because it works so closely with spatial imaginaries related to inclusion, boundaries, and proximity, which are central both in determinations of belonging (or not) to groups of people, tracts of land, or networks of trade.

Given that mathematics is rife with transformations – and since Klein's reworking of geometry, transformations have arguably become more important than objects – inversion is probably not the only device of potential interest in the generating of new spatial imaginaries. For example, sheafs are transformations used in algebraic topology that can be used to "enhance" a mathematical object such as graphs or topological spaces, functioning like a garden on a plot of land, to use Agrios's (2022) metaphor, growing stalks that can be used to produce new vegetables. Like fibers, sheafs remain faithful to the structure of the underlying object. However, what seems to me interesting about sheafs is the way they take up the move between local and global. In Agrios' example (of a sheaf of abelian groups of continuous functions on a topological space X), the sheaf section comes out as a single graph of a continuous function that is made up of the infinitely many pieces of graph, which are images of the group of continuous functions on specific domains of the x-axis (these domains are the open sets, or the chunks of dirt in the garden). This way of producing the global just by applying specific rules on the local – rather than having to use different rules for the global – seems like a compelling image to think with as we reckon with questions of how to address global problems such as climate and immigration at local scales (see Aït-Touati et al. 2019/2022 for a concerted discussion of the need for new ways of seeing the world). It also reified the quantum and fractal imaginaries from the earlier section.

4 Conclusion

The title of this chapter evokes the famed Eugene Wigner's paper *Unreasonable Effectiveness of Mathematics in the Natural Sciences*, written in 1960. According to both Platonic or sociocultural theories, which both adhere to a fundamental distinction between nature and culture, the effectiveness of mathematics in the natural world is indeed unreasonable. However, if we refuse to see mathematical concepts as belonging to some transcendental reality or as emerging uniquely from social foundations (including language, tools) and we acknowledge the material-discursive entanglement of world (Barad 2007) – including mathematics – then the effectiveness of mathematics in the natural world is not so unreasonable. Similarly then, it is not so unreasonable to think that mathematics shapes and is shaped by human and nonhuman experiences in the world. It is not unreasonable to imagine that our very ways of seeing and feeling the world and its relations are caught up in the various forms of logic that we then use in mathematics. Indeed, if one adopts a monist philosophical approach, then it's less clear that we should not be thinking about these examples I've offered as *mere* models or metaphors (relations that impose their own

forms of separateness). Mathematics, in its charming ways, *should* help us understand our (actual and potential) world.

As a mathematics educator, writing this chapter has reminded me of the very narrow scope of *possibilities for* new spatial imaginaries we offer in the K-12 mathematics curriculum. No topology, no fractals, no infinitesimals, no pathologies or paradoxes, and very little infinity and indeterminacy. I imagine that if we did include these topics, they would be handled as natural, continuous extensions of previous mathematical ideas (as we do when we introduce negative numbers or rational numbers), posing no threats to constant, inevitable progress (never addressing that which is lost along the way). Those are, after all, our dominant spatial imaginaries, inherited through modernist values, habits, and beliefs. Since generations of students, who grow up to be teachers, operate with them, it is not surprising that so little changes.[12] What if we moved back into an alliance between mathematics and philosophy, in education – one that was less focused on preparing students to join the workforce, and more intentional about helping them understand different ways of seeing/thinking/feeling?

Finally, readers might wonder why I focus on spatial imaginaries. In one sense, unlike language, these are often left unspoken and structure our assumptions, even if not at a conscious level. This is certainly cultural in nature, given the important role that eyes have been given in Western conceptions of reason – where, for Kant, for example, the eye is the noblest of the senses,[13] closest to providing abstractions. It is also technological in nature, surrounded as we are by images, which function so well on the flat surfaces that dominate our media (paper, screens, billboards, etc.). From a philosophical point of view, it would be interesting to consider what might happen were touch or sound to function in ways similar to sight. Might we consider tactile and aural imaginaries? If so, could mathematics still function as generatively in producing such imaginaries? Any study of the actual practice of mathematics reveals that, in fact, touch, sound, and image are central to mathematical thinking and communication (see, for example, Menz 2015). The current turn toward philosophy of mathematical practice might help expose the ways in which separateness, determinacy, and sequentiality may be good descriptors of published mathematics (including the mathematics of textbooks), but not of the actual doing of mathematics.

[12] Obviously, there are many other factors involved in the tenaciousness of modernist's spatial imaginaries, most important being the capitalist, colonial, individualistic society in which we live, which thrives on the discrete and the calculable, as well as in myths of progress. On one hand, it is quite mad to think that mathematics education could make a difference. On the other, as a discipline that straddles the sciences and the arts, that powerfully operates the gatekeeping functions in schools and universities, mathematics stands out as a compelling option.

[13] And for Plato, it was the voice. We know of the mathematical performances of Ancient Greek geometers, with their drawings in the sand, but what might we learn from speculating about the rhythms and tempos of their oral demonstrations? Could we find new audio-spatial imaginaries involving repetition, refrain, or harmony?

Abstract

Mathematics in finance has prehistoric origins, in fact it is argued that an accounting system of clay tokens used for prehistoric commerce were precursors to both letters and numerals. Furthermore, Hammurabi's code, the first known codified set of laws, has sections governing interest rates and banking operations. Throughout history, many mathematicians have turned their attention to finance. For instance, Fibonacci introduced the numerals to Western Europe in the thirteenth century in order to facilitate trade. Bernoulli first discovered Euler's

constant e in the seventeenth century when investigating compound interest. However it was not until the turn of the twentieth century that quantitative finance began in earnest with the doctoral dissertation of Louis Bachelier where he used Brownian motion and stochastic calculus to determine the price of stock options. The late twentieth century saw the field burgeon into a widely studied discipline after two seminal events: the publication of the Black-Scholes-Merton paper in 1972 and the cancellation of the Texas Superconducting Supercollider by the US Congress in 1993.

1 Introduction

This chapter will present the important ideas in mathematical finance and their historical origins, as well as how an influx of physicists and mathematicians to Wall Street accelerated the field. The chapter will focus on the ideas from mathematics that impacted finance, in so far as the ideas changed the way capital was allocated in Western society.

The first accounting system was discovered around 9000–8700 BCE, coinciding with the onset of agriculture (Schmandt-Besserat 1992). Clay tokens were used to facilitate widespread cereal production and even trade among different civilizations. For instance, the same clay tokens were found dating to the same times in ancient Syria as well as ancient Iran, in the Mesopotamian fertile crescent, near the Tigris and Euphrates river along the shores of the Mediterranean sea. These clay tokens predate both numerals and alphabets and were likely their precursors (Morley and Renfrew 2010). Furthermore, there is evidence that the onset of agriculture, trade, and commerce interest rates were levied, and hence ancient civilizations knew the time value of money. The amount of interest seems to be related to the ease of computations in the counting systems employed, and interestingly the interest rate became lower as the civilizations advanced (Hudson 2000).

2 1202 Liber Abacci: Leonardo Pisano

From the onset of written history until the thirteenth century, mathematical calculations for commerce in Western Europe were done at various times using pebbles as counters, Roman numerals, elaborate finger manipulations, and mechanical abaci – in fact the word “calculus” derives from the Latin word for pebble. This changed in the thirteenth-century CE when Leonardo Pisano, the son of a wealthy Pisan merchant of the Bonacci family, published the book *Liber Abbaci*. This book

introduced the Hindu-Arabic numerals 0–9, introduced arithmetic using these digits, and ushered in a fundamentally new way of conducting trade. Leonardo Pisano is today known as Fibonacci, a contraction of the latin *filius Bonacci* ("son of Bonacci") coined by the historian Guillaume Libri in 1838 (Devlin 2011).

In his early childhood, Fibonacci traveled to Bugia in North Africa, in modern day Algeria. There, he was introduced to the Hindu-Arabic numerals and realized their significance from a commercial point of view. On his travels, he studied mathematics and was influenced by Arabic scholars. Upon his return he wrote *Liber Abbaci*, which included many problems that introduced revolutionary business concepts, such as the law of one price, the value of a firm, and the time value of money.

2.1 The Law of One Price

There are three entire chapters devoted to the concept of the law of one price. Chapter 8, "On Finding the Value of Merchandise by the Principal Method," Fibonacci uses ratios to determine the price of a quantity of merchandise when the price of a different quantity is known. Clearly this type of calculation was done prior to *Liber Abaci* however not in the Hindu-Arabic numeral system where the calculation is straight-forward and can be done by anyone, not solely the dedicated computers who used abaci, Fibonacci had brought the power of computation out of secluded guilds and into the hands of the everyday businesspeople.

Chapter 9, "On the Barter of Merchandise and Similar Things," Fibonacci uses the principal method of valuing merchandise to teach merchants how to barter fairly. In the same chapter, he uses similar techniques to exchange different currencies, since in Italy the thirteenth century, there was no single currency in Italy, but rather dozens minted and in use. Therefore "foreign exchange" was necessary in order to trade with other city-states. Indeed, Chapter 10 is devoted to the alloying of monies in different coins in order to determine their equivalent values.

2.2 The Value of a Firm

The first sentence of the tenth chapter introduces a concept that seems obvious today; however, was an important leap forward for western business:

> It is proposed that certain men together are members sharing unequally in a company which will make some quantity of profit they will wish to divide moreover among themselves according to their shares.

Fibonacci thus ushered in the concept of owning a partial share of a company, in so far as a fair treatment of the profits was concerned, spending the entire chapter on how to use the Hindu-Arabic numbers to equally divide the company's profits.

2.3 The Time Value of Money

Although the time value of money was known since antiquity, Fibonacci understood its fundamental importance to finance, introducing the concept of present value analysis.

Fibonacci poses the following problem:

> A certain man proceeded to Lucca on business to make a profit doubled his money, and he spent there 12 denari. He then left and went through Florence; he there doubled his money, and spent 12 denari. Then he returned to Pisa, doubled his money, and it is proposed that he had nothing left. It is sought how much he had at the beginning.

Note that it is not clear in the problem formulation that the man also pays 12 denari in Pisa at the end of the trip. This is easily solvable by finding x in the equation

$$2(2(2x - 12) - 12) - 12 = 0 \tag{1}$$

However, Fibonacci has a more elegant solution. He notes that the capital doubles with each trip and therefore the initial capital will have to be sufficient such that it grows into the periodic payment in each city. The amount at the beginning – given the man is left with nothing at the end – is the periodic payment "discounted" by the rate at which it grows. There are three "parts" of the initial capital, the amount that grows into the payment in Lucca, Florence, and Pisa, each requiring a subsequent halving

$$x = \frac{12}{2} + \frac{12}{2^2} + \frac{12}{2^3} \tag{2}$$

giving the final answer 10.5 denari. The concept of time here is replaced by the physical movement of the man, the great insight that Fibonacci introduces in this problem is the concept of net present value or NPV. The traveling merchant problem describes an annuity which is a financial security that exchanges a fixed amount of money for a finite number of future fixed periodic payments. In modern parlance, the question would be posed as "what is the present value of a three period annuity that pays a 12 denari coupon at an interest rate of 100%?" The general formula the present value of all future cashflow payments, discounted at the quoted interest rate

$$A = \sum_{n=1}^{N} \frac{c}{(1+r)^n} \tag{3}$$

which can be simplified using the infinite $\sum_{n=0}^{\infty} x^n = \frac{1}{1-x}$ resulting in the closed form formula for an annuity.

$$A = c\left(1 - \frac{1}{(1+r)^N}\right). \tag{4}$$

Substituting $r = 1$, $c = 12$ denari and $N = 3$ leads to the same 10.5 denari as above.

The traveling merchant introduces the concept of NPV; however, Fibonacci goes further and applies it to the analysis of two streams of cashflows, ranking their value based on the higher NPV when he poses the following problem:

> A certain soldier because of his fief received from a certain king 300 bezants each year, and it is satisfied in four payments, and in each payment he takes 75 bezants; this is a payment for three months which by necessity is collected together; he asks for certain compensation in order to accommodate himself for interest because he accepts the 300 bezants instead of the 75 bezants of each payment, namely from payment to payment, of the capital and profit. Voluntarily acquiescing to this, he invests the bezants at a profit of two bezants per hundred in each month. It is sought how many bezants he makes in his investment.

Essentially, the king has decided to change the arrangement from 75 bezants every 3 months to 300 bezants annually, going from periodic payments to a lump sum. The soldier would like to be compensated for this change because he can earn interest quarterly, the question asks what is the difference in NPV of the two streams of cashflows. To solve this, note that the rate at which the soldier can earn is 6%, there are four periods and the payment is 75 bezants. Inserting into the annuity formula above reveals that this stream of cashflows is worth 259.88 bezants, whereas the NPV of a single lump sum payment is 237.62 bezants. Therefore the soldier should ask for an extra 22.25 bezants today, or that the lump sum be augmented by 28.09 bezants (since the NPV of 328.09 is 259.88).

3 1900, 1951 Brownian Motion and Stochastic Calculus: Louis Bachelier and Kiyosi Itō

Some say that March 29, 1900 should be recognized as the birthday of quantitative finance; it was the day that the French mathematician Louis Bachelier – a student of Henri Poincaré – defended his thesis at Sorbonne. The thesis, later published in one of the most influential French scientific journals *Annales scientifiques de l'École Normale Supérieure*, was called *Théorie de la Spéculation* (Bachelier 1900) and contained within it the first use of stochastic processes – although implicitly – to describe Brownian motions, which he applied to the pricing of stock options.

The calculus and analysis required to deal with stochastic processes were not fully developed into its modern form until Weiner and Itō in the 1950s. Stochastic calculus is the application of integral calculus to processes that are nowhere differentiable but everywhere continuous, a class of functions not thought to exist prior to 1872. That year, Karl Weierstrass introduced the pathological function

$$f(x) = \sum_{n=0}^{\infty} a^n \cos(b^n \pi x) \tag{5}$$

where $0 < a < 1$, b is a positive odd integer, and $ab > 1 + \frac{3\pi}{2}$ (Weierstrass 1872). Prior to the introduction of this function, it was believed, almost axiomatically, that if a function was continuous, it could only be nondifferentiable at a finite set of points, perhaps because there was a "proof" in one of André-Marie Ampère's papers – although this point is debated by some. These everywhere continuous but nowhere differentiable functions were met with disdain from the mathematical community, with Poincaré calling these functions "monsters" and Charles Hermite "a lamentable scourge." In fact, some mathematical proofs were upended as a result of the existence of such functions, and this leads to the careful treatment of all concepts and the birth of modern analysis (Gray 2015).

However, there are processes in both physics and finance that could be described by precisely such a function. In 1827, botanist Robert Brown observed both organic and inorganic particles under a microscope undergoing "jittery" motion, now named Brownian motion in his honor. The explanation for this behavior was not explained until 1905 when Albert Einstein wrote a paper attributing the phenomenon to the atomic theory of matter (Einstein et al. 1905) which was surprisingly still not generally accepted at the time. Bachelier realized that stock prices can be described by such processes.

A Brownian motion is a continuous function of time $W(t)$ (denoted W since it is known as a Weiner process (Wiener 1923)) starting at 0. The process up to time T is built up by realizations of normal random draws

$$W(T) = \sum_{i=0}^{N} [W(t_{i+1}) - W(t_i)] \tag{6}$$

where the increments are independent and identically distributed according to the normal distribution with mean 0 and variance Δt

$$W(t + \Delta t) - W(t) \sim \mathcal{N}(0, \Delta t). \tag{7}$$

These processes are martingales which means their expectation in the future is equal to the value today. This was embedded in Bachelier's thesis as the "Principle of Mathematical Expectation":

> *The mathematical expectation of a speculator is nil.* The generality of this principle needs to be appreciated: it signifies that the market, at a given instant, considers as having nil expectation not only the current trading operations, but also those that would be based on a subsequent movement of prices. The mathematical expectation of an operation that may be either positive or negative, if it produces a price movement, is *a priori* nil.

Mathematically this is shown by taking expectations

$$\mathbf{E}[W(t) \,|\, \mathcal{F}_s] = \mathbf{E}[W(t) - W(s) \,|\, \mathcal{F}_s] + \mathbf{E}[W(s) \,|\, \mathcal{F}_s] \tag{8}$$

where the $\mathcal{F}_s$ is technically a filtration, meaning "all of the information known up to the point s." Since this includes the value of $W(s)$, then this is a trivial expectation, and the first expectation is zero based on the property of Brownian motions. Therefore

$$\mathbf{E}[W(t)\,|\,\mathcal{F}_s] = W(s) \tag{9}$$

which is the definition of a martingale (and Bachelier's principle of mathematic expectation).

Stochastic processes differ from deterministic processes by virtue of the fact that they have nonzero quadratic variation, and responsible for the necessity of a new type of calculus in a stochastic setting. The quadratic variation of any process is defined as

$$\langle f,f\rangle[T] \equiv \lim_{\Delta t\to 0}\sum_{i=0}^{N-1}[f(t_{i+1}) - f(t_i)]^2 \tag{10}$$

where $t_i = \frac{i}{N}T$ (this can be relaxed and a nonuniform division of the time interval can be used, as long as the longest subinterval tends to zero). For differentiable functions, the mean value theorem can be used to simplify the summand, since there exists a point t_i^* such that $f'\left(t_i^*\right)(t_{i+1} - t_i) = f(t_{i+1}) - f(t_i)$

$$\langle f,f\rangle[T] = \lim_{\Delta t\to 0}\sum_{i=0}^{N-1}\left|f'\left(t_i^*\right)\right|^2[t_{i+1} - t_i]^2 \tag{11}$$

$$\langle f,f\rangle[T] \le \lim_{\Delta t\to 0}\Delta t\sum_{i=0}^{N-1}\left|f'\left(t_i^*\right)\right|^2[t_{i+1} - t_i].$$

In the limit of vanishing Δt, this expression becomes a Riemann sum

$$\langle f,f\rangle[T] \le \lim_{\Delta t\to 0}\Delta t\int_0^T |f'(t)|^2 dt = 0, \tag{12}$$

however still multiplied by Δt and hence vanishes. Therefore any function that is differentiable almost everywhere (it could be nondifferentiable at a countable number of points, which have mass zero and therefore do not alter the argument) has vanishing quadratic variation.

For Brownian motions, this argument does not hold as they are nowhere differentiable. The resulting quadratic variation can be calculated probabilistically by determining its mean and variance

$$\mu_{\mathrm{QV}} \equiv \mathbf{E}[\langle W,W\rangle[T]] = \lim_{\Delta t\to 0}\sum_{i=0}^{N-1}\mathbf{E}\left[(W(t_{i+1}) - W(t_i))^2\right], \tag{13}$$

the summand is the definition of variance and by 7 is equal to $t_{i+1} - t_i$. Therefore, the average quadratic variation of a Brownian motion is

$$\mu_{\mathrm{QV}} = \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} (t_{i+1} - t_i) = T. \tag{14}$$

The variance of the quadratic variation can be calculated by use of the fourth-order moment of the normal distribution

$$V_{\mathrm{QV}} = \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} 2(t_{i+1} - t_i)^2. \tag{15}$$

As above, this quantity is strictly less than the product of Δt times a Riemann integral giving the total time T, which vanishes as $\Delta t \to 0$. Since the variance is zero, the quadratic variation is not a random variable and is equal to the mean

$$\langle W, W \rangle [T] = T \tag{16}$$

"almost surely," which means that there are outcomes in the probability space where the quadratic variation is not equal to this mean; however, they comprise a set of measure zero, that is the probability of this happening is zero.

Tacitly, Bachelier identified the value of a stock with the Brownian motion $W(t)$, and therefore price movements with the increments of a Brownian motion $W(T) - W(t)$ (later Fisher Black and Myron Scholes will identify the returns of the stock with the increments of this process). Suppose an investor held $\Delta(t)$ shares of that stock, then the value is the product $\Delta(t)W(t)$, and has an amount of money $M(t)$ in an interest-free bank account. Their total portfolio is worth

$$V(t) = \Delta(t)W(t) + M(t). \tag{17}$$

At some future time $T > t$, they change the number of shares to $\Delta(T)$ by using the money available in the bank account, meaning $M(T) = M(t) - (\Delta(T) - \Delta(t))W(T)$ (this is known as a self-financing portfolio, where there is no cash injection or withdrawn, the future trades are funded solely by the movements of the securities in the portfolio). The change in the portfolio value can then be written to be

$$V(T) - V(t) = \Delta(t)\,(W(T) - W(t)). \tag{18}$$

Trading at infinitesimally spaced times t_i produces the result

$$V(T) - V(t) = \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} \Delta(t_i)[W(t_{i+1}) - W(t_i)], \tag{19}$$

which may seem impossible in practice; however, now the Eq. 19 will yield to a similar analysis as the quadratic variation above. Equation 19 is suggestive of an integral, however not of the usual Riemann nor Lebesgue form, this is a new type called Itō integration for its discoverer Kiyoiso Itō between 1944 and 1951 (Itō 1944).

Symbolically an Itō integral is written

$$V(T) - V(t) = \int_t^T \Delta(s) dW(s) \tag{20}$$

even though there is no notion of a differential of a Brownian motion. Writing the integral is merely a short form, and the underlying limit in Eq. 19 is always implied (however the same can be said for Riemann integral). By letting T be infinitesimally greater than t, one can write

$$dV(t) = \Delta(t) dW(t) \tag{21}$$

which is known as a stochastic differential equation (SDE) (Itō 1951b; Oksendal 1992; Shreve 2004).

Itō integrals have zero mean, and quadratic variation given by

$$\langle V, V \rangle [T] = \int_0^T \Delta^2(s)\, ds \tag{22}$$

which can be shown with an argument closely following the quadratic variation proof for Brownian motions.

As previously mentioned, Black and Scholes took the return of the stock to be the normally distributed variable, so it is natural to ask how a function of a Brownian motion changes over time, such as $S(T) = S(t) \exp(W(T) - W(t))$. The first step is to break the time interval into infinitesimal intervals

$$S(W(T)) - S(W(t)) = \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} [S(W(t_{i+1}) - S(W(t_i))], \tag{23}$$

when Taylor expanding the term in bracket, the second-order term will not vanish due to the quadratic variation of the Brownian motion

$$\begin{aligned} S(W(T)) - S(W(t)) = {} & \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} S'(W(t_{i+1}))[W(t_{i+1}) - W(t_i)] \\ & + \frac{1}{2} \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} S''(W(t_{i+1}))[W(t_{i+1}) - W(t_i)]^2. \end{aligned} \tag{24}$$

The first term converges to an Itō integral, whereas care needs to be taken with the second. When the partition is fine enough that the function $S(W(t))$ does not vary significantly, then introducing another partition on each subinterval $[t_{i+1}, t_i]$ leads to

$$S(W(T)) - S(W(t)) = \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} S'(W(t_{i+1}))[W(t_{i+1}) - W(t_i)] + \frac{1}{2} \lim_{\Delta t \to 0} \sum_{i=0}^{N-1} S''(W(t_{i+1}))[t_{i+1} - t_i]. \tag{25}$$

where the second term now converges to a Riemann integral with ultimate result

$$S(W(T)) - S(W(t)) = \int_t^T S'(W(s))dW(s) + \frac{1}{2}\int_t^T S''(W(s))ds. \tag{26}$$

The differential form can be written with the understanding that it is symbolic only and always represents the integral form. The differential form

$$dS(W(t)) = S'(W(t))dW(t) + \frac{1}{2}S''(W(t))dt \tag{27}$$

is known as Itō's formula (sometimes referred to as Itō's Lemma) (Itō 1951a).

Itō's formula can be iterated, for instance a call option will depend on a stock price, which in turn will be a function a process defined by a stochastic differential equation (SDE). For example, the most general SDE for a stock is

$$dS(t) = \mu(t, S(t))dt + \sigma(t, S(t))dW(t) \tag{28}$$

and Itō's formula for a function of this stock $f(S(t))$ is

$$df(S(t)) = \frac{\partial f(S(t))}{\partial S} dS(t) + \frac{1}{2} \frac{\partial^2 f(S(t)}{\partial S^2} d\langle S, S\rangle(t). \tag{29}$$

Bachelier implicitly chose the simplest possible SDE to describe the stock

$$dS(t) = \sigma dW(t) \tag{30}$$

that its price changes are normally distributed with variance $\sigma^2(T - t)$.

In this simple case, the SDE (30) can be solved simply

$$S(T) = S(t) + \sigma[W(T) - W(t)], \tag{31}$$

and the price of a call option is simply the expectation of the hockey stick payoff of the stock price minus the strike

$$C(t, T, S(t), K) = \mathbf{E}[\max(S(T) - K, 0) \,|\, \mathcal{F}_t] \tag{32}$$

$$= \mathbf{E}[\max(S + \sigma[W(T) - W(t)] - K, 0) \,|\, \mathcal{F}_t]. \tag{33}$$

The Brownian increment is normally distributed with zero mean and variance $T - t$, and the expectation can be explicitly written as an integral

$$C(t,T,S(t),K) = \int_{-\infty}^{\infty} \max(S(t) + \sigma z - K, 0) \exp\left(\frac{-z^2}{2(T-t)}\right) \frac{dz}{\sqrt{2\pi(T-t)}} \quad (34)$$

leading to the final solution for the price of a stock option in the Bachelier model

$$C(t,T,S(t),K) = (S(t) - K)N(d_N) + \sigma\sqrt{T}n(d_N) \quad (35)$$

where $N(x)$, $n(x)$ are the cumulative normal density function and probability density function respectively and $d_N = \frac{S(t)-K}{\sigma\sqrt{T}}$.

4 1952 The Efficient Frontier and Matrix Algebra: Harry Markowitz

Prior to the 1950s, mathematics had little to do with asset selection, as investors tended to look at securities in isolation, as opposed to the portfolio as a whole. The fact that diversification was good had been known for a long time, evidence for diversification of business show up in Shakespeare's "The Merchant of Venice":

My ventures are not in one bottom trusted,
Nor to one place; nor is my whole estate
Upon the fortune of this present year:
Therefore my merchandise makes me not sad.

However, it was thought that diversification could reduce the risk of the portfolio completely, whereas Markowitz showed in the Nobel winning paper "Portfolio Selection" (Markowitz 1952) that this was not the case. An investor can reduce the nonsystematic risk inherent in individual stocks; however, they are still left with systematic risk present in the market as a whole. Markowitz showed that correlation between stocks can be used to create a portfolio that maximizes return for a given level of risk.

First, Markowitz defined "risk" as the standard deviation of the portfolio. It is instructive to look at a portfolio containing two securities to build up intuition before tackling the general case. Suppose there is a given amount of wealth that is to be distributed between these two securities. The amount in the first share is $w_1 = w$ and the amount in the second is $w_2 = 1 - w$. The expected return is additive

$$R_p = \mathbf{E}[w_1 R_1 + w_2 R_2] = w_1 \mathbf{E}[R_1] + w_2 \mathbf{E}[R_2] \quad (36)$$

however the risk is not additive

$$\sigma_p = \sqrt{\mathrm{Var}(w_1 R_1 + w_2 R_2)} \equiv \sqrt{\mathbf{E}\left[(w_1 R_1 + w_2 R_2)^2\right] - R_p^2} \quad (37)$$

$$= \sqrt{w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2(\mathbf{E}[R_1R_2] - \mathbf{E}[R_1]\mathbf{E}[R_2])}. \tag{38}$$

Assuming normally distributed returns, the cross term gives rise to a correlation term, and therefore the risk of the portfolio can be written

$$\sigma_p = \sqrt{w_1^2\sigma_1^2 + w_2^2\sigma_2^2 + 2w_1w_2\sigma_1\sigma_2\rho_{12}}. \tag{39}$$

Given the variances and correlations can be estimated from historical (observable) market prices, this equation relates the risk of the portfolio to w, the relative weight between the two securities. The risk-reward trade-off for this portfolio can be plotted with the risk along the abscissa and return along the ordinate. Allowable portfolios lie along the hyperbola connecting $(w_1, w_2) = (1, 0)$ and $(w_1, w_2) = (0, 1)$ corresponding to the entire portfolio in the first and second security respectively. This behavior is shown in Fig. 1. Note that this is a multivalued function, implying there can be two portfolios that have the same risk, but one has a higher return than the other. Markowitz's key insight was that no investor would (or should) purchase the portfolio with a lower return given the same amount of risk. He labeled these portfolios as *inadmissible*. Therefore in Fig. 1, the lower branch of the hyperbola are all inadmissible portfolios, and he defined the admissible portfolios as the efficient frontier. He reasoned that how an investor will choose their individual portfolio depends on where their individual utility function (a hypothetical function that, in this case, quantifies the investor's risk tolerance, i.e., are they risk adverse or risk seeking) touches the efficient frontier.

There are two special cases, which can be seen in the graph. If the two securities are perfectly correlated $\rho = 1$ (the lightest line in Fig. 1), then there are no diversification benefits, as can be seen by the straight line connecting the two extremes (only holding one of the securities), and all intermediate portfolios are admissible and the choice will be made solely by the amount of risk the investor is

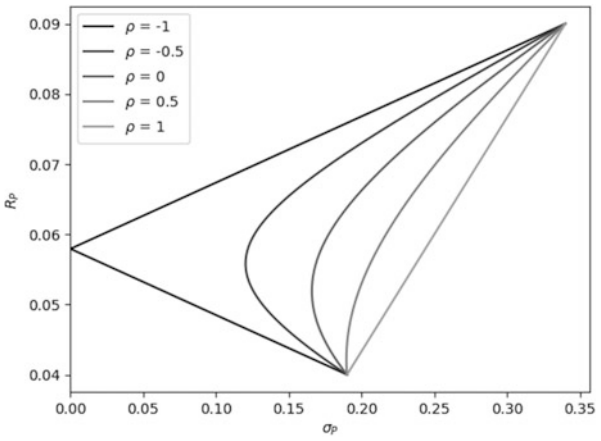

Fig. 1 Risk return profiles for a portfolio of two securities, with expected return [4%, 9%] and historical standard deviation [19%, 34%]. The correlation is varied to determine how it affects overall portfolio

willing to take. The second special case is when the securities are perfectly anti-correlated $\rho = -1$, which is the darkest line in Fig. 1. In this case, the total risk in the portfolio can be eliminated; however, this situation does not occur in reality.

Realistic portfolios contain more than two securities, sometimes upward of hundreds. The expected return of a portfolio with N securities is simply

$$R_P = \sum_{i=1}^{N} w_i \mathbf{E}[R_i] \equiv \mathbf{w} \cdot \mathbf{R} \tag{40}$$

and risk

$$\sigma_P = \sqrt{\mathbf{w}^T \Sigma \mathbf{w}} \tag{41}$$

where $\mathbf{w}$ is a vector of portfolio weights whose entries sum to one $\sum_{i=0}^{N} w_i = 1$, and critically Σ is the covariance matrix

$$\Sigma_{ij} = \mathbf{E}\left[\left(R_i - \mathbf{E}[R_i]\right)\left(R_j - \mathbf{E}\left[R_j\right]\right)\right] \tag{42}$$

whose diagonal is the vector of variances of the returns, and off diagonals are the covariance of the returns. The surface cannot be visualized for $N > 3$; however, the risk-return profile can still be plotted on the same axes as the $N = 2$ case above. In this case, there is not simple parametric form for the weights in the portfolio, the return and risk must be determined by sampling the hypersurface defined by the constraint

$$\sum_{i=1}^{N} w_i = 1 \tag{43}$$

Figure 2 demonstrates the efficient frontier for $N = 10$ stocks of varying risk and expected return.

The analysis of securities in this manner became known as modern portfolio theory (MPT).

4.1 The Capital Asset Pricing Model

Even though MPT was a great leap forward, it required the constant calculation of all variances and correlations in the market – a daunting task for the computation power available in the 1950s. In fact, the work of Markowitz did not permeate the investment community for about a decade, when William Sharpe and John Lintner furthered his ideas and developed the capital asset pricing model (CAPM) around 1964 (Sharpe 1964; Lintner 1965). The idea is based on the realization that not all risks in the market are equivalent. There is idiosyncratic risk, which can be hedged away from a portfolio as demonstrated by Markowitz, and systematic risk, which is

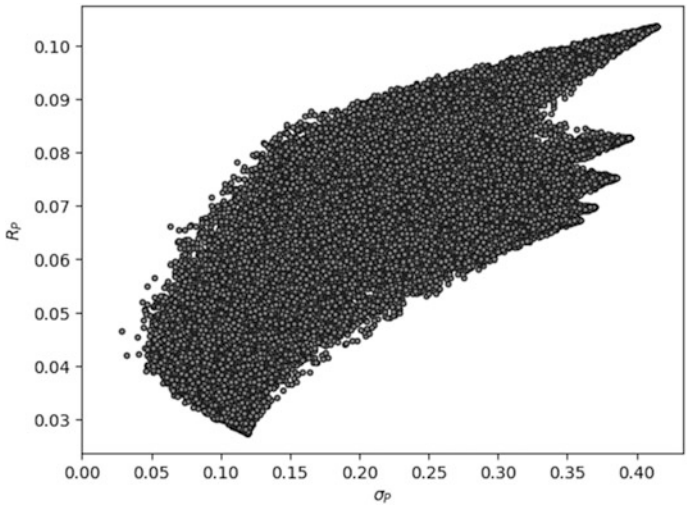

Fig. 2 The efficient frontier of a portfolio of $N = 10$ securities with expected returns [2.74%,4.15%,4.54%,6.57%,6.73%,6.74%,6.97%,7.53%,8.28%,10.38%] and standard deviations [11.95%,15.82%,16.07%,21.19%,35.30%,35.92%,36.98%,38.53%,39.54%,41.48%], using 50,000 sample portfolios, with random correlations between -1 and 1

the risk inherent in the market itself – a risk still present in a truly diversified portfolio. The first is associated with individual company idiosyncrasies, such as the CEO unexpectedly stepping down, or a drug not being approved for mass production. Taking on this type of risk should not be rewarded, since it can be eliminated from a portfolio.

Sharpe realized that there is another asset in the economy that has no risk whatsoever, the treasury bond. A combination of the risk-free asset and a specific portfolio on the efficient frontier will render all other portfolios inadmissible. This market portfolio is called the tangency portfolio, for reasons that will become clear. If the risk-free asset has expected return R_f and the tangency portfolio has return R_t then the expected return of the combined portfolio (investing the fraction ω of the total wealth in the risk-free bond and $(1 - \omega)$ in the tangency portfolio) is simply

$$R_P = R_f + \omega\big(R_t - R_f\big). \tag{44}$$

Sharpe called this the capital market line, the expected return of a portfolio containing both risk-free and risky assets.

> In effect, the market presents him with two prices: the price of time, or the pure interest rate . . . and the price of risk, the additional expected return per unit of risk borne (the. . .slope of the line).

The method of determining the tangency portfolio, as suggested by its name, is to determine the point at which a capital market line is tangent to the efficient frontier.

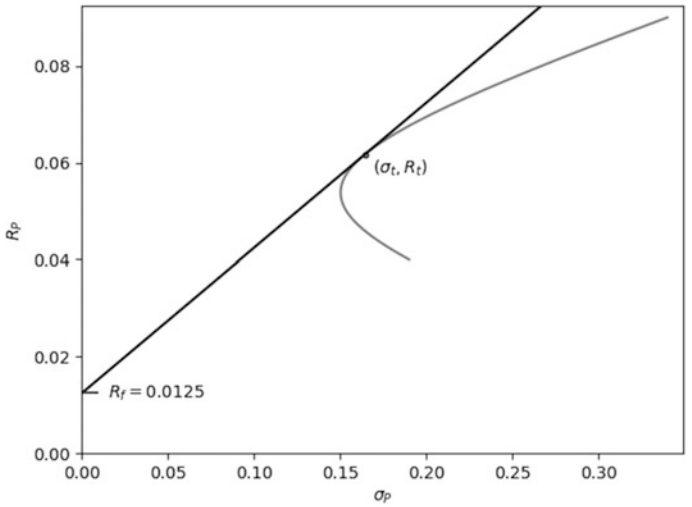

Fig. 3 The efficient frontier of a two security portfolio (expected returns [4%,9%] and standard deviations [19%,34%] with correlation −0.2) together with the tangency capital market line, where the risk-free asset has an expected return of 1.25%. Points past the tangency portfolio represent selling the risk-free asset short (in other words, borrowing money at an interest rate equal to the risk-free rate) and investing more than the investors total wealth in the market portfolio

This combination dominates all other portfolios, in that it has a higher expected return for the given amount of risk, and is shown in Fig. 3.

Sharpe defined the slope of this line as the "market price of risk," and today the ratio of a security's excess return (return above the risk-free rate) to its standard deviation $\frac{R_i - R_f}{\sigma_i}$ is called the Sharpe ratio. The Sharpe ratio can be used to determine the relative expected return per unit of risk for a given portfolio, the higher the Sharpe ratio, the more return an investor expects per unit of risk. The maximum of the Sharpe ratio for all portfolios on the efficient frontier is precisely the tangency portfolio.

In principle, every investor in the market would choose the same tangency portfolio, and for this reason it is also called the market portfolio, and can be thought of as being represented by a broad market index such as the Dow-Jones industrial average or the S&P 500.

So far, nothing has been said about how the individual security's return itself. The CAPM assumes that the Sharpe ratio of an individual security is equal to the market portfolio times the correlation of the security to that portfolio, which can be rearranged to give the security market line (SML)

$$R_i = R_f + \beta\left(R_M - R_f\right) \tag{45}$$

where $\beta = \frac{\rho\sigma_i}{\sigma_M}$. Therefore the excess return of an individual security is equal to the excess return of the market multiplied by the product of the ratio of standard

deviations and the correlation. This can be greater than 1.0 when the correlation is high and the standard deviation of the security is larger than the market, implying that this security's movements will be "amplified" as compared to the market. A $\beta < 1$ implies the opposite, that the security is more subdued than the market.

One could think of the β as a regression coefficient between the returns of the market portfolio and that of the security. In this sense, the CAPM is known as a "one-factor" model, as it ascribes all of the excess return of a security to the market. Fama and French (Fama and French 2004) extend this regression analysis to three factors

$$R_i = R_f + \beta_{iM}\left(R_M - R_f\right) + \beta_{iS}\mathbf{E}[\mathrm{SMB}] + \beta_{ih}\mathbf{E}[\mathrm{HML}] \tag{46}$$

where SMB (small minus big) is the difference between the returns on diversified portfolios of small and big securities (as defined by their market capitalization, or the total value of the shares outstanding) and HML (high minus low) is the difference between the returns on diversified portfolios with high and low book-to-market ratios – the ratio of the "book value" (accounting assets minus liabilities) and its market capitalization (number of shares outstanding multiplied by share price, which gives an estimation of how valuable the market perceives the company to be). This three-factor model performs quite well (Fama and French 2004), and this framework is the basis of modern models used in risk management.

5 1973 Option Pricing: Fischer Black, Myron Scholes, and Robert Merton

Prior to the seminal paper of Black and Scholes (Black and Scholes 1973; Merton 1973), the connection between option prices and differential equations was well known (Samuelson 1965; Sprenkle 1961; Thorp and Kassouf 1967). However, these predecessors typically have unknown parameters, such as the expected return of the underlying security, or a parameter quantifying the investor's risk tolerance, which the authors either attempt to estimate from market data or to derive from other models, such as the CAPM. Occasionally, the formulas were incredibly close to the Black-Scholes, as pointed out by Black and Scholes in their original paper.

Black and Scholes added a key insight based on the general equilibrium behavior of a continuously hedged portfolio with the following argument. Suppose an investor has a portfolio consisting of the option $C(t, S)$ (for ease of notation, the dependence on the maturity T and strike K have been suppressed) plus a short position in an uncertain amount of shares in the stock $\Delta(t)S(t)$

$$V(t) = C(t, S) - \Delta(t)S(t). \tag{47}$$

The investor will continuously change $\Delta(t)$ in order to keep this position instantaneously hedged. By Itō's formula, the change in the portfolio is given by the SDE

$$dV(t) = \frac{\partial C(t,S)}{\partial t}dt + \left(\frac{\partial C(t,S)}{\partial S} - \Delta(t)\right)dS(t) + \frac{1}{2}\frac{\partial^2 C(t,S)}{\partial S^2}d\langle S,S\rangle(t) \quad (48)$$

The distributional assumptions of $S(t)$ are encapsulated in the second condition, which states "the stock price follows a random walk in continuous time with a variance rate proportional to the square of the stock price. Thus the distribution of possible stock prices at the end of any finite interval is lognormal. The variance of the rate of the return on the stock is constant." Today this statement is encapsulated in the SDE

$$dS(t) = \mu S(t)dt + \sigma S(t)dW(t), \quad (49)$$

for some (unknown) drift μ of the underlying stock. The quadratic variation of this process is $S^2(t)\sigma^2 t$ and therefore can be used to simplify Eq. 48

$$dV(t) = \left(\frac{\partial C(t,S)}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 C(t,S)}{\partial S^2}\right)dt + \mu S\left(\frac{\partial C(t,S)}{\partial S} - \Delta(t)\right)dS(t) \quad (50)$$

the last term can be eliminated by taking $\Delta(t) = \frac{\partial C(t,S)}{\partial S}$, and therefore the stochastic part of the portfolio is gone, making this portfolio instantaneously hedged. This implies that the derivative of the option price is the correct number of shares to short in order to perfectly hedge the portfolio, which makes intuitive sense, and was actually posited in the Black-Scholes paper as opposed to derived.

The big insight that Black and Scholes had was that this portfolio is now economically equivalent to a money market account, and therefore by the law of one price, must accumulate interest at the instantaneous rate of interest $dV(t) = rV(t)dt = r(C(t, S) - \Delta(t))$, otherwise an investor could go long an option and short this hedged portfolio and make riskless profits at greater than the risk-free rate. This violates the law of no-arbitrage and therefore the option must have the same value as this hedged portfolio. By equating these and simplifying, the value of the hedged portfolio must be the solution of the celebrated Black-Scholes partial differential equation (PDE)

$$\frac{\partial C(t,S)}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 C(t,S)}{\partial S^2} + rS\frac{\partial C(t,S)}{\partial S} = rC(t,S). \quad (51)$$

Note that the above treatment is not precisely true, as Shreve notes in Exercise 4.10 in Shreve (2004) as $\Delta(t)$ is also a stochastic process and its quadratic variation and covariation with $S(t)$ need to be taken into account. Once this is done, the resulting equation is the same, and this simpler argument is presented here for its clarity of exposition, as well as being true to the original derivation. The argument is cleared up by Merton, which will be presented below.

Black and Scholes state that the solution of this PDE is the celebrated Black-Scholes formula

$$C(t,S) = SN(d_+) - Ke^{-r(T-t)}N(d_-), \tag{52}$$

where $N(x)$ is the standard normal cumulative density and

$$d\pm = \frac{\ln \frac{S}{K} \pm \left(r - \frac{1}{2}\sigma^2(T-t)\right)}{\sigma\sqrt{T-t}}. \tag{53}$$

The hedging argument in Black and Scholes (1973) is then followed by another derivation using CAPM described above. As explained by Merton (Merton 1973)

> . . .the portfolio weights are chosen to eliminate all "market risk." By the assumptions of the capital asset pricing model, any portfolio with a zero ("beta") market risk must have an expected return equal to the risk-free rate. Hence, an equilibrium condition is established between the expected return on the option, the expected return on the stock, and the risk-less rate.

Merton was initially skeptical, and therefore set out to relax some of the conditions set forth in the Black and Scholes paper. He added stochastic interest rates, dividends, and considered both puts and American options. However the most important insight in the paper was noting that the Black-Scholes formula implied that investors could disagree over the expected return of the stock but still agree on the price of an option, a characteristic not present in any previous option formula. For instance in Sprenkle (1961), the option price is tantalizingly close to the BS

$$C(t,S) = aSN(d_+) + (1 - P_e)KN(d_-) \tag{54}$$

$$d_\pm = \frac{\ln \frac{aS}{K} \pm \left(r - \frac{1}{2}\sigma^2(T-t)\right)}{\sigma\sqrt{T-t}}$$

where $a = \mathbf{E}\left[\frac{S(T)}{S(t)}\right]$, the investors expectation of the ratio of the stock price at expiry to the stock price today, and P_e quantified the risk-seeking behavior of the investor, related to how much the investor was willing to pay for leverage/financial risk.

Merton realized that despite the appeal of this characteristic, it must be understood how it comes about without appealing to homogeneous expectations explicit in the CAPM. Merton only assumed that the investors agreed on the variances and covariances of the stochastic stock and bond processes, and not their rates of return.

> This assumption is much more acceptable than the usual homogeneous expectations. It is quite reasonable to expect that investors may have quite different levels of information for current (and future) expected returns due to different levels of information, techniques of analysis, etc. However most analysts calculate estimates of variances and covariances in the same way: namely, by using previous price data. Since all have access to the same price history, it is also reasonable to assume that their variance-covariance estimates may be the same. (Merton 1973)

Merton then constructs a portfolio of the stock, the option, and a bond that matures at the expiry of the option. When this portfolio is made to be instantaneously riskless, a system of equations results that conspire to remove these expectations from the PDE. This concept would later be generalized into the fundamental theorem of asset pricing, formulated by Harrison and Pliska (1981).

This theorem connects arbitrage freedom with complete markets and martingale measures. A complete market is one in which there are enough securities to construct hedging portfolios for all possible contingent claims (otherwise known as derivatives) in the market. In the Black-Scholes discussion above, the option could be hedged exactly because it shares the same source of risk as the underlying stock. So a complete market has enough "sources of risk" to hedge the risks of all traded derivatives.

The fundamental theorem of asset pricing states that if a market is complete then there is no arbitrage and there exists a probability measure under which a discounted security price is a martingale, which is the probabilistic measure theory terminology for Bachelier's "principal of mathematical expectation," namely that the expectation of the future quantity is today's value. Therefore the fundamental theorem of asset pricing states that the discounted future value of the portfolio is a martingale

$$D(0,t)V(t) = \mathbf{E}[D(0,T)V(T) \mid \mathcal{F}_t]. \tag{55}$$

The probability measure under which this expectation is taken is known as the risk neutral measure.

While this is mathematically true, and extremely useful in finance, some disagree that this should be called a fundamental theorem.

> Finances objects of interest markets, money, assets, and securities are also abstractions. The aim of finance is finding true relationships between the abstractions they represent, and hence between the realities they should be pinned to. In that sense, like physics, finance cannot be a branch of mathematics. Finance could conceivably have a fundamental law *Money tends to flow into the hands of people who will let it reproduce most rapidly* might be one but it surely cannot have a fundamental theorem, for the world is not conditional. Derman (2013)

6 October 19, 1993

If there is 1 day that changed the future of quant finance, and therefore by consequence, the way in which capital gets allocated on Wall street, it is October 19, 1993. This is the day that the US Congress canceled funding for the Texas Superconducting Super Collider (SSC).

The SSC was a particle accelerator designed to probe energies higher than Large Hadron Collider at CERN and therefore explore physics at a smaller scale. The goal was noble, to determine whether the standard model of particle physics – the most successful physical theory ever conceived by humanity – was correct. It was

approved in May 1990 and construction began in early 1993 and thousands of academic positions were created and filled.

Once the project was canceled by Congress, these thousands of professional physicists were released into an academic marketplace that did not have the capacity to adsorb this magnitude of people. This army of people with advanced degrees started looking elsewhere to apply their skills. This was over 20 years after the Black-Scholes seminal paper and when options first started trading on exchanges at the Chicago Board of Options Exchange (CBOE) so there was definitely an understanding that mathematicians and physicists could add value to Wall Street firms and banks. And hence the first great influx of nonfinance PhDs migrated to Wall Street.

7 1947 Modern Techniques of Quantitative Finance: The Feynman-Kac Theorem

This chapter will now pivot from a historical perspective of the mathematics ideas that altered the way capital was allocated to the modern mathematical techniques used in quantitative finance, which will help explain why applied mathematicians and physicists find it a natural home. There is a deep link between stochastic calculus, Monte Carlo, and partial differential equations, all three being welded together in what is known as the Feynman-Kac Theorem.

At Cornell University in 1947, physicist Richard Feynman presented results from his thesis on the path integral approach to quantum mechanics, work for which he later shared the 1965 Nobel prize. Mark Kac, a Polish American mathematician was in the audience and approached Feynman afterwards remarking that the two of them were working on the same problem from a differing point of view. After a few days of calculation, Kac had connected his probabilistic approach to the Feynman path integral approach, thus discovering the Feynman-Kac formula. Kac was impressed by Feynman, stating "It is only fair to say that I had Wiener's shoulders to stand on. Feynman, as in everything else he has done, stood on his own, a trick of intellectual contortion that he alone is capable of."

The Feynman-Kac formula relates expectation values to the solutions of partial differential equations (PDEs) and thus gives the connection between random stock movements and the heat equation (Kac 1949). On one side is an expectation value – which can be calculated using Monte Carlo methods – whereas on the other is a PDE, whose solution is the expected value.

Although very difficult to prove, the formula can be motivated by topics already covered in this chapter. Suppose a random variable obeys the SDE

$$dX(t) = \mu(X(t), t)dt + \sigma(X(t), t)dW(t), \tag{56}$$

which is Markov as can be seen by its integral form

$$X(T) = X(t) + \int_t^T \mu(X(s), s)ds + \int_t^T \sigma(X(s), s)dW(s) \tag{57}$$

since it only depends on the initial point $X(t)$ and not by any of the previous values.

Consider today's expectation of the time T value of a function of the stochastic variable

$$C(t,X(t)) = \mathbf{E}[\phi(X(T))\,|\,\mathcal{F}_t]. \tag{58}$$

This too will be Markov since it also has a SDE by Itō's formula, namely

$$dC(t,X(t)) = \left(\frac{\partial C(t,X(t))}{\partial t} + \mu(X(t),t)\frac{\partial C(t,X(t))}{\partial x} + \frac{1}{2}\frac{\partial^2 C(t,X(t))}{\partial x^2}\sigma^2(X(t),t)\right)dt + \frac{\partial C(t,X(t))}{\partial x}\mu(X(t),t)dW(t) \tag{59}$$

and therefore the expectation satisfies the Chapman-Kolmogorov equation. This equation states that, for Markov processes, the transition probability $\rho(xztT)$, which gives the probability that the random variable starting at $X(t) = x$ at time t transitions to the value $X(t) = z$ at time $T > t$ can be calculated by introducing an intermediate time s, where $t < s < T$, and summing over all possible intermediate states

$$\rho(xztT) = \int_{-\infty}^{\infty} \rho(xyts)\rho(yzsT)dz \tag{60}$$

By writing the expectation 58 as an integral, and introducing the Chapman-Kolmogorov equation (and letting $y = X(s)$)

$$C(t,x) = \int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty}\phi(z)\rho(yzsT)dz\right]\rho(xyts)dy. \tag{61}$$

The term inside the square brackets is precisely the expectation at the intermediary time $C(s,X(s)) = \mathbf{E}[\phi(X(T))\,|\,\mathcal{F}_s]$ and therefore the expectation itself is a martingale

$$C(t,X(t)) = \mathbf{E}[C(s,X(s))\,|\,\mathcal{F}_t]. \tag{62}$$

Since it is a Martingale, the drift term in Eq. 59 must vanish, therefore

$$\frac{\partial C(t,x)}{\partial t} + \mu(X(t),t)\frac{\partial C(t,X(t))}{\partial x} + \frac{1}{2}\frac{\partial^2 C(t,x)}{\partial x^2}\sigma^2(x,t) = 0 \tag{63}$$

with boundary condition $C(T, x) = \phi(x)$.

The original Feynman-Kac theorem was stated more generally than Eq. 58, specifically the expectation value

$$C(t,x) = \mathbf{E}\left[\int_t^T e^{-\int_t^s V(X(\tau),\tau)d\tau} f\big(X(s),s\big)ds + e^{-\int_t^T V(X(\tau),\tau)d\tau}\phi(X(T))\,|\,X(t)=x\right], \tag{64}$$

where the stochastic process obeys the same SDE 56, is the solution to the differential equation

$$\frac{\partial C(t,x)}{\partial t} + \mu(x,t)\frac{\partial C(t,x)}{\partial x} + \frac{1}{2}\sigma^2(x,t)\frac{\partial^2 C(t,x)}{\partial x^2} - V(x,t)C(t,x) + f(x,t) = 0. \tag{65}$$

The function $f(x,\ t)$ can represent cashflows before maturity, if a bond pays $c \times P$ at times t_i then $f(x,\ t) = \sum_i cP\delta(t - t_i)$, and pays P at maturity $\phi(X(T)) = P$ then the expectation becomes

$$C(t,x) = \sum_i cP\mathbf{E}\left[e^{-\int_t^{t_i} V(X(\tau),\tau)d\tau}\right] + P\mathbf{E}\left[e^{-\int_t^T V(X(\tau),\tau)d\tau}\right] \tag{66}$$

from which $V(X(t),\ t)$ can be identified as the stochastic term structure of interest rates. Indeed the Black-Scholes Eq. 51 is identical to Eq. 65 with $V(x,\ t) = r$ and $f(x,\ t) = 0$.

The Feynman-Kac theorem connects expectation values to partial differential equations – simulating a process is equivalent to solving a PDE. As with any PDE, a closed form solution only exists in a small number of situations, which is fortunately the case in the Black-Scholes model. In other situations, the PDE must be solved numerically. However, when the dimensionality is high – which occurs for basket options where the derivative payoff depends on many securities and therefore many stochastic factors – solving the PDE numerically becomes too computationally expensive and therefore the left-hand side of the Feynman-Kac theorem can be used to simulate the stochastic processes using a numerical technique called Monte Carlo Simulation, a technique developed at Los Alamos during World War II (Metropolis et al. 1953).

8 1977 Monte Carlo Methods: Phelim Boyle

Phelim Boyle earned a PhD in physics from Queens University Belfast in 1960, before the watershed event in quant finance. Therefore there was no established path from physics to finance, and therefore Phelim became an actuary – a mathematical discipline that still attracts physics graduates to this day. Boyle published a seminal paper in quantitative finance (Boyle 1977), introducing Monte Carlo methods to the field.

The Black-Scholes model is one of a small number of models that permit a closed-form such a way that the ultimate payoff depends not only on the value of the stochastic factor at maturity, but also the entire path of the stochastic factor, then the price of this option is not Markov, and the mathematical machinery so far

described will not be applicable. The entire path of the stochastic process must be known, and this is precisely what Boyle described.

The Monte Carlo price of a derivative security is the simple average over all realizations of random variables

$$\mathbf{E}\left[f(S(T))\,|\,\mathcal{F}_t\right] \approx \frac{1}{N}\sum_{i=0}^{N} f(S_i) \tag{67}$$

as long as the random variables are sampled using the correct distribution, coming from the SDE of the underlying. For instance, the SDE for a lognormal distribution

$$dS(t) = S(t)rdt + \sigma S(t)dW(t) \tag{68}$$

by the transformation $X(t) = \ln S(t)$ and an application of Itō's formula

$$X(T) = X(t) + \left(r - \frac{1}{2}\sigma^2\right)(T-t) + \sigma(W(T) - W(t)), \tag{69}$$

leading to

$$S(T) = S(t)\exp\left(\left(r - \frac{1}{2}\sigma^2\right)(T-t) + \sigma(W(T) - W(t))\right). \tag{70}$$

Recall that the increments of a Brownian process are normally distributed with zero mean and variance equal to the time increment. Therefore a simple Monte Carlo on a European call option can be computed

$$C(t,S) \approx \sum_{i=0}^{N} \max\left[S(t)\exp\left(\left(r - \frac{1}{2}\sigma^2\right)(T-t) + \sigma\sqrt{T-t}z_i\right) - K, 0\right] \tag{71}$$

where the $z_i \sim \mathcal{N}(0,1)$ are standard normal variates. Of course this integral can be performed exactly leading again to the Black-Scholes formula; however, if there are any "exotic" features of the option, the integral does not admit a closed form solution. These exotic features could be as simple as the ability to exercise the option at any time up until maturity – so-called American style options – or the payoff depending on an average of the stock price throughout the lifetime of the option – so-called Asian style options. In these cases, the Monte Carlo procedure can still be used, as it provides a method to sample not only the underlying at maturity, but also to create a path that the underlying takes. In this case the SDE is interpreted literally, for example the simplest approach to generating a path is the Euler method (a name borrowed from the simplest method to solve a differential equation)

$$S(t+\Delta t) \approx S(t)\left(r - \frac{1}{2}\sigma^2\right)\Delta t + \sigma\sqrt{\Delta t}z_0 \tag{72}$$

where $z_0 \sim \mathcal{N}(0,1)$ is a standard normal variate. This process can then be iterated to determine a possible path for the underlying $S(t)$ up until maturity.

In this way, the entire path of the security can be computed, and the price of path-dependent options can be calculated statistically by taking the average over a large number of simulations. The more simulations performed, the higher the accuracy as the standard deviation of the resulting mean is proportional to $N^{-1/2}$, where N is the number of simulations.

9 1978 Partial Differential Equations: Eduardo Schwartz and Michael Brennan

Pricing options with early termination features are not possible in closed form, as again the price of the option will not be a Markov process. In order to determine the arbitrage-free price of the option in this case, one could use the Monte Carlo technique pioneered by Philem Boyle; however, this method suffers from inaccuracies due to its random nature. Another method is commonly used when early exercise is possible, and the number of stochastic factors are low, namely solving the PDE numerically.

In order to discretize the Black-Sholes PDE 51, following Brennan and Schwartz (1978), a log transformation $y = \ln(S)$ is first applied to make the PDE have constant coefficients, and the time is transformed to be relative to maturity $\tau = T - t$. The resulting PDE

$$\frac{\partial C(\tau, y)}{\partial \tau} = \left(r - \frac{1}{2}\sigma^2\right)\frac{\partial C(\tau, y)}{\partial y} + \frac{1}{2}\sigma^2\frac{\partial^2 C(\tau, y)}{\partial y^2} - rC(\tau, y) = 0 \tag{73}$$

is cast as an operator equation

$$\frac{\partial C(\tau, y)}{\partial \tau} = \mathcal{L}\, C(\tau, y) \tag{74}$$

where $\mathcal{L} = \left(r - \frac{1}{2}\sigma^2\right)\frac{\partial}{\partial y} + \frac{1}{2}\sigma^2\frac{\partial^2}{\partial y^2} - r$. The "spatial" variable (the value of the underlying stochastic process) is discretized into an evenly spaced grid with spacing $\Delta y : y \to j\Delta y, j \in [0, N]$. The differential operator is replaced by a second-order discrete operator

$$\mathcal{L} \to \left(r - \frac{1}{2}\sigma^2\right)\left[\frac{\delta_{+1} - \delta_{-1}}{2\Delta y}\right] + \frac{1}{2}\sigma^2\left[\frac{1}{2}\,\frac{\delta_{-1} - 2\delta_0 + \delta_{+1}}{\Delta y^2}\right] + r, \tag{75}$$

where δ_n is an operator that discretely moves the value of y, $\delta_n C(t, y_j) = C(t, y_{j+n})$.

Time is also discretized with spacing $\Delta t\, \tau \to \tau_i = i\Delta t, i \in [-M, M]$, $\frac{\partial C(\tau, y_j)}{\partial \tau} \to \frac{C(\tau_{i-1}, y_j) - C(\tau_i, y_j)}{\Delta t}$. The index M is chosen by asymptotic considerations, and will depend on the boundary condition handling described later. There is a choice as to which time step appears in the function acted upon by the differential operator, which lead to three different methods of numerically solving the PDE. These γ "stencils," are (where $C_{ij} \equiv C(\tau_i, y_j)$).

1. Explicit

$$\frac{C_{i-1,j} - C_{ij}}{\Delta t} = \mathcal{L}C_{ij} \tag{76}$$

2. Implicit

$$\frac{C_{i-1,j} - C_{ij}}{\Delta t} = \mathcal{L}C_{i-1,j} \tag{77}$$

3. Crank-Nicolson

$$\frac{C_{i-1,j} - C_{ij}}{\Delta t} = \frac{1}{2}\left(\mathcal{L}C_{i-1,j} + \mathcal{L}C_{ij}\right) \tag{78}$$

The three stencil choices are depicted graphically in Fig. 4. Essentially, the time at which the τ derivative is taken is different in the three methods. The explicit uses the backwards finite difference approximation based at τ_{i+1}, the implicit the forward approximation based at τ_i, and the Crank-Nicolson uses the centered approximation based at the mid-point $\frac{1}{2}(\tau_{i+1} + \tau_i)$. The centered approach is best from the accuracy (in time) point of view, because centered finite differences are second-order approximations and have error $O(\Delta\tau^2)$, whereas the forward and backward have error $O(\Delta\tau)$, see Andersen and Piterbarg (2010) for details.

In the fully explicit case, the discretized equations become

$$\frac{C_{i+1,j} - C_{i,j}}{\Delta t} = \left(r - \frac{1}{2}\sigma^2\right)\left(\frac{C_{i,j+1} - C_{i,j-1}}{2\Delta y}\right) + \frac{1}{2}\sigma^2\left(\frac{C_{i,j-1} - 2C_{i,j} + C_{i,j}}{\Delta y^2}\right) - rC_{i,j}. \tag{79}$$

Since $C_{0,j}$ is the payoff, this equation can be cast entirely in terms of known quantities – hence the "explicit" title – and solved forwards in time (recall that $\tau = T - t$, so the option is being priced backwards in time).

Of course these techniques were well known prior to the Black and Scholes formula; however in 1978, Micheal Brennan and Eduardo Schwartz found an interesting connection between the numerical procedures and jump diffusion

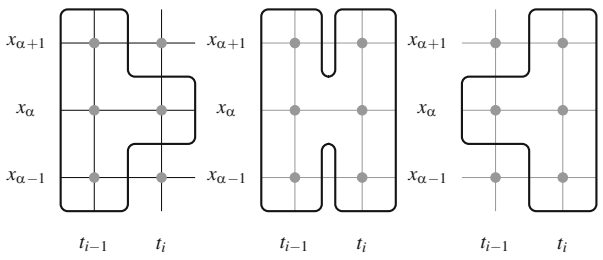

Fig. 4 Options for discretization for numerically solving a partial differential equation. From right to left, the implicit, Crank-Nicolson, and explicit methods

processes (Brennan and Schwartz 1978). They noted in this explicit case, the solutions to the equations are of the form

$$C_{i-1,j} = \frac{1}{1+r\Delta t}\left[p_+ C_{i,j+1} + pC_{ij} + p_- C_{i,j-1}\right] \tag{80}$$

where

$$p_\pm = \left[\frac{1}{2}\left(\frac{\sigma}{\Delta x}\right)^2 \pm \frac{1}{2\Delta x}\left(r - \frac{1}{2}\sigma^2\right)\right]\Delta t \tag{81}$$

$$p = \left[1 - \left(\frac{\sigma}{\Delta x}\right)^2\right]\Delta t. \tag{82}$$

Since $\sum_i p_i = 1$, Brennan and Schwartz point out that these equations are identical to a stochastic jump model that had been written down by Cox and Ross in 1976 (Cox and Ross 1976), and therefore the implicit PDE approach can be thought of as taking discounted estimations in a jump diffusion model, where the price can jump to one of three states.

Brennan and Schwartz also show that the fully implicit case, which is more complicated, also describes a stochastic jump diffusion process, however with infinite states. The ultimate price of a derivative security can be written in a form of a discounted expectation in a jump diffusion model

$$C_{i-1,j} \approx \frac{1}{1+rk}\sum_{q=-\infty}^{\infty} p_q^* C_{i,j+q} \tag{83}$$

where $\sum_{q=-\infty}^{\infty} p_q^* = 1$ and can be interpreted as the probability that the logarithm of the underlying security price jumps to y_q.

Brennan and Schwartz omit the Crank-Nicolson case, where the equations have the highest accuracy, without sacrificing any computational speed – as the matrices are still tridiagonal. To see this, the discretized equations

$$\begin{aligned}\frac{C_{i+1,j} - C_{i,j}}{\Delta t} = &\frac{1}{2}\left[\left(r - \frac{1}{2}\sigma^2\right)\left(\frac{C_{i,j+1} - C_{i,j-1}}{2\Delta y}\right) + \frac{1}{2}\sigma^2\left(\frac{C_{i,j-1} - 2C_{i,j} + C_{i,j}}{\Delta y^2}\right) - rC_{i,j}\right] \\ &+\frac{1}{2}\left[\left(r - \frac{1}{2}\sigma^2\right)\left(\frac{C_{i+1,j+1} - C_{i,j-1}}{2\Delta y}\right) + \frac{1}{2}\sigma^2\left(\frac{C_{i+1,j-1} - 2C_{i+1,j} + C_{i+1,j}}{\Delta y^2}\right) - rC_{i+1,j}\right],\end{aligned} \tag{84}$$

can be simplified to

$$\begin{aligned}&C_{i+1,j-1}\left(-\frac{a}{4} + \frac{b}{2}\right) + C_{i+1,j}\left(1 - \frac{r\Delta t}{2} - b\right) + C_{i+1,j+1}\left(\frac{a}{4} - \frac{b}{2}\right) = \\ &C_{i,j-1}\left(\frac{a}{4} - \frac{b}{2}\right) + C_{i,j}\left(1 + \frac{r\Delta t}{2} + b\right) + C_{i,j+1}\left(-\frac{a}{4} - \frac{b}{2}\right),\end{aligned} \tag{85}$$

where

$$\begin{aligned} a &= \frac{\left(r - \frac{1}{2}\sigma^2\right)\Delta t}{\Delta x} \\ b &= \frac{\sigma^2 \Delta t}{2\Delta x^2}. \end{aligned} \tag{86}$$

These equations can be cast in matrix form in the interior of the system

$$A\mathbf{C_{i+1}} = B\mathbf{C_i}. \tag{87}$$

However to implement this on a computer, the spatial boundary conditions $j \in \{-M, M\}$ must be handled, and there are many ways of approaching this. For very simple options, the value at the edge of the matrix can be replaced by the value of the payoff. However this method has two drawbacks, first it only applies to situations where there is no early exercise so cannot be applied generally, and second care must be taken that the equation is truly in the asymptotic region, and could therefore could be computationally expensive. Second, one could impose some smoothness of the solution, such as imposing that the second derivative vanishes

$$\frac{\partial^2 C_{i+1,\pm M}}{\partial y^2} = 0, \tag{88}$$

which is more general and can be applied in more situations, such as early exercise, however still imposes a careful asymptotic analysis is done and therefore could require a larger spatial grid. Finally, a method that overcomes both can be used where the equations themselves determine the boundary condition, with the drawback that the matrix is no longer tridiagonal and therefore less efficient computational methods are required to be used.

Since there are no nodes past the boundaries, the centered finite difference approximations 75 can no longer be used. In order to continue to have $O(\Delta y^2)$ accuracy at the boundaries, a higher order purely forward and backward finite difference approximation must be used. At the lower boundary, all translation operators δ_n must move back into the grid and therefore be positive

$$\begin{aligned} \left.\frac{\partial}{\partial y}\right|_{y=-(M+1)\Delta y} &\to \frac{1}{2\Delta y}\left[-3\delta_0 + 4\delta_1 - \delta_2\right] + O\left(\Delta y^2\right) \\ \left.\frac{\partial^2}{\partial y^2}\right|_{y=-(M+1)\Delta y} &\to \frac{1}{\Delta y^2}\left[2\delta_0 - 5\delta_1 + 4\delta_2 - \delta_3\right] + O\left(\Delta y^2\right). \end{aligned} \tag{89}$$

On the other hand, the maximum grid nodes must be translated downwards in order to remain in the grid

$$\begin{aligned}\left.\frac{\partial}{\partial y}\right|_{y=(M+1)\Delta y} &\to \frac{1}{2\Delta y}[3\delta_0 - 4\delta_{-1} + \delta_{-2}] + O(\Delta y^2)\\ \left.\frac{\partial^2}{\partial y^2}\right|_{y=M+1\Delta y} &\to \frac{1}{\Delta y^2}[2\delta_0 - 5\delta_{-1} + 4\delta_{-2} - \delta_{-3}] + O(\Delta y^2).\end{aligned} \tag{90}$$

The trick is to add one more point just outside the grid using this technique and keep track of this "ghost" node ($j = M + 1$) at each iteration. The boundary matrix elements in 87 are augmented to be

$$\begin{aligned}A_{i,-M} &= \left(1 - \frac{r\Delta t}{2} - b + \left(-a + \frac{5}{2}b\right)c_1\right)\\ A_{i,-M+1} &= \left(\frac{1}{4}a + \frac{1}{2}b + \left(\frac{1}{4}a - 2b\right)c_1\right)\\ A_{i,-M+2} &= \frac{1}{2}bc_1\\ B_{i,-M} &= \left(1 + \frac{r\Delta t}{2} + b - \left(-a + \frac{5}{2}b\right)c_1\right)\\ B_{i,-M+1} &= \left(-\frac{1}{4}a - \frac{1}{2}b - \left(-\frac{1}{4}a - 2b\right)c_1\right)\\ B_{i,-M+2} &= -\frac{1}{2}bc_1\end{aligned} \tag{91}$$

where

$$c_1 = \frac{\left(-\frac{a}{4} + \frac{b}{2}\right)}{1 - \frac{r\Delta t}{2} - \frac{3}{4}a + b}. \tag{92}$$

The matrix at the upper bound must be similarly altered

$$\begin{aligned}A_{i,M} &= \left(1 - \frac{r\Delta t}{2} - b + \left(a + \frac{5}{2}b\right)c_2\right)\\ A_{i,M-1} &= \left(-\frac{1}{4}a + \frac{1}{2}b + \left(-\frac{1}{4}a - 2b\right)c_2\right)\\ A_{i,M-2} &= \frac{1}{2}bc_2\\ B_{i,M} &= \left(1 + \frac{r\Delta t}{2} + b - \left(a + \frac{5}{2}b\right)c_2\right)\\ B_{i,M_1} &= \left(\frac{a}{4} - \frac{b}{2} - \left(-\frac{1}{4}a - 2b\right)c_2\right)\\ B_{i,M-2} &= -\frac{1}{2}bc_2\end{aligned} \tag{93}$$

where

$$c_2 = \frac{\left(\frac{a}{4} + \frac{b}{2}\right)}{1 - \frac{r\Delta t}{2} + \frac{3}{4}a + b}. \tag{94}$$

The ghost node at the lowest edge of the grid evolves according to

$$\begin{aligned} C_{i+1,-(M+1)}\left(1 - \frac{r\Delta t}{2} - \frac{3}{4}a + b\right) &= C_{i,-(M+1)}\left(1 - \frac{r\Delta t}{2} - \frac{3}{4}a + b\right) \\ &+ C_{i+1,-M}\left(-a + \frac{5}{2}b\right) + C_{i+1,-M+1}\left(\frac{1}{4}a - 2b\right) \\ &+ C_{i+1,-M+2}\frac{1}{2}b + C_{i,-M}\left(-a + \frac{5}{2}b\right) \\ &+ C_{i,-M+1}\left(\frac{1}{4}a - 2b\right) + C_{i,-M+2}\frac{1}{2}b \end{aligned} \tag{95}$$

and at the maximum

$$\begin{aligned} C_{i+1,M+1}\left(1 - \frac{r\Delta t}{2} + \frac{3}{4}a + b\right) &= C_{i,M+1}\left(1 + \frac{r\Delta t}{2} - \frac{3}{4}a - b\right) + C_{i+1,M}\left(a + \frac{5}{2}b\right) \\ &+ C_{i+1,M-1}\left(-\frac{1}{4}a - 2b\right) + C_{i+1,M-2}\frac{1}{2}b \\ &+ C_{i,M}\left(a + \frac{5}{2}b\right) + C_{i,M-1}\left(-\frac{1}{4} - 2b\right) + C_{i,M-2}\frac{1}{2}b. \end{aligned} \tag{96}$$

Finally, the evolution equation to solve including boundary conditions is

$$A\mathbf{C_{i+1}} = B\mathbf{C_i} + \mathbf{g} \tag{97}$$

where the vector $\mathbf{g}$ is zeros except for the maximum and minimum entries

$$\begin{aligned} g(M) &= C_{i,M+1}\left(-\frac{a}{4} - \frac{b}{2} - \left(1 + \frac{r\Delta t}{2} - \frac{3}{4}a - b\right)c_2\right) \\ g(-M) &= C_{i,-(M+1)}\left(\frac{a}{4} - \frac{b}{2} - \left(1 + \frac{r\Delta t}{2} + \frac{3}{4}a - b\right)c_1\right). \end{aligned} \tag{98}$$

Thus, the PDE can be solved easily by numerical means, as A is the only matrix that needs to be inverted, and this maintains its tridiagonal nature for all the boundary conditions described above.

10 Conclusions

This chapter has explored the mathematical ideas that changed how capital was allocated – although the history of financial risk was deliberately omitted despite it being central to modern portfolio construction, since it is a topic deserving of its own treatment and chapter.

Interest rates, and thus the time value of money, are a concept that predates writing – likely dating to the onset of the agricultural transition over 12,000 years ago. It is fascinating to note that the first discovered set of codified laws include a cap on interest rates and rules regulating borrowing and lending – the first banking regulations were included in the first historical set of laws.

The full power of the time value of money was not realized until 1202 when Fibonacci demonstrated that capital allocation decisions could be made using net present value analysis. Together with the law of one price and the value of the firm, Fibonacci revolutionized the way trade was done in the thirteenth century. It has been argued that a well-developed financial and commercial system was a key prerequisite for the Italian renaissance and enlightenment.

Between the thirteenth and twentieth centuries, mathematics evolved immensely, but curiously finance did not. It was not until Louis Bachelier's thesis, defended on March 29, 1900, that the machinery of advanced mathematics was applied to the financial markets. Even then it took another 50 years for the mathematics in Bachelier's thesis to be put on a solid analytical footing. Incredibly, Bachelier must have intuited many of the mathematical advancements in the twentieth century, including stochastic calculus and the analytical foundations of probability theory. Although many of the great mathematicians had worked on probability theory prior to the twentieth century, it was only put on a solid analytical foundation by Kolmogorov, much like Cauchy, Reimann, and Weierstrauss only put calculus on a solid mathematical foundation after hundreds (if not thousands) of years of use.

In 1953, Harry Markowitz came out with "Portfolio Selection" and a whole new quantitative method was introduced for deciding which investments enter into portfolios. From there, the capital asset pricing model was born and mathematical methods became a necessary tool for investing. Prior to Markowitz, correlations were understood as important; however, it was believed that all risk could be removed from a portfolio with enough diversity. Therefore, mathematical tools, such as covariance analysis, were not evident in the asset selection process. Although not used by asset managers in their original form, the modern portfolio theory and CAPM are still subjects that are taught, and many concepts deriving from these ideas, such as the Sharpe ratio, are still commonly used as portfolio metrics today.

In 1973, the mathematical toolkit used by asset managers to grow to include advanced mathematics, as the price of an option was shown to be the solution of a partial differential equation (although almost certainly this was known to Thorpe prior to the Black-Scholes paper), a mathematical object not regularly taught in finance nor economic curricula. The amazing thing about the Black-Scholes option price was not that it can be derived using the same mathematics that governs how

heat diffuses, but that it did not contain any unobservable quantities, such as the investors expectation, or their risk aversion. Incredulous, Robert Merton set to rederive the results and found that this was the case, introducing the ideas that would later lead to the fundamental theorem of asset pricing written down by Harrison and Pliska.

Tools from mathematical physics and applied mathematics are being applied constantly to the complex world of financial derivatives, and some early methods have been presented in this chapter. New mathematical ideas are continuously being applied to quantitative finance. As of the writing of this chapter, machine learning and artificial intelligence are just being tested as a way to allocate capital and hedge derivatives (Hutchinson et al. 1994; Buehler et al. 2019). Thus, the future of quantitative finance may look very different from its past.
