The confluence of practical, historical, and philosophical instances of probability is represented, here, as a problem. A simple problem, really, but the investigation of said problem is purposely presented in a manner that raises practical, historical, and philosophical problems. In this instance, while solving the problem, different individuals differently become privy to different information. At first glance, no problem. Upon further inspection, probabilistic implications are revealed. After-all, while, yes, the Four of Hearts is the Four of Hearts, it is also a four of hearts. In other words, it is, concurrently, many things (not a queen, a four, a red card, not a spade, etc.). This information, while appearing mundane, becomes important to consider when examining different answers to the problem. As one might expect, having two people, standing right next to or across from each other, both staring at the same deck of cards, but with different probabilities that the next card drawn is a queen, can be a recipe for disaster. It can also be a window into how information about events is interpreted and shared. A probabilistically rooted answer to an enduring question: Do you see what I see? Well, let's do the math.

At the confluence of practical, historical, and philosophical instances of probability, for me, is a problem, technically, two problems. These two problems beget numerous other problems.

Here is the first problem:

> A card is drawn from the deck, the card is replaced, and a second card is drawn from the deck. What is the probability that the second card drawn is a queen?

The answer to the first problem is 4/52 or 1/13.

Here is the second problem:

> A card is drawn from the deck, the card is not replaced, rather, it is placed face down beside the deck, and a second card is drawn from the deck. What is the probability that the second card drawn is a queen?

The answer to the second problem is, of course, 4/52 or 1/13.

Beginning begotten problems, these two problems, taken in concert, present answers that are counterintuitive in nature, albeit not for everyone. Given the long history of counterintuitive probability problems (e.g., Problem of Points, Monty Hall Problem, The Two Child Problem, Birthday Problem, Bertrand's Box Paradox, and many, many others) running into a counterintuitive probability problem should come as no surprise. Given the prominent plethora of research questioning whether or not humans are intuitive statisticians (e.g., Kahneman and Tversky 1972 and many others) also adds to a lack of surprise. As Sir David Spiegelhalter succinctly noted in his commendation for *Probabilistic Thinking: Presenting Plural Perspectives* (Chernoff and Sriraman 2014), "I often get asked why people find probability so unintuitive and difficult. After years of research, I have concluded it's because probability really is unintuitive and difficult." Therefore, getting back to the counterintuitive situation at hand, and a little more specific, that the answer for the first problem, a probability question *with* replacement, is the same as the answer for the second problem, a probability question *without* replacement, rattles what Fischbein (1975) denotes as a *secondary intuition*, that is, an intuition built up through the process of schooling.

Typically, as documented in research regarding the teaching and learning of mathematics, *replacement* is a trigger warning for independent events, whereas *no replacement* triggers dependent events. Quasi-conversely, independent events get associated with replacement and dependent events with no replacement. Those grappling with their schooled intuition for 4/52 being the answer for both a problem with replacement, and also a similar problem without replacement, can defer to a calculation to help alleviate concerns that "obviously" the answer to the second problem is 4/52.

$$\begin{aligned}
P(Q2) &= P(Q1 \text{ and } Q2 \text{ or } \neg Q1 \text{ and } Q2) \\
&= P(Q1 \times Q2) + P(\neg Q1 \times Q2) \\
&= (4/52 \bullet 3/51) + (48/52 \bullet 4/51) \\
&= (4/52 \bullet 3/51) + (4/52 \bullet 48/51) \\
&= 4/52(3/51 + 48/51) \\
&= 4/52(51/51) \\
&= 4/52(1) \\
&= 4/52
\end{aligned}$$

Comforted with a cold calculation, further problems emerge from an extension of the second problem. Consider, for example, a card is drawn from the deck, the card is not replaced, rather, it is placed face down beside the deck; a second card is drawn from the deck, which is also not replaced, rather, it is placed face down beside the first card that was not replaced; then, a third card is drawn from the deck. What is the probability that the third card drawn is a queen? The answer is, which can also be confirmed by those who take a moment to attend to the more laborious calculation for this case, 4/52 or 1/13. Extending the problem along the same line of reasoning, that is, three cards drawn and placed face down beside each other, beside the deck, the probability that the fourth card drawn is a queen is 4/52 or 1/13. Not looking to continue the extension solely for the purpose of completing further and further crass calculations, we stop this particular extension path at the fourth version of the problem, as witnessed in Fig. 1, which provides the backdrop for the emergence of a new set of problems.

Up until this point, the largest hurdle to establishing that the fourth card drawn from the deck being a queen is 4/52 is a shaking off of a secondary intuition, one rooted in a school-based understanding of dependent and independent events, and keeping track of a bunch of fractions, whether with pencil and paper or some form of technology aiding the calculation. However, more problems emerge – practical, historical, and philosophical problems – when conditioning events get considered.

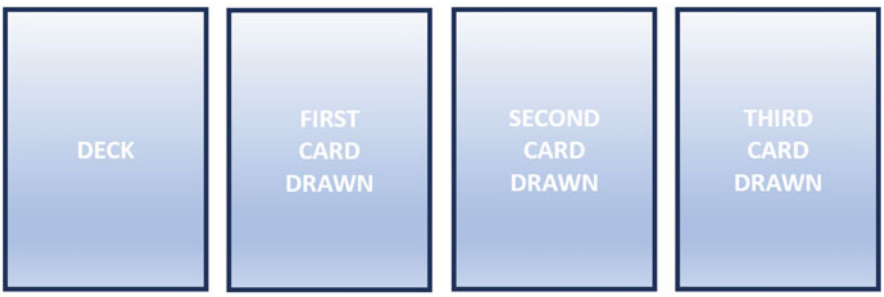

Fig. 1 Deck of cards (left). The three drawn cards and not replaced, rather, placed next to the deck and each other (right)

Imagine, as a new problem, two individuals taking part in the above scenario, as detailed in Fig. 1. Let us call them Thomas and Blaise. At the moment, for both individuals, the probability that the fourth card drawn is a queen is 4/52. However, let us now imagine a scenario, a practical scenario, were one of the two individuals, Thomas, curious about the cards placed beside the deck, casually picks up, say, the first card drawn and placed next to the deck, takes a look at the card, and then places it back where they got it from. At this point, the probability that the fourth card drawn is a queen remains 4/52 for Blaise; however, the probability that the fourth card drawn is a queen may now be different for Thomas, the one who picked up and took a look at the face of that first card drawn from the deck. Now there are two different individuals with two different probabilities for the fourth card drawn being a queen. Looking to extend this new thread of problems even further, similar scenarios, with more and different people peeking at cards, can be put into play.

Continuing from the scenario presented in Fig. 1, more different probabilities are possible, especially when Thomas and Blaise are joined in the room by Pierre-Simon, Bruno, Andrey, Abraham, Richard, and Jacob. Joining Thomas, who took a look at the first card drawn, imagine a scenario where Pierre-Simon snuck a peek at the second card drawn from and placed next to the deck, and Bruno became privy to the face of the third card drawn from and placed next to the deck. At that point, there are four different individuals each with a different probability that the fourth card drawn from the deck is a queen. Well, "potentially" four different probabilities would be safer to say at this point, but I do not wish to lose the forest for the trees at this moment.

To recap, the probability that the fourth card drawn is a queen is still 4/52, albeit for Blaise. For Thomas, Pierre-Simon, and Bruno, the probability that the fourth card drawn is a queen needs to take into consideration the information each of them obtained when looking at the face of their respective cards. Similarly, but slightly differently, Andrey, Abraham, and Richard in this scenario become privy to information regarding two cards. In particular, Andrey accustoms himself with the faces of the first and second cards drawn, Abraham acquaints himself with the faces of the first and third cards drawn, and Richard recognizes information associated with the faces of the second and third cards drawn. While we are it, Jacob gains access to the faces of the first, second, and third card that is drawn. Let us recap.

In the scenario being presented we have Blaise who is still not privy to any of the information contained on the faces of the three cards placed next to the deck. As for Thomas, Pierre-Simon, and Bruno, they have each gained information from seeing one card, albeit different cards. Whereas Andrey, Abraham, and Richard garnered information from two cards, albeit two different cards, for each of them. Lastly, Jacob is aware of the faces of all the cards that were drawn. In sum, now there are eight different individuals, each with knowledge of different, relevant information.

Like students in a math class, I imagine tasking each of the individuals with calculating the probability that the fourth card drawn is a queen, and to share their results with the rest of the group. Perhaps I am projecting a bit, but what I imagine happening next is all hell breaking loose.

One conversation theme emerging from the group discussion would be temporally based. I could see Thomas and Bruno having a discussion about "when" they learned about the face of their card, and if, and how, that impacts the probability the fourth card drawn is a queen. Differences between sneaking a peek at the face of the card after it has been laid down and seeing the face of the card, in real time, as the card is placed next to the deck would get hashed out, but temporal issues would remain. Worthy of note, should Thomas, in discussion with Bruno, share details associated with the face of his card, then, actually, Bruno would have a new probability where his calculation is no longer solely based on the information from the face of the card he saw, but also on now knowing what card Thomas saw, as well. To remedy this situation, we enter into the mix, of course, a neuralyzer.

For those of you well versed in the *Men in Black* film franchise, you know what a neuralyzer is and what it does. On the off chance you are not familiar with a *neuralyzer*, it is a cigar-sized metal tube that, when a particular button is pressed, emits a bright flash, like that of a camera. Unlike a camera, however, the flash erases memories for any person or persons who see the flash. The period to be erased, that is, how many seconds, minutes, hours, days, weeks, months, and years, is entered into the neuralyzer, via buttons and dials, before the flash takes place. Presently, the neuralyzer is not real. It is from a movie. A science fiction, action, comedy film. However, in what follows, as one would when watching a movie, I ask you to suspend reality (even if just for a few moments) and embrace the notion that seeing a flash results in a memory wipe.

Back to the discussion between Thomas and Bruno, where Thomas let slip information about the face of his card, to get the boys back on track, that is, working out the probability that the fourth card drawn is a queen, albeit with each of them having seen the face of a different card, we flash the neuralyzer for Bruno. (Flash!) Just like that, Bruno is no longer saddled with the information about Thomas's card. In other words, Bruno is back to his original calculation with one card.

A similar theme, that is, a temporally based one, could also be taking place between Andrey, Abraham, and Richard, the individuals who were able to take a look at two, albeit different, cards in their calculation of the probability of the fourth card being a queen. A discussion focused on the different probabilities that could emerge based on the cards they were assigned would take place. I also envision, in that discussion, a sidebar conversation about the differences between seeing one card then another versus seeing both cards at once. Andrey, for example, who sees the first and second card, could have garnered the information by seeing (1) the first card next to the deck and then the second card next to the deck; (2) the second card and then the first card; or (3) both cards at the same time. All of which causes Jacob to chime in, then, that he might have to rethink his calculation because of the different ways in which the faces for one, two, and three cards could be digested. It would probably be best, at this point, to give Andrey, Abraham, and Richard a quick flash, in case Jacob let something slip in their conversation before going back to work on his own in the corner. (Flash!) Before or after, left versus right, all at once or one at a time, one card, a couple of cards and on and on; and, the conversation, thus far, has not even addressed the faces of the cards.

Getting back to Thomas, let us say, for the sake of argument, the face of his card, that first card that was drawn and placed beside the deck, is the Four of Hearts. His reporting back to the group of the probability that the fourth card drawn was a queen would be a window into whether Thomas saw the Four or Hearts as the Four of Hearts.

The Four of Hearts, yes, is the Four of Hearts. However, the Four of Hearts is also a four of hearts. The Four of Hearts is multivalent, that is, concurrently, it is many things. The Four of Hearts is not a queen, for example. It is also not a seven. The Four of Hearts is a four. It is a red card. It is a four and a heart. This information, while mundane, is important when assessing Thomas's probability that the fourth card drawn is a queen. After all, to say that the four of hearts is not a queen is correct. Should Thomas interpret the four of hearts as not a queen, this would be sussed out from his probability that the fourth card is a queen. The probability of the fourth card being a queen, then, is a window into one's interpretation of an event, which, in this instance, is seeing the face of the first card placed next to the deck.

It could be argued that the face of the card, when revealed to Thomas, exists in a state of superposition. In other words, the card concurrently exists in all the different ways that it could be interpreted: not a queen, not a spade, four, heart, red card, four or hearts, rank, suit, rank without suit, suit without rank, and on and on. It is Thomas's answer to the task, then, the probability, that sheds light on Thomas's interpretation of the face of the card he saw. Thomas's answer, arguably, reveals his particular collapse of the superposition and, thus, how the card was interpreted.

In line with this reasoning, an exposed card, yes, does provide new information; however, how said information is interpreted and shared, how the card is actually seen, is garnered from the answer stemming from the calculation of the probability that the fourth card drawn is a queen. Attending to an old quandary, that is, do you see what I see, for example, when a card is flipped over for "you" and "I" to see, cue the calculations. Also, cue a discussion on whether or not the information is *in* the cards.

Taking temporal troubles and multivalent musings together, more problems may emerge. Having Thomas (who saw the face of the first card placed next to the deck) talking with Andrey (who saw the faces of the first and second) and Abraham (who saw the faces of the first and third) could make him privy to information concerning all three faces of the cards placed next to the deck. Before resorting to a quick neuralyzer flash, lest we forget, too, that all these people under discussion are from the human race.

Members of the human race suffer from many difficulties. Our memories are not like video camera recordings. Some of us have particular predilections for telling the truth or saving face. Not everyone is of keen eyesight. Some of us, myself included, live with color blindness. Others may not be intimately familiar with the particulars, such as rank and suit, of a deck of cards. Beyond just the issues with ourselves, communicating well with others is no easy task. As Red Auerbach (a famous basketball coach) once said, it does not matter what is said, what matters is what is heard. On and on I could go about members of the human race. Instead, the larger point attempting to be made here is that humans are fallible when interpreting and

sharing information garnered from events, like what one sees when seeing the face of a playing card or many playing cards, which could have probabilistic implications.

These implications hold true for other probabilistic situations and scenarios. Different probabilities may emerge from the timing of verbal information received from another. Similarly, different observers, those given access to the same circumstances, but with different underlying knowledge of the scenario, might emerge with different probabilities. Stated more generally, "probabilities quantify not events but our *information* about events" (Devlin 2014, p. xii). As demonstrated throughout the above problems, our information about events, how said information is interpreted, how it is shared, can be established probabilistically.

I began this introduction by declaring that I have a problem. Problems, really. My biggest problem, I see now, would be to end an introduction to a section on practical, historical, and philosophical instances of probability by aligning myself with a particular philosophical interpretation of probability. Fortunately, for me, I think I have a way out of this mess that I've gotten myself into. . .

Flash!

As noted by Gillies (2000), "The theory of probability has a mathematical aspect and a foundational or philosophical aspect. There is a remarkable contrast between the two. While an almost complete consensus and agreement exists about the mathematics, there is a wide divergence of opinions about the philosophy" (p. 1). Within the wide divergence of opinions about the philosophy of probability (e.g., logical, subjective, frequency, propensity, and others), there is one significant bifurcation that has been recurrently acknowledged since the emergence of probability around 1600 (Hacking 1975). Hacking describes this duality of probability as the "Janus-faced nature" (p. 12) of probability, explaining "on the one side it is statistical, concerning itself with stochastic laws of chance processes" (ibid.); and "on the other side it is epistemological, dedicated to assessing reasonable degrees of belief in propositions quite devoid of statistical background" (ibid.). Throughout history, when asking do you see what I see, with respect to philosophical interpretations of probability, individuals have not seen eye to eye on the matter, to put it mildly.

Given the tumultuous history over differing philosophical interpretations of probability (Hacking 2001), treading into said arena is not for the faint of heart. I thank, then, Professors Jeffrey Rosenthal, Jason Douglas Rosenhouse, and Christian Martin Hennig for helping me bring this section on practical, historical, and philosophical instances of probability to fruition.

Abstract

We discuss Andrey Andreyevich Markov's early twentieth century idea of a Markov chain, which generalized the traditional notion of independent random variables to a model that was more general but still mathematical tractable. We then describe how that led to the hugely popular modern statistical approach of using Markov chain Monte Carlo algorithms to estimate complicated quantities such as Bayesian posterior distributions.

1 Introduction

It was the beginning of the twentieth century, and Andrey Andreyevich Markov was not happy. The field of mathematical probability was flourishing, with seminal contributions from de Moivre and Fermat through to Gauss, Laplace, Cauchy, Poisson, Chebyshev, and many others. And yet, most of the key results – laws of large numbers, the central limit theorem, and so on – were always about independent random variables, i.e., random quantities which have no effect on each other. This assumption seemed very limiting and unrealistic. However, without this assumption, the random variables could behave however they wanted, and it seemed impossible to make mathematical progress. How could the independence assumption be generalized, while still allowing for valid theorems to be proven?

Markov eventually settled on a model in which each random variable depended on the others, but only through the adjacent ones. That is, a sequence of jointly defined random variables X_0, X_1, X_2,... form a Markov chain if the conditional distribution of X_n, conditional on all the other variables, is completely determined by X_{n-1} and X_{n+1}. This setup was more general than independence, but still tractable enough to analyze mathematically.

Markov published his results in 1906 (Markov 1906), adding a new model to the world of probability theory. He proved a version of the law of large numbers, and later of the central limit theorem, for his new concept of Markov chains. In the decades following, many mathematical papers about Markov chains were published. Moreover, Markov chains had some success as models of card shuffling, diffusions, branching processes, and later to stock prices. Further yet, genuine applications remained somewhat limited. In fact, Markov's original example had been the pattern of consonants and vowels in written language, but they surely do *not* really follow a Markov chain. For example, a vowel is much less likely to occur of the last three letters were all vowels, than if just the last one letter were a vowel. It was challenging to find real-world examples of random sequences in which X_n was indeed influenced by X_{n-1}, but completely conditionally independent of X_{n-2}.

Then, in the latter half of the twentieth century, a whole new application of Markov chains emerged, in the burgeoning field of computer simulation. In 1953, Metropolis et al. (1953) used a simple iterative computer simulation to study the behavior of interacting molecular systems, for up to 224 particles. This was an early application of a Monte Carlo algorithm which uses random simulation to estimate complicated quantities. In doing so, they created the Metropolis algorithm, the world's first Markov chain Monte Carlo (MCMC) algorithm. Their algorithm was later generalized to the Metropolis-Hastings algorithm (Hastings 1970), the Gibbs sampler (Gelfand and Smith 1990; Geman and Geman 1984; Tanner and Wong 1987), and many other variations; see e.g (Tierney 1994). The term "Markov chain Monte Carlo (MCMC)," emphasizing that these new algorithms applied Markov's model to the Monte Carlo paradigm, originated in (Geyer 1992). MCMC algorithms are now hugely popular in many branches of statistics, especially in Bayesian inference, as well as many other fields from molecular dynamics to engineering to machine learning to financial modeling. The volume (Brooks et al. 2011) contains

thousands of references, and a casual Google search for "Markov chain Monte Carlo" (in quotation marks) returns over two million web pages, indicating just how far Markov's little idea has come.

In this chapter, we review Markov chains and MCMC algorithms and explain how they have been so useful in modern statistical analysis.

2 Random Variables

A random variable is a mathematical model of an uncertain quantity. It is defined on some underlying probability space $(\Omega, \mathcal{F}, \mathbf{P})$, where Ω is an underlying sample space, $\mathcal{F}$ is a σ-algebra of subsets of Ω, and $\mathbf{P}$ is a probability measure on $(\Omega, \mathcal{F})$. A random variable is then a measurable function from $(\Omega, \mathcal{F})$ to a measurable range space $(\mathcal{X}, \mathcal{G})$, most commonly to $(\mathbf{R}, \mathcal{B})$ (the real numbers with the Borel subsets). The probability that a random variable X takes a value within a subset $A \in \mathcal{G}$ is then given by

$$\mathbf{P}[X \in A] := \mathbf{P}\{\omega \in \Omega : X(\omega) \in A\}. \tag{1}$$

(If Ω is finite or countable, then we can let $\mathcal{F}$ be the collection of all subsets of Ω, and simply take $\mathbf{P}[X \in A] = \sum \{\mathbf{P}(\omega) : X(\omega) \in A\}$, i.e., define probabilities by a simple sum over individual points.)

Individual random variables can be studied in terms of their probability distributions $\{\mathbf{P}[X \in A] : A \in \mathcal{G}\}$, including such familiar notions as binomial, normal, exponential, Poisson, and other univariate distributions, perhaps extended to distributions of functions h of random variables as $\{\mathbf{P}[h(X) \in A] : A \in \mathcal{G}\}$.

The situation gets more intricate when there are multiple random variables defined jointly on the same underlying space $(\Omega, \mathcal{F}, \mathbf{P})$. If X_1 and X_2 are two such random variables, then we can define their joint probability distribution by

$$\mathbf{P}[X_1 \in A, X_2 \in B] = \sum \{\mathbf{P}(\omega) : X_1(\omega) \in A \text{ and } X_2(\omega) \in B\}, \tag{2}$$

for any $A, B \in \mathcal{G}$. This leads to questions about the relationship between the random variables.

The simplest case is independent random variables, meaning random quantities which do not affect each other, or formally for which

$$\mathbf{P}[X_1 \in A, X_2 \in B] = \mathbf{P}[X_1 \in A]\ \mathbf{P}[X_2 \in B] \tag{3}$$

for all $A, B \in \mathcal{G}$. More generally, a collection $\{X_i\}_{i \in I}$ of random variables are all independent if for all subsets $I_0 \subseteq I$, and all choices $\{A_i\}_{i \in I_0}$ of elements of $\mathcal{G}$, we have

$$\mathbf{P}[X_i \in A_i \text{ for all } i \in I_0] = \prod_{i \in I_0} \mathbf{P}[X_i \in A_i]. \tag{4}$$

Related, a collection $\{X_i\}_{i \in I}$ is identically distributed if for each fixed $A \in \mathcal{F}$, the value $\mathbf{P}[X_i \in A]$ is the same for all $i \in I$.

If a sequence $X_1, X_2, \ldots$ of random variables is both independent and identically distributed (i.i.d.), then many results are known. For example, the law of large numbers says that the sample averages $\frac{1}{n}\sum_{i=1}^{n} h(X_i)$ converge to their common mean $\mu := \mathbf{E}[h(X_i)]$, and the central limit theorem says $\frac{1}{\sqrt{n}}\sum_{i=1}^{n}[h(X_i) - \mu]$ converges in distribution to a Normal $(0, \sigma^2)$ distribution if $\sigma^2 := \mathbf{E}[(h(X_i) - \mu)^2] < \infty$. These two fundamental theorems, and many others, give a fairly rich and detailed picture of the behavior of independent random variables.

3 Markov Chains

As mentioned, Markov provided a generalization of the independence assumption. In particular, a sequence $X_0, X_1, X_2, \ldots$ forms a time-homogeneous Markov chain if there is a fixed transition kernel $\{P(x, A)\}_{x \in \mathcal{X}, A \in \mathcal{G}}$ with the property that

$$\mathbf{P}[X_n \in A | X_0, X_1, \ldots, X_{n-1}] = P(X_{n-1}, A), \quad A \in \mathcal{G}. \tag{5}$$

That is, given the history up to time $n - 1$, the probabilities for the value at time n depend only on the most recent value X_{n-1}, in an explicit way given by the transition kernel P.

For a concrete example, suppose $\mathcal{X} = \{1, 2, 3, \ldots\}$, with $\mathcal{G}$ the collection of all subsets of $\mathcal{X}$, and with transition kernel P defined by $P(x, \{x + 1\}) = 1/4$ for all $x \in \mathcal{X}$, $P(x, \{x - 1\}) = 1/2)$ for all $x \geq 2$, $P(x, \{x\}) = 1/4$ for all $x \geq 2$, and $P(1, \{1\}) = 3/4$, together with additivity. This Markov chain has, at each time, a probability 1/4 of increasing by 1, a probability 1/4 of staying the same, and a 1/2 probability of decreasing by 1 (unless it is already at the state 1, in which case the probability 1/2 is added to staying at 1); see Fig. 1.

Over time, a Markov chain might settle into a "stable pattern," or more precisely a stationary distribution. A probability distribution π on $(\mathcal{X}, \mathcal{G})$ is called *stationary* for the Markov chain $\{X_n\}$ if it has the property that whenever X_n has the distribution π, then X_{n+1} will also have the distribution π. That is,

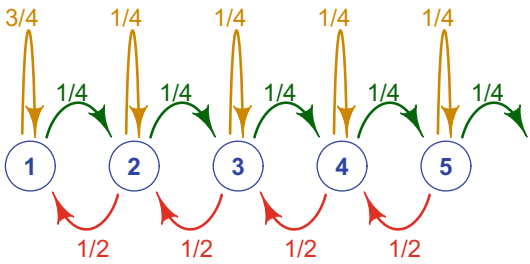

Fig. 1 The transition probabilities of the Running Example Markov chain

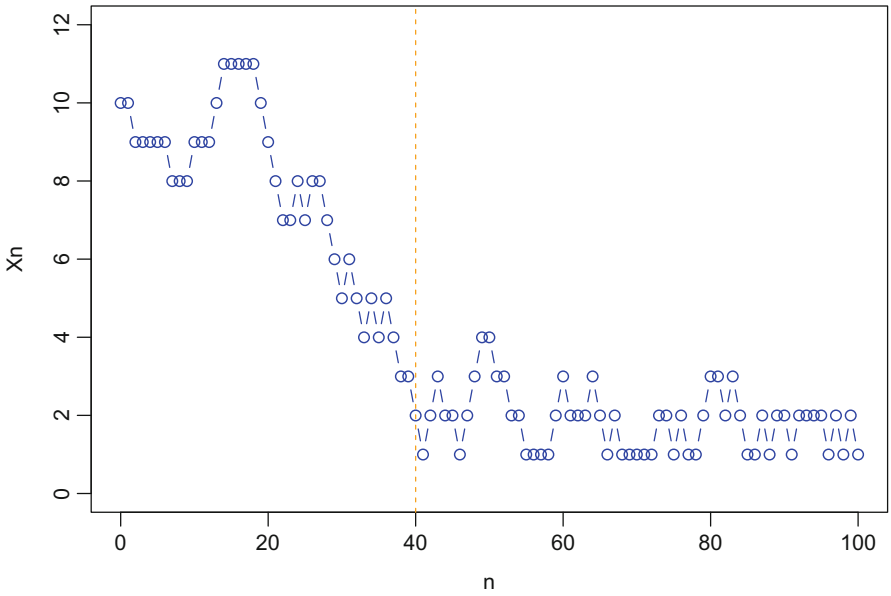

Fig. 2 A typical realization of the Running Example Markov chain

$$\int_{x\in\mathcal{X}} \pi(dx)P(x,A) = \pi(A). \tag{6}$$

On a discrete space, this can be written as

$$\sum_{x\in\mathcal{X}} \pi\{x\}P(x,A) = \pi(A). \tag{7}$$

Intuitive, the probability distribution π is invariant for the chain, i.e., its probabilities do not change while the chain runs.

The importance of stationary distributions is the Markov Chain Convergence Theorem which says that, under the mild assumptions of irreducibility and aperiodicity (nearly always satisfied and not considered further here), a chain will eventually *converge* to its stationary distribution. That is, if a Markov chain has a stationary distribution π, and is irreducible and aperiodic, then for all $A\in\mathcal{G}$,

$$\lim_{n\to\infty} \mathbf{P}[X_n\in A] = \pi(A). \tag{8}$$

Informally, the chain will settle down into its stationary distribution in the long run.

To see this more concretely, consider the above Running Example. Figure 2 shows a typical realization of that Markov chain. Although it starts with larger

values, from approximately time $n = 40$ onwards, it appears to be in a stable pattern, visiting approximately the same states with approximately the same probabilities.

This "settling down" Markov chain convergence property is enough to prove a law of large numbers and central limit theorem for Markov chains, similar to the i.i.d. case but under stronger assumptions; for a modern treatment, see, e.g., the monograph (Meyn and Tweedie 1993). Thus, the time-homogeneous Markov assumption helps to re-capture some of the power and utility of i.i.d. sequences, but in a more general context.

4 Markov Chain Monte Carlo (MCMC)

When they were first introduced, Markov chains served as models of certain natural scientific (and even social) phenomenon. However, in the latter half of the twentieth century, it was slowly realized that Markov chains could be used in an entirely different way, as computational algorithms.

The basic idea of a Monte Carlo algorithm is simple. Suppose π is a "target" probability distribution on $(\mathcal{X}, \mathcal{G})$, and $h : \mathcal{X} \to \mathbf{R}$ is some measurable function, and you want to estimate the expected value

$$\mu := \mathbf{E}_\pi(h) := \int_{x \in \mathcal{X}} h(x)\pi(dx) \tag{9}$$

(so, on a discrete space, $\mu = \sum_{x \in \mathcal{X}} h(x)\pi(x)$). In principle, μ could be calculated directly by an integral or sum, but in a complicated application on a high-dimensional state space that might be quite infeasible. However, if you could simulate random variables $X_1, X_2, \ldots, X_M$ which are i.i.d. with distribution π, then you could estimate μ by

$$E := \frac{1}{M} \sum_{i=1}^{M} h(X_i). \tag{10}$$

Indeed, the law of large numbers says that as $M \to \infty$, the estimator E will converge to μ.

The problem is that, if $\mathcal{X}$ is high-dimensional and π is complicated, there is no feasible computer program to simulate independent random variables $X_1, X_2, \ldots$ which each have the distribution π. However, it turns out to be surprisingly easy to simulate a *Markov chain* $X_0, X_1, X_2, \ldots$ which has π as a stationary distribution and will thus converge to π in distribution. This gives rise to Markov chain Monte Carlo (MCMC) algorithms which simulate a Markov chain $X_0, X_1, X_2, \ldots$ which converges to π and then estimate μ by

$$E := \frac{1}{M - B} \sum_{i=B+1}^{M} h(X_i). \tag{11}$$

If the burn-in period B is large enough that the distribution of X_B is approximately π, and $M - B$ is large enough that the Markov chain law of large numbers approximately holds, then this estimator E will again provide a good approximation to μ.

5 The Metropolis Algorithm

While there are many ways to construct Markov chains which leave π stationary, the oldest and simplest one is the Metropolis algorithm (Metropolis et al. 1953). Assume the state space $(\mathcal{X}, \mathcal{G})$ has a reference measure ρ (e.g., counting measure on a discrete state space, or Lebesgue measure on $\mathbf{R}$), with respect to which π has a density function f so that $\pi(dx) = f(x)\rho(dx)$. The algorithm uses proposal distributions $Q(x, dy) = q(x, y)\rho(dy)$ for $x, y \in \mathcal{X}$, which are symmetric (i.e., $q(x, y) = q(y, x)$). (For example, on a discrete state space, $Q(x, \cdot)$ might give probability 1/2 to each of $x + 1$ and $x - 1$. Or, on the real line, $Q(x, \cdot)$ might correspond to a Normal(x, v) distribution for some fixed variance parameter $v > 0$. Importantly, $Q(x, \cdot)$ should be easy to sample from on a computer.)

The algorithm then proceeds as follows. First choose some initial state $X_0 \in \mathcal{X}$. Then, iteratively for $n = 1, 2, \ldots$, given $X_{n-1} \in \mathcal{X}$, generate X_n as follows. First, generate a *proposal* state Y_n sampled from the probability distribution $Q(X_{n-1}, \cdot)$ and independently generate a random variable U_n sampled from the uniform (Lebesgue) measure on the interval [0,1]. Then define X_n by

$$X_n = \begin{cases} Y_n & U_n < f(Y_n)/f(X_{n-1}) \\ X_{n-1} & \text{otherwise} \end{cases} \tag{12}$$

That is, if $U_n < f(Y_n)/f(X_n)$, then the proposed new state Y_n is "accepted" so we set $X_n = Y_n$; otherwise Y_n is "rejected" so we keep $X_n = X_{n-1}$. Incredibly, this simple algorithm, which only barely mentions π via its density f in the accept/reject rule, actually makes π a stationary distribution to which it will converge:

Theorem 1 *The above Metropolis algorithm defines a Markov chain $\{X_n\}$ which has π as a stationary distribution. Furthermore, if the chain is irreducible and aperiodic, then it will converge in distribution to π.*

Proof. For $y \neq x$, the only way for the chain to move from x to y (or to a neighborhood dy of y) is to first propose such a move and then accept it. Thus, for $y \neq x$,

$$\begin{aligned} P(x,dy) &:= \mathbf{P}[X_n \in dy \,|\, X_{n-1} = x] \\ &= \mathbf{P}[Y_n \in dy \,|\, X_{n-1} = x]\ \mathbf{P}[U_n < f(Y_n)/f(x)] \\ &= Q(x,dy)\ \min[1, f(Y_n)/f(x)] \\ &= q(x,y)\rho(dy)\ \min[1, f(y)/f(x)]. \end{aligned} \tag{13}$$

It follows that the bivariate measure

$$\begin{aligned}\pi(dx)P(x,dy) &= \pi(dx)\ \mathbf{P}[X_n \in dy \,|\, X_{n-1} = x] \\ &= f(x)\rho(dx)q(x,y)\rho(dy)\ \min[1, f(y)/f(x)] \\ &= q(x,y)\ \min[f(x), f(y)]\rho(dx)\rho(dy).\end{aligned} \tag{14}$$

Since $q(x,y) = q(y,x)$, this measure is symmetric upon swapping x and y, i.e., $\pi(dx)\ P(x,dy) = \pi(dy)\ P(y,dx)$, which says that $\{X_n\}$ is a reversible Markov chain. (The above argument only shows this for $y \neq x$, but it is immediately true for $y = x$ too.) It follows that if X_{n-1} has the distribution π, then

$$\begin{aligned}\mathbf{P}[X_n \in A] &= \int_{x \in \mathcal{X}} \pi(dx)\ \mathbf{P}[X_n \in A \,|\, X_{n-1} = x] \\ &= \int_{x \in \mathcal{X}} \int_{y \in A} \pi(dx)\ P(x,dy) \\ &= \int_{x \in \mathcal{X}} \int_{y \in A} \pi(dy)\ P(y,dx) \\ &= \int_{y \in A} \pi(dy)\ P(y,\mathcal{X}) \\ &= \int_{y \in A} \pi(dy)\ \ (1) = \pi(A),\end{aligned} \tag{15}$$

so X_n also has the distribution π. Therefore, π is a stationary distribution.

The second statement follows immediately from the first one and the Markov Chain Convergence Theorem. □.

In summary, the Metropolis algorithm provides a simple method – propose a new state symmetrically, then accept or reject it according to a simple rule – which guarantees that π is a stationary distribution, to which (under very mild conditions) the chain will converge. This is what makes MCMC possible. For a graphical simulation of the Metropolis algorithm in action, see the web page at (Rosenthal 2020).

6 MCMC in Practice

To see how the Metropolis algorithm actually works, suppose the state space is $\mathcal{X} = \{1, 2, 3, \ldots\}$, so ρ is counting measure, and suppose the target probability distribution given by $\pi(\{x\}) = 2^{-x}$ for $x \in \mathcal{X}$. Suppose we choose the simple proposal distributions $Q(x,\ \{x - 1\}) = Q(x,\ \{x + 1\}) = 1/2$. Then, at each iteration, our algorithm proposes a new state $Y = X_{n-1} \pm 1$ which increases or decreases the current state by one (with probability 1/2 each), and then with probability $\min[1,\ \pi(Y)/\pi(X_{n-1})] = \min\left[1,\ 2^{-Y}/2^{-X_{n-1}}\right]$, it accepts the proposal and sets $X_n = Y$; otherwise it rejects the proposal and sets $X_n = X_{n-1}$.

So, what are the resulting transition probabilities? Well, since $\pi(\{0\}) = 0$, proposed moves from state 1 to state 0 are always rejected. However, for $x \geq 2$, since $\pi(\{x-1\}) > \pi(\{x\})$, proposed moves from $x-1$ to x are always accepted. Meanwhile, for any $x \in \mathcal{X}$, proposed moves from x to $x+1$ are accepted with probability $\min[1, 2^{-(x+1)}/2^{-x}] = 1/2$. Further, whenever a move is rejected, then the chain stays at x. A careful inspection shows that these transition rules are exactly the same as those in the diagram of Fig. 1. That is, this Metropolis algorithm exactly coincides with our Running Example, which therefore by Theorem 1 has stationary distribution π, given by $\pi(\{x\}) = 2^{-x}$ for $x \in \mathcal{X}$ as above.

Hence, a typical realization of this Metropolis algorithm will be something like that in Fig. 2. In particular, it might start at some larger state (e.g., $X_0 = 10$), but after some burn-in period B, it will send to settle into a pattern of sampling the different states with probabilities roughly equal to the target stationary distribution π. So, as above, if the burn-in period B and total run length M are both large enough, then $\frac{1}{M-B}\sum_{i=B+1}^{M} h(X_i)$ will be a good estimate of the expected value $\mu := \mathbf{E}_\pi(h)$.

For MCMC algorithms to be successful, we need to choose the burn-in value B large enough that the distribution of X_B is approximately equal to π. While there have been some attempts to provide precise mathematical bounds on this burn-in time (see, e.g., (Rosenthal 2002) and the references therein), such bounds cannot usually be obtained. Instead, convergence is usually assessed empirically, by monitoring the output from the Markov chain and using statistical or time-series approaches to decide if the chain seems to have reached a steady state. For example, for chain output as in Fig. 2, it might be determined empirically that roughly $B = 40$ iterations (the orange dotted line) are sufficient to approximately reach stationarity.

Of course, the distribution π in our Running Example is so simple that it can easily be sampled without using MCMC. However, MCMC is indeed very commonly required in more complicated situations. In particular, it is very often needed for Bayesian inference. The basic Bayesian paradigm is as follows. We wish to estimate some unknown parameters θ, given some observed data $D = d_0$, a prior distribution $\{\mathbf{P}[\theta \in A]\}_A$, and a statistical likelihood model $\{\mathbf{P}[D \in A|\theta]\}_{\theta,A}$. The all-important posterior distribution, which tells us the final probability distribution of the unknown parameters θ given the observed data and the model, is then given (using Bayes' Rule) by

$$\pi(d\theta) := \mathbf{P}[\theta \in d\theta | D = d_0] = \frac{\mathbf{P}[\theta \in d\theta]\ \mathbf{P}[D = d_0|\theta]}{\mathbf{P}[D = d_0]}, \tag{16}$$

which is proportional to the prior $\mathbf{P}[\theta \in d\theta]$ times the likelihood $\mathbf{P}[D = d_0|\theta]$.

In principle, the formula (16) gives precise information about the nature of the posterior distribution, usually expressible as a posterior density function. That should be sufficient to compute posterior probabilities $\pi(A)$, or more generally posterior expectations $\mathbf{E}_\pi(h)$, by computing an integral (or sum) with respect to π as in (9). However, in practical statistical applications, the posterior distribution π is often very complicated and high-dimensional, so that these integrals cannot be computed directly, nor even well approximated by numerical integration, so their

computation was thought to be infeasible. This challenge presented a major obstacle to the use of Bayesian inference in practical statistical problems and limited it for most of the twentieth century primarily to theoretical and philosophical and foundational interest rather than to genuine application. However, it was realized around 1990 (Gelfand and Smith 1990; Tanner and Wong 1987; Tierney 1994) that MCMC algorithms such as the Metropolis algorithm can provide good estimates of $\mathbf{E}_\pi(h)$ as in (11), often quite easily with good accuracy and limited computational effort.

These MCMC algorithms are now routinely used in Bayesian statistics, which accounts for their extreme popularity. They have transformed the entire field of Bayesian statistics, from a theoretical curiosity to one of the most influential areas of statistical analysis, with significant applications to physics and finance and machine learning and so much more.

7 Conclusion

This chapter has explained how Markov chains, introduced in 1906 as a tractable generalization of independent random variables, found tremendous application many years later as a tool for statistical computation, which completely transformed statistics by making the application of Bayesian inference computationally feasible, thus allowing its application to so many modern fields of study.

Andrey Andreyevich Markov died one hundred years ago, in 1922. If he were alive today, he would surely be astonished and thrilled by the incredible amount of progress that has been achieved in statistical computation and so many other areas, as a direct result of that little idea that he proposed so long ago.

Abstract

Darwin's publication of *The Origin of Species* in 1859 situated biology firmly within the "probabilistic revolution" in the history of science. One consequence of this was an increased emphasis on probability and statistics in mathematical practice. The earliest attempts to test Darwin's theory relied on statistical analyses of phenotypic traits in various species. With the rediscovery of Mendel's work in the late nineteenth and early twentieth centuries, emphasis shifted to the development of genetical models based on combinatrics and discrete probability. The interplay between evolution and probability continues in the present, for example, in the development of coalescent theory and the study of Markov models on trees. We will survey this history, and we will discuss a few of the ideas underlying some of these mathematical models. We will also consider, and reject, certain probabilistic arguments presented by critics of evolutionary theory.

1 Introduction

Charles Darwin presented his theory of evolution in *The Origin of Species*,[1] published in 1859. In so doing, he fundamentally transformed the practice of biology. Prior to Darwin, biology was mostly a descriptive discipline concerned with dissecting organisms and with arranging species into coherent systems of classification. After his work, biology was a proper theoretical science, one worthy of a place right alongside physics and chemistry. In the light of evolution, the patterns of anatomical similarities and differences among species were no longer brute facts, but were instead the logical outcome of a comprehensible historical process. Classification now had an objective basis in the one true tree of life and no longer had to be based on arbitrary human preferences.[2] The empirical and philosophical questions raised by evolution gradually initiated a panoply of research programs that continue to bear fruit in the present.

There has been extensive scholarship exploring the historical effect of evolution on biological practice.[3] Less well-explored is the effect of Darwin's work on mathematical practice. I do not mean by this that evolution altered the way mathematicians viewed the philosophical underpinnings of their discipline. Rather, I mean that evolution offered surprising new opportunities for mathematical modeling, especially with regard to probability theory and statistics.

Darwin himself was famously ambivalent about mathematics, and the *Origin* contains no equations or mathematical models. That notwithstanding, the eventual ascent of his ideas to the centerpiece of biological thought was in large measure the result of abstract, probabilistic modeling undertaken first by Ronald Fisher and later by Sewall Wright and J. B. S. Haldane, in the early twentieth century. Probability is a major part of modern evolutionary theory, playing a central role in models of short-term allelic change in gene pools, as well as in methods of phylogenetic reconstruction.

[1] The full title of Darwin's book is *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*. Since this title is rather long, it is customary to refer to it simply as *The Origin of Species*. We should note that in this context, "races" does not refer to human races, but instead refers to local populations of organisms.

[2] The only diagram in *The Origin of Species* illustrates Darwin's idea of a tree of life. The tree metaphor is based on the idea that genes are only transferred "vertically" from ancestors to descendants. Recent research has suggested that "horizontal" gene transfer, meaning transfers of genetic material among contemporary populations, was prevalent in the earliest stages of evolution. This suggests that the tree metaphor is inapt for early evolution (Martin 2011). However, most researchers continue to regard the tree metaphor as appropriate for most of natural history.

[3] Among many excellent references on the scientific, philosophical, and theological legacy of Darwin's ideas, I recommend the books by Ruse (1979), Bowler (2003), and Larson (2004).

Darwin's theory implied that chance was an ineliminable part of natural history and, therefore, that probability and statistics were essential to understanding it. From the mathematical side, many innovations in probability and statistics arose from a desire to model evolutionary processes.

However, for as long as there have been evolutionists, there have also been anti-evolutionists, meaning those who believe that no fully naturalistic process can explain the broad sweep of natural history and that it is necessary to appeal in some way to the actions of an intelligent designer. They make a variety of arguments in defense of their views, and some of these arguments rely explicitly on probability. Scientists are mostly dismissive of these arguments, finding them to be both biologically and mathematically fallacious.[4] I agree with this view. However, their superficial sophistication and their cachet among lay audiences in cultural disputes about the proper relations between church and state make them worth taking seriously. Science and mathematics should not be seen merely as ivory tower disciplines, and when their methods are abused to serve political agendas, it behooves scholars to take notice.[5]

This chapter is organized as follows: Section 2 provides definitions for certain key terms that may be unfamiliar to some readers. Section 3 describes those elements of Darwin's theory of evolution relevant to our later discussions. Section 4 situates Darwin's work in the broader historical context of the so-called probabilistic revolution and notes some interesting parallels between Darwinian natural selection and the introduction of statistical techniques in physics.

The decades following the publication of the *Origin* saw the emergence of two schools of thought on how to test Darwinian hypotheses. The so-called "biometricians" applied statistical methods to the study of naturally occurring variations, while the "Mendelians" preferred methods drawn from combinatorics and discrete probability. This dichotomy is explored in Sect. 5. While both approaches had merit, it was the methods of the Mendelians that had more relevance specifically to evolution. Their work led to the modern science of population genetics, and we present some of the basic models and equations of this discipline in Sect. 6. Section 7 presents a brief discussion of more modern uses of probability in evolutionary studies. Finally, we discuss the probabilistic arguments of evolution's critics in Sect. 8.

[4] In 2015, the Pew Research Center released polling data on the views of members of the American Association for the Advancement of Science (AAAS), one of the main professional societies for scientists in America. They found that 90% of all AAAS members agreed that human evolution was due to natural processes. This number ticked up to 92% for working Ph.D. biomedical scientists. A majority of the rest believe that evolution was "guided by a supreme being," but this should not be taken to imply that they agree with the specific anti-evolutionist arguments I will discuss. Moreover, we could note that thousands of research papers in evolutionary biology appear every year, compared to almost none that are supportive of creationism, intelligent design, or any other non-naturalistic approach to natural history.

[5] The cultural, sociological, and religious aspects of evolution, especially in the context of disputes over public school science curricula in the United States, are beyond the scope of this article. However, some useful references in this regard are the books by Nelkin (1982), Forrest and Gross (2004), Scott and Branch (2006), Miller (2008), Scott (2009), Berkman and Plutzer (2010), Ravitch (2011) and Rosenhouse (2011).

A short survey article of this sort must inevitably begin with an apology for everything that has been left out. Whole books get written on the subject matter of any of the major sections of this paper. It is hoped, however, that these brief remarks will serve as an introduction to a fascinating chapter in the history of both mathematics and biology.

2 Biological Terminology

As we go along, it will be necessary to employ some of the standard terminology used by geneticists and evolutionary biologists. It will be convenient to have all the needed definitions in one place, to avoid frequent disruptions to our story later on. Readers familiar with basic biology can skip this section.

It is customary to make a distinction between *genotype* and *phenotype*. The genotype of an organism is its collection of genes. Its phenotype is the sum total of its observable characteristics. When we are discussing a population of interbreeding organisms, the collection of all genes found in any of the individuals is called the *gene pool* for that population. A particular version of a gene that appears in a specific organism is called an *allele*. The location on a chromosome where an allele resides is called the *locus* of that allele.

The two main mechanisms of evolutionary change are *natural selection* and *genetic drift*. In both cases, we imagine that an allele initially appears with some frequency in a population and that, at some later time, we find that frequency has changed. If the change in frequency occurred because the presence or absence of the allele affects the probability that an organism will survive long enough to reproduce, then we say the change resulted from natural selection. If instead the change occurred because of random sampling bias or some other stochastic factor, then the change is attributed to genetic drift.

If we sequence a particular genetic locus in a large number of interbreeding organisms, we invariably find many variations of the same gene. This variation is referred to as *genetic polymorphism*. A common scenario among sexually reproducing organisms is that an individual inherits one copy of a gene from its mother and one from its father. If the two copies are the same, then the individual is said to be *homozygous* for this gene. Otherwise, it is said to be *heterozygous*.

Finally, *phylogenetics* refers to the branch of evolutionary biology devoted to working out the evolutionary relationships among modern species, or possibly extinct species in the context of paleontology. Such relationships are typically expressed in the form of trees of descent.

3 The Basics of Darwinian Evolution

Darwin's theory begins with two empirical observations:

1. Species are comprised of individuals that vary from one another, and at least some of these variations are heritable.

2. Species tend to reproduce at a geometric rate, implying that their numbers would increase quickly if this tendency is not checked by environmental constraints.

We then draw two conclusions from these observations:

3. There is a struggle for existence among the individuals of a species. Some individuals will fortuitously possess variations that give them an advantage in this struggle, and they will tend to leave more offspring than those not possessing those variations.
4. These variations will accumulate through the generations, to the point where they alter the average physical characteristics of the species.

Darwin referred to the process through which favorable variations accumulate over time as "natural selection."[6]

None of these points is controversial, and they have been readily agreed to by everyone from Darwin onward. Items (1) and (2) are simple empirical facts, and items (3) and (4) seem like undeniable conclusions from them. The controversy did not arise until Darwin extended these ideas beyond what many of his contemporaries felt were their appropriate scope.

Darwin believed that natural selection was so powerful that over time the accumulation of small variations could lead to new species. He argued that all modern species arose through a process of descent with modification from more ancient species, which themselves arose from more ancient species still. Eventually, this process traces back to the origin of life, or perhaps to a small number of very ancient original life forms. Darwin made no attempt to explain the origin of life, but instead took as given some relatively simple form of ancient life. He argued that through all the eons in which that ancient life was evolving, natural selection was an especially important mechanism of organic change.

To persuade others of this conclusion, Darwin began *The Origin of Species* with a chapter about pigeons. He noted the success of human breeders in producing pigeon varieties by selectively breeding from among those possessing characteristics the breeder found desirable. This was meant as proof of concept for the notion that small, naturally-occurring variations could add up to significant change in the average traits of a species. This chapter was followed by several others of a theoretical nature, in which Darwin laid out the central concepts underlying the process of natural selection and responded to possible objections to his ideas.

This led to the heart of the book, in which Darwin laid out the evidence for evolution. His argument took the form of a consilience of inductions, meaning that he showed how evolution neatly accounted for the facts in several seemingly distinct

[6]For a quick overview of modern evolutionary biology, try the book by Charlesworth and Charlesworth (2003). The textbook by Kardong (2007) strikes a good balance between rigor and readability. The more advanced textbooks by Herron and Freeman (2014) and Futuyma and Kirkpatrick (2017) are also very helpful. It is a testament to Darwin's genius and clarity of thought that *The Origin of Species* (Darwin 1859) is still worth reading today. He anticipated questions that continue to inspire modern research, even as he lacked the tools in his own time to answer them.

branches of the life sciences. In particular, he pointed to facts drawn from the fields of biogeography, classification, morphology, and paleontology. In each case, he argued that the facts were best explained by a process of descent with modification, rather than through a process of separate or special creations.

These ideas raise a host of scientific and philosophical questions, and Darwin's critics were quick to point them out. Was natural selection really so powerful that it could transform one species into another? Could complex structures like wings or eyes actually arise through a fully natural process? Can a scientific theory legitimately be defended by a consilience of inductions in the absence of direct experimental confirmation? Does evolution entail nominalism over essentialism with regard to species? If evolution plays out through natural selection, then what room is there for teleology, final causes, or divine action?

These are all good questions, and all have been the subject of intense discussion from Darwin's time right through to the present. For our purposes, however, the most important part of his theory, and arguably the most radical, is that he placed chance right at the heart of natural history.

4 Evolution as Part of the "Probabilistic Revolution"

A modern mathematical reader will quickly note the probabilistic machinery appropriate to Darwin's theory. Evolution has the structure of a Markov chain. Roughly, the states of the chain are the gene pools of organisms and their environments. The transition probabilities are such that states genetically close to what already exist are more likely to arise in the next generation than those that are far away. The process is "memoryless" in the sense that the future evolution of a species depends only on its current state and not on the historical vagaries leading to that state. More specifically, we see aspects of a random walk, as when genetic drift and neutral mutations lead to evolutionary change in the absence of natural selection, as well as branching processes, as when a local population becomes isolated from its ancestral stock and eventually becomes a new species.

However, this sort of mathematical machinery did not exist in 1859. Probability itself was in a somewhat rudimentary state at that time and was still mostly concerned with combinatorial problems related to games of chance.[7] Philosophically, probability was dominated by the work of Laplace, who took an epistemic view of the subject. Having accepted the law-bound picture of the universe inherent in Newtonian physics, he believed that statements of probability could only be expressions of human ignorance. This view was considered so fundamental that he opened his *Philosophical Essay on Probabilities* by writing:

[7] Todhunter (1865) remains the definitive reference for the state of probability at this time.

> All events, even those which on account of their insignificance do not seem to follow the great laws of nature, are a result of it just as necessarily as the revolutions of the sun. In ignorance of the ties which unite such events to the entire system of the universe, they have been made to depend upon final causes or upon hazard, according as they occur and are repeated with regularity, or appear without regard to order; but these imaginary causes have gradually receded with the widening bounds of knowledge and disappear before sound philosophy, which sees in them only the expression of our ignorance of the true causes.[8]

Laplace did not present this as a viewpoint in need of defense, but simply as an obvious conclusion of then-modern science.

Given the prevalence of this view, you can imagine the response of many of Darwin's contemporaries to his theory, which featured two distinct roles for chance: favorable variations were said to arise fortuitously, and selection was understood as a statistical tendency of certain members of a population to leave more offspring than their competitors. This ran into philosophical opposition from those who deplored the idea of chance playing an explanatory role in natural history, as well as theological opposition from those who feared that Darwin was ruling out a role for divine providence in the origin of species.

"Chance" can be a challenging notion to pin down since it means different things in different contexts.[9] To say that some event occurred by chance might mean that it occurred with no cause at all, as is sometimes suggested in modern discussions of quantum mechanics. It might mean that the event did not result from the plan of an intelligent agent. Sometimes the intent is that the event was inherently unpredictable beforehand on account of the limitations on human knowledge. Still another meaning is that the event was the result of a large number of independent causal chains, as when we consider all of the things that had to happen just so for a traffic accident to occur.

Darwin's notion of chance was not really any of these.[10] He certainly did not mean the variations were uncaused. Rather, his intention was that the variations among organisms are random with respect to the needs of the organisms. He argued that we should not imagine that an organism senses that a particular variation would be useful and then through some inner drive manifests just that variation. In a passage from his book *The Variation of Plants and Animals Under Domestication*, he offered a useful analogy:

> [I] have spoken of selection as the paramount power, yet its action absolutely depends on what we in our ignorance call spontaneous or accidental variability. Let an architect be

[8] Laplace (1951, 3). For recent discussions of the philosophical interpretations of probability most appropriate to evolutionary biology, see the two papers by Millstein (2003, 2016).

[9] Eble (1999) provides a lucid discussion of different uses of chance specifically in the context of evolution and paleobiology.

[10] For a discussion of Darwin's understanding of chance in biology, see the book by Johnson (2015) and the paper by Beatty (2006). For discussions of chance in evolutionary biology more generally, see the anthology edited by Ramsey and Pence (2016), and the papers by Beatty (1984), Shanahan (1991), and Millstein (2000).

> compelled to build an edifice with uncut stones, fallen from a precipice. The shape of each fragment may be called accidental; yet the shape of each has been determined by the force of gravity, the nature of the rock, and the slope of the precipice – events and circumstances, all of which depend on natural laws; but there is no relation between these laws and the purpose for which each fragment is used by the builder. In the same manner the variations of each creature are determined by fixed and immutable laws; but these bear no relation to the living structure which is slowly built up through the power of selection.[11]

However, with regard to scientists' openness to chance as an explanatory factor in nature, there was a fortuitous aspect to the timing of *The Origin of Species*. The mid-nineteenth century is a period in scientific history referred to by some scholars as the "probabilistic revolution."[12] Researchers in a variety of disciplines were coming to realize that statistical and probabilistic techniques were not just useful, but essential to solving practical problems.

In an interesting historical coincidence, Darwin published his book just a year before James Clerk Maxwell published his seminal work on the probability distribution appropriate to the velocities of individual particles in large ensembles of gas molecules, which later became foundational in the development of statistical mechanics.[13] This is especially noteworthy since Darwinian evolution has some interesting parallels with statistical mechanics.

At the heart of statistical mechanics is the idea that order can arise from randomness. The predictable, law-like behavior of matter arises from the random motions and collisions among large ensembles of microscopic particles. This approach led to tremendous advances in our understanding of thermodynamics. For example, the second law holds that entropy will never spontaneously decrease in an isolated system. In practical terms, this means that the energy of an isolated system tends to assume more dissipated forms and becomes less available for doing work. In classical thermodynamics, this was simply an empirical observation that was believed in general because it was seen to hold in any specific system in which the principle could be tested. Statistical mechanics, with its distinction between macrostates and microstates, provides insight into why energy dissipation in isolated systems is to be expected.

Darwin was essentially doing for natural history what statistical mechanics had done for thermodynamics. He showed there was no need to reference the master plan of an omnipotent engineer to explain the existence of modern species. Instead, they could arise from a chaotic jumble of random variations passed through the sieve of natural selection. Moreover, taking this view allowed tremendous insight into other aspects of biology.

Philosophically, the scientists of Darwin's time might have been more willing to countenance chance explanations than were their counterparts in previous eras.

[11] Darwin (1868, 236).
[12] Krüger et al. (1987).
[13] Maxwell (1860a, b).

However, that still left open a central question: How can we put Darwinian natural selection to empirical tests?

5 Biometry Versus Mendelism

Darwin was largely successful in convincing the scientists of his time that evolution had occurred. The numerous lines of evidence he adduced from various branches of anatomy, coupled with the evidence from paleontology and biogeography, were sufficient to convince scientists that modern species shared a far higher degree of relatedness with one another than had previously been appreciated.[14]

However, Darwin was far less successful in convincing people that natural selection was the primary mechanism of evolution. Skeptics wondered if the small, random variations central to Darwin's theory could really accumulate to the point of creating new species. Moreover, the favored theory of heredity at the time held that the characteristics of the offspring were a literal blend of the characteristics of the parents. If this were correct, then small variations would quickly vanish when the organism possessing the variation mated with those who did not. Regression to the mean would quickly occur, making significant directional evolution impossible.

A rival explanation of evolutionary change relied on so-called sports, meaning offspring that exhibited large variations relative to their parents. According to this school of thought, it was the variations themselves that led to significant evolutionary change. Natural selection, to the extent it was relevant at all, served only to affect minor changes in the characteristics of species. Advocates of this view came to be known as "mutationists."[15]

Plainly, the impasse could only be broken through a careful, quantitative study of naturally occurring variation among individuals. However, this presented a problem since the physical basis of heredity was entirely unknown at that time. The very existence of genes, much less their chemical structure, would not be confirmed until the early twentieth century. Consequently, scientists could only study observable, phenotypic variations in organisms. This led to an area of research known as "biometry."

The general philosophy underlying this approach was clearly expressed by Walter Weldon, an especially prominent biometrician, in a commentary on one of his papers:

> The questions raised by the Darwinian hypothesis are purely statistical, and this statistical method is the only one at present obvious by which that hypothesis can be experimentally checked.[16]

[14] This history is recounted in Ruse (1979), Mayr (1991), and Morange (2021, 157–222), among many other references.

[15] Provine (1971) and Gigerenzer et al. (1989, Ch. 4) are especially useful references here.

[16] Weldon (1895, 381).

Elsewhere he elaborated on what this meant:

> It cannot be too strongly urged that the problem of animal evolution is essentially a statistical problem: that before we can properly estimate the changes at present going on in a race or species we must know accurately (a) the percentage of animals which exhibit a given amount of abnormality with regard to a particular character; (b) the degree of abnormality of other organs which accompanies a given abnormality of one; (c) the difference between the death rate per cent. in animals of different degree of abnormality of parents, with respect to any organ; (d) the abnormality of offspring in terms of the abnormality of parents and *vice versa*. These are all questions of arithmetic; and when we know the numerical answers to these questions for a number of species we shall know the direction and the rate of change in these species at the present day – a knowledge which is the only legitimate basis for speculations as to their past history and future fate.[17]

In Weldon's view, the main problem of evolutionary research was to determine, for some measurable trait in an organism, the extent of its variation around the population's mean and its degree of correlation with the same trait in the previous generation. In other words, how much variation was there and how heritable was this variation?

Reading Weldon's papers today, it is impossible not to be impressed by the sheer patience and attention to detail this work required. In an example we can take to be representative of biometrical research generally, Weldon examined variations in the carapaces of the abundant crab species *Carcinus moenas*. By taking measurements on thousands of samples and then comparing those measurements with those taken on ancestral samples by prior researchers, Weldon was able to measure the degree of selective advantage of certain carapace designs over others. Here is a typical passage:

> The belief in which the work was undertaken was, that the law of variation would be found throughout to be that of the ordinary probability equation and this belief was tested in the following way: – In each of the thirty-five groups, the arithmetic mean of the frontal breadths, and the mean of all the deviations from it, were determined; and from the "mean error" found in this way the modulus of the probability function was calculated. Then, by calling the mean of each group zero, and expressing the deviations from the mean in terms of the modulus, a number of curves were obtained, in each of which the modulus was unity and mean zero; a similar curve of adults was constructed, and the corresponding ordinate of all the thirty-six curves so obtained were added together.[18]

To clarify, "the ordinary probability equation" is what we today call the normal or Gaussian distribution. However, in Weldon's time this distribution was called the "law of errors," from its historical roots in studying measurement errors in experimentation. This explains Weldon's references to "mean errors." We should note, however, that this term has some biological significance as well. Prior to Darwin, the general belief was that species had immutable essences and that individual variation

[17] Weldon (1893, 329).

[18] Weldon (1894, 363).

represented a distraction from understanding that essence.[19] Darwin reversed that thinking since it was a consequence of his theory that species were ephemeral and that it was the variations themselves that mattered. That Weldon was still thinking of variations as "errors" is suggestive that he had not fully absorbed Darwin's way of thinking, even while trying to collect data in support of evolution by natural selection.

The theoretical development of statistical methods in the late nineteenth century owes a lot to biometry and especially to the work of its most distinguished practitioner, Karl Pearson. Among other contributions, Pearson developed several techniques for determining curves of best fit, as well as the "chi squared" test for statistical significance. Pearson published a series of 18 papers under the title "Mathematical Contributions to the Theory of Evolution," and believe me when I tell you they do not make for light reading.[20]

Biometricians focused on traits that varied continuously, such as height, weight, and shell length. They sided with Darwin against the mutationists by emphasizing the importance of selection acting on small variations. They produced examples, such as Weldon's crab studies, showing that this process could lead to directional change.

Starting around 1900, however, they faced a strong challenge from researchers focusing on discrete character traits. The challengers took the pioneering work of Gregor Mendel as their inspiration. Mendel was a Moravian monk who undertook some of the first systematic investigations of inheritance. He focused on varieties of peas, distinguishing, in particular, those that were wrinkled from those that were smooth. He cross-bred various combinations of pea plants, keeping careful track of the frequency of each variety in subsequent generations. He discovered that a trait might be absent from one generation, only to reappear later on. Data of this sort eventually led him to the now standard notions that there were particles of heredity (today called "genes," of course), that offspring received one copy of each gene from its parents, and that some genes were dominant and others recessive.

Mendel's work was largely ignored in his own time, but it was reintroduced to the scientific community in the early twentieth century by researchers such as Hugo De Vries. The sort of mathematics appropriate to understanding particulate inheritance of discrete traits differs from the sort appropriate to studying continuous variation. Contrary to Weldon's assertions about statistics, the new mathematics of inheritance was combinatorial and probabilistic.[21]

An early success in this vein is the Hardy-Weinberg law, named for the mathematician (Hardy) and geneticist (Weinberg) who published it independently in 1908.

[19] Mayr (1991, 40–42).

[20] See Stigler (2012) for a discussion of Pearson's major contributions to statistics and evolutionary studies.

[21] For a discussion both of this point and of the conflict between biometricians and Mendelians generally, see Provine (2001, Chs. 2–3) and Gigerenzer et al. (1989, 123–161). Presenting the history of this period as a stark contrast between two clearly defined schools of thought is inevitably a bit simplistic. For a more nuanced discussion of this history, see the paper by Shan (2021).

It is an example of a "one locus, two allele" model, meaning that we imagine a single genetic locus that is home to one of two alleles, which we shall denote A_1 and A_2. Suppose that A_1 and A_2 initially appear with frequencies p and $q = 1 - p$. We want to determine the frequencies of these alleles in the next generation, if we assume there is no migration, selection, or genetic drift.

Given our set-up, there are three possible genotypes at this locus, which we can denote by A_1A_1, A_1A_2, and A_2A_2. Let us assume that the population is very large and that mating is random with respect to this allele. The frequencies p and q can be interpreted as the probabilities that a randomly chosen allele from the population will be A_1 or A_2, respectively. In this case, it is easy to see that the frequencies of the three genotypes in the next generation will be p^2, $2pq$, and q^2, respectively. Note that this conclusion depended only on the initial frequencies of the two alleles and that these frequencies did not change from one generation to the next. Consequently, these frequencies will be constant down through the generations, at least until the environment changes so as to make one of our assumptions no longer valid.

Hardy published this in a letter to the editor that opened like this:

> I am reluctant to intrude in a discussion concerning matters of which I have no expert knowledge, and I should have expected the very simple point which I wish to make to have been familiar to biologists. However, some remarks of Mr. Udny Yule, to which Mr. R. C. Punnett has called my attention, suggest that it may still be worth making.[22]

Yule had muffed a question about the frequency of dominant alleles in Mendelian populations, and one can sense Hardy's frustration at having to ride in to set things right. Historically, it tells us something about the novelty of the combinatorial approach at this time that a distinguished geneticist like Yule could have erred on a point that is mathematically elementary.

The combinatorial approach of the Mendelians was initially seen as anti-Darwinian, in the sense that particulate inheritance seemed to support discontinuous evolution through the appearance of sports and not gradual evolution through the accumulation of small variations. However, the work of Ronald Fisher, culminating in his 1930 book *The Genetical Theory of Natural Selection*, reconciled Darwinian gradualism with particulate inheritance. Fisher's mathematical modeling showed that the biometrical emphasis on continuous variation was entirely compatible with Mendelian combinatorics.

Fisher's work was supplemented with additional efforts from Sewall Wright and J. B. S. Haldane, and the modern science of population genetics was born. This body of work was seen as putting natural selection on a firm theoretical footing.[23] Their work made it clear that even small variations conferring tiny reproductive advantages on their possessors would eventually spread through the population, under a variety of plausible assumptions about nature.

[22] Hardy (1908, 49).

[23] See Dobzhansky (1951) and Huxley (2010).

6 Some Equations of Population Genetics

Evolutionary biology addresses big questions about human origins and our place in the natural world. This is why it is sometimes perceived as intruding on religion's territory and why it receives so much attention from the general public.

However, the quotidian concerns of professional biologists are generally more mundane than this. The grand sprawl of natural history does not really lend itself to mathematical modeling, forcing theoreticians to focus instead on the short-term fate of specific alleles over a few generations. It was precisely this sort of modeling that was pioneered by Fisher, Haldane, and Wright, and it remains a focus of attention for researchers today.

Biologist John Gillespie offers the following humorous description of population genetics:

> Population geneticists spend most of their time doing one of two things: describing the genetic structure of populations or theorizing on the evolutionary forces acting on populations. On a good day, these two activities mesh and true insights emerge.[24]

On the theoretical side, the goal is to develop models reflecting various assumptions about the environment and mating habits of a hypothetical species. We then use these models to prove theorems about the likely fate of a given allele, or perhaps a collection of alleles. In these models, there is always a huge trade-off between biological plausibility and mathematical tractability. Evolutionary change in gene pools is governed by so many factors that our models can easily come to look like alphabet soup. That notwithstanding, it is impressive how often biologically simplistic models still turn out to be useful. To experience some of the flavor of this field, let us derive a standard result.[25]

For our starting point, we consider a single genetic locus at which two alleles, still denoted A_1 and A_2, reside. We assume that A_1 initially appears with frequency p and that A_2 appears with frequency $q = 1 - p$. Our interest is in the frequency of A_1 as the generations go forth.

Now, there are four factors that might affect the frequency of A_1 through the generations: migration, mutation, genetic drift, and natural selection. A proper model would contain variables for all of them, but to keep things tractable we will focus primarily on natural selection. We will assume that mating is random with respect to A_1 and A_2, meaning that individuals choose their mates without any regard for their genotype at this locus.

Recall that genetic drift refers to changes in gene frequency that result from stochastic causes. It is intuitively clear, and easy to prove mathematically, that genetic drift will be a more powerful force in small populations than in

[24] Gillespie (1998, 1).

[25] I have based my presentation primarily on the book by Gillespie (1998) and the article by Okasha (2012). The textbook by Hamilton (2021) is also very lucid.

large ones.[26] For this reason, when modeling natural selection, it is customary to assume the population is so large that it is effectively infinite.

Now, with two alleles we have the three genotypes A_1A_1, A_1A_2, and A_2A_2. We assume that initially the three genotypes are at their Hardy-Weinberg frequencies of p^2, $2pq$, and q^2, respectively. The three phenotypes each have a certain probability of surviving long enough to reproduce, and we will denote these probabilities by w_{11}, w_{12}, and w_{22}, respectively. Each probability individually is said to represent the "fitness" of its associated genotype.

We can also define the mean fitness of the population by the formula

$$\overline{w} = p^2 w_{11} + 2pqw_{12} + q^2 w_{22}.$$

In probabilistic terms, this is the expected fitness of a randomly chosen individual in the population.

The number of successful gametes produced by each genotype is proportional to its fitness. If the population size is N, then the total number of successful gametes produced is $N\overline{w}$. If we let p' denote the frequency of A_1 among the offspring, then we can write

$$p' = \frac{Np^2 w_{11} + \frac{1}{2}(2Npqw_{12})}{N\overline{w}} = \frac{p^2 w_{11} + pqw_{12}}{\overline{w}}.$$

If this is unclear, note that the A_1A_1 genotype only produces A_1 gametes, while the A_1A_2 genotype produces A_1 and A_2 gametes in equal number.

Finally, we denote the change in frequency of A_1 due to selection by $\Delta_s p$. We compute

$$\Delta_s p = p' - p = \frac{p^2 w_{11} + pqw_{12} - p\overline{w}}{\overline{w}}.$$

Keeping in mind that $q = 1 - p$, this eventually simplifies to

$$\Delta_s p = \frac{pq[p(w_{11} - w_{12}) + q(w_{12} - w_{22})]}{p^2 w_{11} + 2pqw_{12} + q^2 w_{22}}. \tag{1}$$

We have summarized our findings in Table 1.

Equation (1) becomes easier to study if we employ the following notational convention: Scale the fitnesses of the three genotypes so that A_1A_1 has fitness 1 (implying that A_1A_2 and A_2A_2 have fitnesses w_{12}/w_{11} and w_{22}/w_{11}, respectively). We now let s denote the "selection coefficient" for the relative fitnesses of the homozygous genotypes, and we let h denote the "heterozygous effect," which measures the

[26] This is comparable to saying that in a small number of coin tosses the frequencies of Hs and Ts might differ greatly from the expected 50:50, but in the long run we expect the ratio to be very close to 50:50.

Table 1 Our set-up for analyzing the effect of selection on the frequency of an allele

Genotype	A_1A_1	A_1A_2	A_2A_2
Fitness	w_{11}	w_{12}	w_{22}
Frequency in newborns	p^2	$2pq$	q^2
Frequency after selection	$p^2w_{11}/\overline{w}$	$2pqw_{12}/\overline{w}$	$q^2w_{22}/\overline{w}$

fitness of the heterozygote relative to the selective difference between the homozygotes. With this notation, we can express the fitnesses of A_1A_1, A_1A_2, and A_2A_2 respectively, as 1, $1 - hs$, and $1 - s$. A positive value of s indicates that A_1 has a selective advantage over A_2, while a negative value indicates the reverse.

Equation (1) now simplifies to

$$\Delta_s p = \frac{pqs[ph + q(1-h)]}{\overline{w}}.$$

In this form, it becomes straightforward to analyze the effect of selection on the frequency of p given different assumptions about s and h.

By analyzing the various cases, one is led to the conclusion that natural selection will always alter the frequency of p in a direction that increases the mean fitness of the population. This result is known as the "fundamental theorem of natural selection."[27]

Models of this sort played a central role in the establishment of the so-called synthetic theory of evolution, or simply the "modern synthesis," in the 1940s. Prior to this theoretical modeling, many believed that the small genetic variations on which Darwin put so much emphasis would simply be invisible to natural selection. It was argued that in a typical case, whatever reproductive advantage such variations provided would be too small for selection to overcome other environmental forces. Population genetic models can be used to show that this objection is unfounded.

[27] The fundamental theorem has its own literature attached to it. One can make a stronger statement than mine regarding selection and mean fitness, but doing so requires defining further technical vocabulary, which for the purposes of this brief survey I preferred to avoid. The theorem was first presented by Fisher (1930), but his presentation was a bit muddled and hard to follow. Mathematically rigorous formulations of the theorem can be found in Price (1972) and Edwards (1994). For philosophical analyses of its meaning and significance, see Plutynski (2006) and Okasha (2008). For a more reader-friendly discussion of the theorem, see Grafen (2003). In light of our earlier discussion about statistical mechanics, it is worth noting that Fisher himself saw a connection between his theorem and thermodynamics:

> It will be noted that the fundamental theorem proved above bears some remarkable resemblances to the second law of thermodynamics. Both are properties of populations, or aggregates, true irrespective of the nature of the units which compose them; both are statistical laws; each requires the constant increase of a measurable quantity, in the one case the entropy of a physical system and in the other the fitness … of a biological population. (Fisher 1930, 36)

Even very small selective advantages will be sufficient for natural selection to notice, so to speak.[28]

Models of the sort we have considered in this section are sometimes said to comprise "classical population genetics." Let us now briefly consider a more modern approach to the subject.

7 Coalescent Trees and Phylogenetic Reconstruction

The study of heredity has made a lot of progress since the time of the Mendelians and the biometricians. Today we understand genes down to the molecular level. Researchers no longer have to make do with measurable phenotypic traits of organisms or with hypothetical entities existing only in mathematical equations. Instead, they can study evolution down to the level of individual base pair substitutions in DNA molecules.

The widespread availability of genetic sequence data has opened up new possibilities for population genetics. Whereas the classical approach looked forward in time to model the short-term evolution of allele frequencies, the modern approach looks backward to model the evolutionary history of polymorphism data collected in the present. The result of such an analysis is a rooted, binary tree. The tree's leaves represent the genetic sequence data in the present, while its root represents the most recent common ancestor. If we orient the tree vertically with the root on top, then we can follow time backward from the bottom to the top. We would then see initially disparate nodes gradually uniting, with the number of tree branches decreasing by one with each such unification. In the terminology of population genetics, each such unification is called a "coalescence," and the resulting diagram is called a "coalescent tree."

This is illustrated in Fig. 1, which shows two possible coalescent trees on a starting sample of size four. The two trees have different topologies, corresponding to different possible evolutionary histories for the sample. The subscripts on the time units to the right of the figure indicate the number of branches at that stage of the

[28] There is some debate among evolutionary biologists about the importance of mathematical population genetics. The founding document of the modern synthesis is the book by Huxley (1942), and he devotes considerable space to the work of Fisher, Haldane, and Wright. Nonetheless, Ernst Mayr, another of the major architects of the synthesis, famously derided the combinatorial approach as "beanbag genetics" and believed that the models were too simple to be worth anything (Mayr 1963, 263). This provoked a strong response from Haldane (1964), and the inevitable vast literature ensued. A few of the many references that are worth a look are Lynch (2007), Ewens (2008), Pigliucci (2008), and Crow (2009). For a readable discussion of the differences between Mayr and Haldane, see the book by Dronamraju (2011). Few nowadays would go as far as Mayr, and there is no question that the field of theoretical population genetics has much to be proud of. However, there is a more nuanced objection that the field places too much emphasis on genes and not enough on other factors like embryological development. We will not attempt to adjudicate that dispute here.

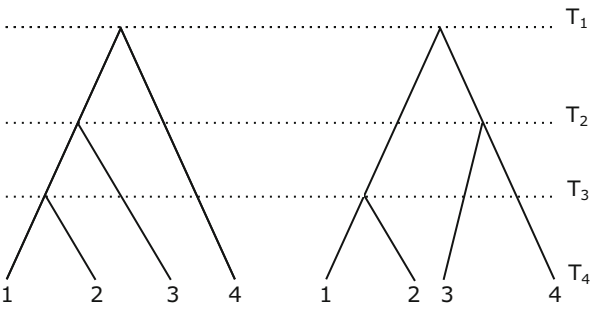

Fig. 1 Two coalescent trees on samples of size four

evolutionary process. We can interpret $T(k)$, where $1 \leq k \leq N$, to be a random variable that records the length of time during which the number of branches is k.

The goal of coalescent analysis is to develop mathematical models for understanding genetic polymorphisms in modern species. The sequence data of the present presumably arose through a lengthy and complex evolutionary process that was influenced by numerous variables. We want to be able to use coalescent analysis to look at the data and say something like, "Data of precisely this sort is what we would expect if the variables X, Y, and Z were at play in the evolutionary process." Clearly, any such model will have to be stochastic. There are so many chance factors in evolution that our conclusions about genealogical relationships, except in the most trivial cases, will have to be probabilistic.

In what follows, to keep our models mathematically tractable, we will assume there is no selection or migration. For our purposes, evolution proceeds solely by genetic drift, with possible mutations along the way.

Probability distributions on evolutionary trees were extensively studied in the 1960s, most notably by Motoo Kimura and Warren Ewens. They based their models on an analogy between genetic drift and Brownian motion. In a stochastic evolutionary process, random interactions among genes in one generation lead to further such interactions in later generations, leading to essentially chaotic changes in gene frequencies further down the line. This is roughly analogous to Brownian motion, in which the chaotic movements of microscopic particles in a medium are explained by a cascading sequence of collisions among other microscopic particles.

There is a rich mathematical theory underlying Brownian motion. This theory is based on diffusion equations, which are a subset of partial differential equations more generally. Even though we generally think of evolution as a discrete time process, it can nonetheless be effectively studied with continuous time models. Kimura and Ewens adapted the theory of diffusion equations to the needs of population genetics, thereby developing probabilistic models for evolutionary trees. These models were then tested against the results of Monte Carlo simulations using computers, which was very pioneering at the time.[29] Modern coalescent theory

[29] Dietrich (1996).

is largely based on adapting their models to look backward in time instead of forward.[30]

Let us see a standard, if somewhat basic, calculation in this field.[31] Our model assumes that all evolution is random, meaning that in any generation, any individual is as likely to reproduce as any other. This implies that as we go backward in time, any two lineages are as likely to coalesce as any other. Likewise, any tree topology will be as probable as any other as well.

If N is the number of endpoints in the present, then the probability that a pair of lineages coalesce one generation back in time is just $1/N$, and the probability that they remain distinct is therefore $1 - (1/N)$. The probability that they remain distinct for at least τ generations is then $(1 - (1/N))^{\tau}$.

If we scale time so that one unit corresponds to N generations, then the probability that two lineages stay distinct for more than t time units is

$$\left(1 - \frac{1}{N}\right)^{\lfloor Nt \rfloor} \to e^{-t},$$

as $N \to \infty$. With this scaling, the coalescence time is exponentially distributed with a mean of 1 in the limit.

We can extend this to k lineages. The probability that none of them coalesce in the previous generation is

$$\prod_{i=0}^{k-1} \frac{N-i}{N} = \prod_{i=1}^{k-1} \left(1 - \frac{i}{N}\right) = 1 - \frac{\binom{k}{2}}{N} + O\left(\frac{1}{N^2}\right),$$

and the probability that more than two do so is $O(1/N^2)$. If N is very large, then this last probability is negligible.

It is illuminating to ask for the expected time to the most recent common ancestor for the entire sample (as opposed to the ancestor for a subset of the initial sample). Our previous work implies that $T(k)$ is exponentially distributed with mean $2/k(k-1)$. Using $E(X)$ to denote the expected value of the random variable X, we now compute

$$E\left(\sum_{k=2}^{N} T(k)\right) = \sum_{k=2}^{N} E(T(k)) = \sum_{k=2}^{N} \frac{2}{k(k-1)} = 2\left(1 - \frac{1}{N}\right).$$

[30] Diffusion equations were first introduced into evolutionary analysis in Fisher (1922), but it was Ewens (1964) and Kimura (1964) who really developed the theory.

[31] The calculations that follow are taken from the video presentation by Nordborg (2018). See also the survey article by Felsenstein (2007) and the textbook by Wakeley (2009) for more about coalescents.

On the other hand, we also have $E(T(2)) = 1$. We conclude that the expected time during which there are only two branches is greater than half the total expected height of the tree.

A useful analogy is to picture a group of cannibalistic beetles in a box. In each beetle encounter, one beetle eats the other. When there are many beetles in the box, collisions will happen frequently and the number of beetles will quickly go down. When there is a small number of beetles in the box, collisions will be far more infrequent.[32]

Let us conclude this section by noting that coalescent theory is a subfield of phylogenetic reconstruction more generally. The grand project of evolutionary biology is to work out the one true tree of life that produced the modern riot of extant species. Trees are fundamentally combinatorial objects, and similar mathematical questions arise whether our data comes from microscopic DNA sequences or macroscopic data of the sort paleontologists might study. The study of Markov models on trees is very highly developed, and this theory is increasingly finding applications in the development of phylogenetic research.[33]

8 The Abuse of Probability by Anti-Evolutionists

With the previous section, we complete our brief survey of the relationships between probability theory and evolutionary biology. We have seen that, historically, the relationship has gone both ways. A desire to test Darwin's ideas led to progress in statistics, and probabilistic modeling was essential to placing evolutionary biology on a solid theoretical footing. The relationship continues into the present, with ever more sophisticated probabilistic methods being applied to the problems of phylogenetic reconstruction.

However, this is not the end of our story. More so than most branches of science, evolutionary biology has a political dimension, especially in the United States. Within certain faith communities, evolution is seen as contrary to religion, and this sometimes leads to conflicts over the science curriculum to be taught in public schools. Given this social relevance, and given that evolution's critics frequently employ probability theory in their discourse, it behooves us to take a look at their arguments, if only to understand why most scientists find them unconvincing.

Leaving aside religious considerations, evolution really does seem to run afoul of a powerful intuition that natural forces do not construct complex, functional systems, no matter how much time you give them. Our everyday experience is that machines break down and fall apart unless energy and intelligence are expended to maintain them, but evolution claims that organisms have become more complex over time. Mathematical anti-evolutionism is about trying to place that intuition on a more rigorous footing. Since probability theory is the branch of mathematics that

[32] This analogy is used by Nordborg (2018) who attributes it to Joseph Felsenstein.

[33] See Semple and Steel (2003) and Steel (2016).

quantifies our notions of what is likely and what is not, it is unsurprising that evolution's critics rely so heavily on it in their writing.

In this regard, a classic anti-evolutionist argument points to the emergence of complex proteins as the thing that is too improbable to countenance. Proteins can be viewed as long chains of amino acids in which each link is drawn from among 20 possibilities. This makes it possible to think of protein formation in combinatorial terms. Here is an especially clear version of the argument, as presented in a mainstream American periodical:

> The specificity of hemoglobin is described by the improbability of the specific amino acid sequence occurring by random chance. Such specificity is capable of exact calculation in the permutation formula
>
> $$P = \frac{N!}{n_1! \times n_2! \times n_3! \ldots \text{etc.}},$$
>
> where N is the total number of amino acids in hemoglobin (574); n_1, etc. are the number of separate kinds of amino acids; . . . In the case of hemoglobin, . . . the specific numerical value of the solution is $P = 10^{654}$. Thus, we can state that the improbability of hemoglobin occurring by random selection can be represented by the infinitely small number 10^{-654}, which means 10 divided by itself 654 times: as near to zero as one could consider.[34]

Arguments of this general sort are ubiquitous in anti-evolutionist literature.[35]

There are many variations on the basic theme, but the logic always conforms to the following general scheme:

1. Identify a complex biological structure, such as a specific gene or protein.
2. Model its evolution as a process of randomly selecting one item from a very large space of equiprobable possibilities.
3. Use elementary combinatorics to determine the size of the space, which we shall call S.
4. Conclude that the probability of the structure having evolved by chance is $1/S$, and assert that this is too small for evolution to be plausible.

I shall refer to this as the Basic Argument from Improbability (BAI).

Since proteins arise ultimately from genes, let us speak, for the moment, of "genotype space" as opposed to "protein space." Mathematically speaking, genotype space is a metric space equipped with a probability distribution. The metric is such that genotypes that are mutationally close to our starting point are assigned a smaller distance than those that are far away. The probability distribution assigns a higher probability to genotypes that are more fit than it does to genotypes that are less fit.

[34] Foster (1999, 80). We should note that 10^{-654} does not really mean to divide 10 by itself 654 times, but this is not the main error with this argument.

[35] Other examples can be found in Roth (1998, 69–70) and Meyer (2013, 173).

The BAI is fallacious because it completely ignores the effect of natural selection on the probabilistic and metric structures of genotype space. Evolution does not navigate genotype space by choosing points at random. Instead, it finds its starting point at the origin of life and then carries out a series of local searches in the neighborhood of wherever it happens to be. The probabilistic and metric structures guarantee that most of the space has a probability close to zero of ever arising, while fit genotypes close to our starting point have a high probability of arising. The probability distribution appropriate to genotype space is highly non-uniform, and this fact shows that the calculation put forth by the BAI is based on a hopelessly unrealistic model.[36]

Moving on, a more sophisticated probabilistic, anti-evolutionary argument has been put forward by mathematician William Dembski in a series of books and articles.[37] He defines a quantity he calls "complex, specified information (CSI)." His basic idea is that it is not improbability by itself that suggests design, but rather improbability coupled with a recognizable pattern. Any sequence of Hs and Ts is as unlikely as any other when we flip a coin 100 times, but 100 Hs, or a perfect alternation of Hs and Ts, show a clear pattern and would therefore suggest trickery of some sort. Any pattern of crags and grooves on a mountain is highly unlikely, but the faces on Mt. Rushmore also fit a pattern and therefore must be explained by intelligent design. Thus, "complex" means low probability, and "specified" means that we find a recognizable pattern. "Information" refers to any event or object whose origin we wish to explain.

As applied to evolutionary questions, the argument might play out like this: Choose a functional structure like the flagellum used for propulsion by some bacteria. It is complex in the sense that it is composed of many individual proteins that must be arranged in a precise way. It is specified in the sense that it functions in a way that is strongly analogous to an outboard motor on a boat. Thus, the flagellum is complex and specified and, therefore, must be designed.

If we are to treat this as a rigorous argument, then within Dembski's framework we must answer two questions: How do we carry out a meaningful probability calculation to establish complexity in the sense he intends? And how do we distinguish the design-suggesting patterns from those we impose on nature through excessive imagination? (For example, it is very easy to look at a fluffy, cumulus cloud and imagine that you see a dragon.) Let us see how Dembski tries to answer these questions.

[36] Since we are only interested in specifically probabilistic arguments, the response we have given is sufficient for our purposes. The question of whether a complex protein really can evolve in a gradual, stepwise manner is separate from the question of whether the BAI is a good argument. However, we should note that protein evolution has been a major area of scientific investigation for many decades. One of the main findings in this area is that standard evolutionary mechanisms are fully capable of exploring large swaths of protein space. See Yeates (2007), Ferrada and Wagner (2010), or Wagner (2014), for example.

[37] See Dembski (2002) for the most formal presentation of his ideas.

To justify the reduction of probability to combinatorics, Dembski relies on the notion of an "irreducibly complex" system. In this context, this idea is the brainchild of biochemist Michael Behe who defined an irreducibly complex system to be one in which several distinct parts work together to carry out some function, such that the removal of any one part causes the system to cease functioning. In his 1996 book *Darwin's Black Box*, Behe argued that such a system could not evolve gradually because the precursor systems would inevitably be missing some of the parts and therefore could not function. Since natural selection has no foresight, it will not preserve a non-functional system in the hope that later developments will somehow render it useful.

Dembski now explains the relevance of irreducible complexity to carrying out probability calculations:

> An irreducibly complex system is a discrete combinatorial object. Probabilities therefore naturally arise and attach to such objects. Such objects are invariably composed of building blocks. Moreover, these building blocks need to converge on some location. Finally, once at this location the building blocks need to be configured to form the object. It follows that the probability of obtaining an irreducibly complex system is the probability of originating the building blocks required for the system, multiplied times the probability of locating them in one place once the building blocks are given, multiplied times the probability of configuring them once the building blocks are given and located in one place.[38]

Dembski's argument was recently endorsed in an article published in the academic *Journal of Theoretical Biology*. Authors Steinar Thorvaldsen and Ola Hössjer present the argument like this:

> [D]embski proposes an equation based on three independent events: A_p: originating the building blocks (protein chains) of the protein complex . . ., A_l: localizing the building blocks in the same place, and A_c: configuring the building blocks correctly to form the complex. Then the probability of a protein complex is the multiplicative product of the probabilities of the origination of its constituent parts, the localization of those parts in one place, and the configuration of those parts into the resulting system (contact topology). This leads to the following estimate for the probability of a protein complex (PC) composed of N independent building blocks:
>
> $$\widehat{P}(A_{PC}) = \prod_{n=1}^{N} \left[P\left(A_p^{(n)} | \widehat{\theta}_p^{(n)}\right) \cdot P\left(A_l^{(n)} | \widehat{\theta}_l^{(n)}\right) \cdot P\left(A_c^{(n)} | \widehat{\theta}_c^{(n)}\right) \right],$$
>
> where $\theta_p^{(n)}, \theta_l^{(n)}$, and $\theta_c^{(n)}$ are the parameters involved in forming the protein chain, the localization, and the configuration of the nth building block.[39]

While this argument is an improvement over the BAI, it is not difficult to find grave errors in its formulation. The first is that it is not legitimate to treat an irreducibly complex system as a discrete, combinatorial object because there are

[38] Dembski (2002, 290–291).

[39] Thorvaldsen and Hössjer (2020, 7).

several plausible scenarios for how such a system could evolve gradually. For example, the removal of redundancy can lead to irreducible complexity, as when a scaffold supports an arch during its construction. When the arch is complete, the scaffold is removed, leaving behind an irreducibly complex structure (the arch cannot support itself without its capstone, and the capstone has nothing to rest on without the arch.) An interdependence of parts can also arise when one or more parts is not required when it is first introduced, but later becomes essential because of changes in the surrounding system.[40]

Moreover, modeling the evolution of a complex structure as a threefold process of origination, localization, and configuration is biologically unrealistic. Instead of combinatorial arrangements of proteins or other sorts of component parts, we should be thinking about the underlying genetic instructions leading to the finished system. However, the same instructions that dictate which proteins get produced also direct those proteins to specific locations and mandate the relationships among them. This shows that the three probabilities in Thorvaldsen's and Hössjer's equation are not independent and therefore cannot be multiplied.

Now let us see how Dembski deals with specification. To address the problem of distinguishing design-suggesting patterns from those we simply impose on nature, he argues that the pattern must be "detachable" from the object itself.

To see the basic idea, we imagine firing an arrow at the wall of a barn. After the arrow embeds itself in the wall, we could paint a small circle around it, thereby making it appear that we hit a small target.[41] This is a non-detachable pattern since

[40] Again, since our interest here is solely in probabilistic arguments, this response is sufficient for our purposes. The anti-evolutionist argument presupposes that an irreducibly complex system cannot evolve in a gradual, stepwise manner, but our hypothetical scenarios show that this is not true. However, we should note that these scenarios are not mere speculation, but seem to have played out in natural history. For example, my scenario about irreducible complexity arising as a result of the removal of redundancy is strongly implicated in the evolution of the bone structure in the mammalian inner ear (Gould 1993). There are numerous other such supposedly irreducibly complex systems for which researchers have found strong evidence for likely evolutionary trajectories. These include the human blood clotting cascade (Miller 1999, 152–158), the avian fight apparatus (Gishlick 2004), and the bacterial flagellum (Musgrave 2004; Beeby et al. 2020), among many others. Interestingly, Darwin himself already noted the possibility that the removal of redundancy could explain the evolution of complex adaptations, in *The Origin of Species*:

> We should be extremely cautious in concluding that an organ could not have formed by transitional gradations of some kind. Numerous cases could be given amongst the lower animals of the same organ performing at the same time wholly distinct functions . . . In such cases natural selection might easily specialise, if any advantage were thus gained, a part or organ, which had performed two functions for one function alone and thus wholly change its nature by insensible steps. Two distinct organs sometimes perform simultaneously the same function in the same individual . . . In these cases, one of the two organs might with ease be modified and perfected so as to perform all the work by itself, being aided during the process of modification by the other organ, and then this other organ might be modified for some other quite distinct purpose, or be quite obliterated. (Darwin 1859, 220)

[41] Mathematicians and statisticians sometimes refer to this as the "Texas sharpshooter fallacy."

we had to see where the arrow landed before identifying the target. A detachable pattern can be described separately from the object or event itself.

Dembski provides a very technical definition of "detachability":

> Given a reference class of possibilities w, a chance hypothesis H, a probability measure induced by H and defined on w (i. e. $P(\cdot \mid H)$), and an event/sample E from w, a rejection function f is *detachable* from E if and only if a subject possesses background knowledge K that is conditionally independent of E (i.e., $P(E \mid H\&K) = P(E|H)$) and such that K explicitly and univocally identifies the function f. Any rejection region R of the form $T^{\gamma} = \{w \in w \mid f(w) \geq \gamma\} T_{\delta} = \{w \in w \mid f(w) \leq \delta\}$ is then said to be *detachable* from E as well. Furthermore, R is then called a *specification* of E and E is said to be *specified*.[42].

Readers with some statistical background will recognize this as standard Fisherian hypothesis testing. In the present context, however, this definition seems unhelpful because we have no way of matching up Dembski's formalism with biologically realistic counterparts in real life. If we are pondering the origins of a bacterial flagellum, for example, then what, exactly, are playing the roles of w, K, E, f, T^{γ}, and T_{δ}?

Indeed, when it comes time to discuss "specification" in the context of particular systems, Dembski does not refer back to this formalism. Instead, he writes:

> Biological specification always refers to function. An organism is a functional system comprising many functional subsystems. In virtue of their function, these systems embody patterns that are objectively given and can be identified independently of the systems that embody them.[43]

This is too casual to serve as an argument that functional systems are specified in the precise technical sense required by his theorizing. Biologists say that evolution by natural selection produces functional systems as a matter of course, and this lends some urgency to the question of whether the function of a system can serve as a proper specification. Does the flagellum instantiate a design-suggesting pattern, or is it just the sort of thing that evolution is able to do?

Our conclusion, then, is that Dembski's theorizing about CSI is not persuasive. We have no way of carrying out meaningful probability calculations, and we have no way of distinguishing design-suggesting patterns in biology from those that can arise through natural causes.

There are many other mathematical arguments in anti-evolutionist discourse, but inevitably they are unsuccessful for the kinds of reasons discussed here.[44] The metaphor of evolution exploring a vast genotype space can be helpful in many contexts, and biologists often employ it in explaining their reasoning. However, the

[44] I have written more extensively about mathematical anti-evolutionism elsewhere (Rosenhouse 2016, 2017, 2022). See also Sober (2002) and Elsberry and Shallit (2011), among many other references.

probabilistic and metric structures of the space are too complex to permit broad mathematical conclusions to be drawn regarding what is possible and what is not.

9 Conclusion

Biologist Sergey Gavrilets, himself a major contributor to the mathematical theory of evolution, writes:

> Since the time of the Modern Synthesis, evolutionary biology has arguably remained one of the most mathematized branches of the life sciences, in which mathematical models and methods continuously guide empirical research, provide tools for testing hypotheses, explain complex interactions between multiple evolutionary factors, train biological intuition, identify crucial parameters and factors, evaluate relevant temporal and spatial scales, and point to the gaps in biological knowledge, as well as provide simple and intuitive tools and metaphors for thinking about complex phenomena.[45]

Indeed, among Darwin's most important legacies is the discovery that probability theory is essential to mathematical modeling in biology. With some clear thinking and technical skill, probability can elucidate many formally mysterious aspects of natural history. When its methods are abused by ideologues, it can create obfuscation and confusion. Regardless, explorations of the connections between evolutionary biology and probability have significantly affected the practice of both disciplines, much to their mutual benefit.

Abstract

The application of mathematical probability theory in statistics is quite controversial. Controversies regard both the interpretation of probability and approaches to statistical inference. After having given an overview of the main approaches, I will propose a re-interpretation of frequentist probability. Most statisticians are aware that probability models interpreted in a frequentist manner are not really true in objective reality, but only idealizations. I argue that this is often ignored when actually applying frequentist methods and interpreting the results, and that keeping up the awareness for the essential difference between reality and models can lead to

a more appropriate use and interpretation of frequentist models and methods, called "frequentism-as-model." This is elaborated showing connections to existing work, appreciating the special role of independently and identically distributed observations and subject matter knowledge, giving an account of how and under what conditions models that are not true can be useful, giving detailed interpretations of tests and confidence intervals, confronting their implicit compatibility logic with the inverse probability logic of Bayesian inference, re-interpreting the role of model assumptions, and appreciating robustness and the role of "interpretative equivalence" of models. Epistemic probability shares the issue that its models are only idealizations, and an analogous "epistemic-probability-as-model" can also be developed.

1 Introduction

Ever since the time of Bernoulli (1713), mathematical probability has been used for statistical inference. Kolmogorov (1933) has given probability a mathematical axiomatic foundation that is the basis of the mathematical theory of probability to this day.

Whereas mathematical probability theory is largely uncontroversial, its application to statistical inference and data analysis is and has been highly contentious throughout the history of probability. This concerns both the very meaning of probability (e.g., Venn (1866); Ramsey (1926); Galavotti (2005)) and how it can be used for learning from data about the world (e.g., Barnard and Cox (1962); Wasserstein et al. (2019); Mayo (2022), the latter even referring to the "statistics wars").

Here I will present a view of some of the central concepts of this controversy that is based on the constructivist philosophy of mathematical modeling elaborated in Hennig (2010), along with some practical consequences. The main idea is that mathematical models are tools for thinking about reality, and they are essentially different from reality. Asking whether a mathematical model is true in reality constitutes a category error; mathematical models have other jobs than being true and need to be assessed based on how well they do these other jobs.

Although many statisticians tend to agree with George Box's famous quote that "all models are wrong but some are useful" (Box 1979) when asked directly, the statistical literature and statistics teaching are full of statements of the kind that "model assumptions have to be fulfilled" and references to "true distributions" and "true parameters" in reality. Many philosophical contributions to the foundations of statistics even more explicitly demand models to be true, or to be "believed." From the perspective of mathematical modeling taken here, such a mindset easily leads to over-interpretation of the results of statistical analysis. It also opens up any position

in the controversy about the foundations of statistics to criticism that could be avoided by a more modest and honest acknowledgement of the role and limitations of the use of probability models.

In Sect. 2, I will give an overview over several key concepts, namely interpretations of probability, approaches to statistical inference, and a constructivist philosophy of mathematical modeling. In Sect. 3, the central part of this chapter introduces "frequentism-as-model," a new re-interpretation of frequentist probability, and inference separating appropriately models and reality and discusses many of its implications. An analogous version of epistemic probability, "epistemic-probability-as-model," is sketched in less detail in Sect. 4 before the chapter is concluded.

2 Basic Concepts

The basic concepts for this chapter are different interpretations of probability, different approaches to statistical inference, and a constructivist philosophy of the relation between mathematical models and reality. Here I give an overview of these. Note that in much literature the distinction between interpretations of probability and approaches to inference is blurred. Often, Bayesian reasoning is identified with a (subjective) epistemic interpretation of probability, but there are non-Bayesian approaches to do inference with epistemic probabilities, and Bayesian reasoning can be combined with frequentist probabilities as well.

2.1 Interpretations of Probability

Interpretations of probability connect probability as mathematical object with the real world by explaining what mathematical probability statements are supposed to mean. There are two major classes of interpretations of probability, aleatory, and epistemic.

2.1.1 Aleatory Probability

Aleatory probability, sometimes referred to as "chance," is a generic term for thinking of a probability as an observer-independent feature of what Hacking (1965) calls "chance setup" or a data generating process in reality. The best-known aleatory interpretation is frequentism. In frequentism, the chance setup is conceived as an experiment or a situation that can be repeated in principle infinitely often, and the probability of an event, $P(A)$, say, is then thought of as the limiting relative frequency of the occurrence of A when the number of random repetitions tends to infinity. I will refer to chance setups as "experiments" in the following, in line with the use of "random experiments" in the literature. This does not necessarily imply controlled experimentation. The axioms of probability are motivated from mathematical properties of relative frequencies.

There have been various attempts to make this notion precise. The most famous of them are probably due to Venn (1866) and von Mises (1939). Both of them

acknowledge that frequentist probabilities are an idealization. Their existence cannot be assured based on finite sequences of observations; in fact, any behavior in any finite part of the sequence is compatible with any limit value from a mathematical point of view. Requiring identical repetitions is an idealization as well. This is bypassed by von Mises (1939) instead requiring the specification of an ideally infinite "Kollektiv" of experiments within which probability is defined rather than relying on "identity." Venn (1866) and many later frequentists take a hypothetical point of view; their probabilities refer to what would happen if the experiment were to be repeated infinitely. Hajek (2009) gives 15 arguments against such a view, many of which have to do with subtleties of mathematical limits, but he also attacks the anti-empirical nature of the idea.

Another key difficulty is the definition of randomness. Randomness can be defined based on algorithmic complexity, i.e., a sequence can count as random if it cannot be generated by certain finitely describable algorithms, see Martin-Löf (1966), in which case he also could prove that limiting relative frequencies exist. However, this cannot be checked given only a finite number of observations. Fine (1973) even showed, given suitable definitions, that "apparently random" finite sequences will automatically look as if their relative frequencies "apparently converge," without any condition regarding what will really happen if that sequence is infinitely continued. Looking at a sequence of relative frequencies of the occurrence of a set A in a "randomly enough" repeated experiment will give the impression that these relative frequencies stabilize. This is a major motivation to think that frequentist probabilities might exist in the real world, but Fine's result shows that the impression is an implication of what kind of sequences an observer attributes randomness to and does not imply anything about the real existence of a limiting frequency.

An alternative aleatory concept is the interpretation of probabilities as "propensities," going back to Popper (1959b). A propensity is conceived as an objective feature of an experiment to have the tendency to produce certain results. If indeed the experiment were repeated infinitely, the idea is that it would produce relative frequencies according to its propensities, but there is no necessity for this to happen for a propensity to be defined. In this way, the propensity interpretation of probability allows to speak of probabilities connected to single realizations of an experiment, and it does not have to be concerned about issues with mathematical limits, although the propensity interpretation does not put the researcher in a better position to make empirical statements about the values or even the very existence of probabilities compared to frequentism.

There are several varieties of propensity interpretations, see Gillies (2000). Gillies' own propensity approach basically postulates that propensities behave according to the probability axioms, and in case repetitions are observed, it can then be tested empirically whether outcomes behave as they should behave given the postulated probability model. Such tests can of course not be very powerful if the number of repetitions is low.

The biggest problems with aleatory probability interpretations stem, in my view, from the idea that their use requires them to exist objectively in reality. Treating

mathematical models as fundamentally different from reality, as I will outline below, an aleatory interpretation of probability should refer to thinking of reality *as if* it behaved in this way, without postulating or believing that it really does, which cannot be ensured, or even very convincingly argued, due to the lack of infinite random repetition in reality. I will call this "frequentism-as-model" (in the following I will mostly refer to "frequentism," as this is in much more frequent use in the literature than "aleatory"). Obviously, there needs to be a justification how models used in this way contribute to science. Many scientists think that objectivity is a main reason to use aleatory probabilities, but they can be called "objective" only in the sense that they *refer* to observer-independent reality, not in the sense that their observer-independent existence could be granted.

2.1.2 Epistemic Probability

An epistemic probability $P(A)$ refers to the belief or knowledge of an agent regarding the event A. Epistemic probabilities do not require any repeatability of experiments; they apply to single situations as well as to experiments that are part of a sequence. The probably simplest and historically original way to explain $P(A)$ in an epistemic way is as a betting rate; the agent would be willing to pay up to $P(A)$ for a gamble in which she receives 1 in case that A obtains and 0 otherwise. The axioms of probability can be motivated from requirements of fair betting prices requiring "coherence," i.e., bets on several events have to be offered in such a way that an opponent cannot put together a system of bets so that the agent incurs sure loss. This was formalized by Ramsey (1926) and de Finetti (1937).

As for aleatory probability, there are various versions of the epistemic interpretation. Ramsey (1926) and de Finetti (1937) held that probabilities are subjective. An agent makes subjective initial prior assignments of probability, and probability theory imposes the coherence of these assignments and how these have to be coherently updated when new evidence occurs, namely following Bayes's Theorem. Different agents can have different probabilities for the same event, even if they hold the same information.

Subjective probabilities may seem unsuitable for science if the aim of science is assumed to be producing objective statements that hold independently of the researcher. Keynes (1921) interpreted probability as an extension of logic to uncertain propositions, the plausibility of which, given the evidence, could be quantified as a probability. Such a probability is epistemic, but there is no subjective agent; the probability is meant to be determined by the evidence without further subjective input. Keynes constrained numerical probabilities to propositions concerning a finite number of cases that are equiprobable, i.e., they have the same probability assigned based on the "Principle of Indifference" in case that for none of them there are reasons to think of them as more likely than the others. Ramsey and de Finetti criticized this as far too restrictive, and there are further issues with the Principle of Indifference; see Gillies (2000). More recent developments of logical and objectivist epistemic interpretations of probabilities, e.g., Jaynes (2003), are less restricted.

Bayesian updating of prior probability assessments ("priors") is central according to many proponents of epistemic probability, which is therefore often identified with

"Bayesianism." At the time of Bayes (1763), there was no explicit distinction between aleatory and epistemic probabilities. Bayes's original paper is somewhat ambiguous on the matter, and his theorem holds as well for aleatory probabilities. Williamson (2010), despite calling his interpretation "Bayesianism," is an example for an epistemic interpretation that does not rely on Bayesian updating.

The major difference between objectivist and subjectivist epistemic interpretations is how the priors should be chosen. The subjective approach may lead to potentially arbitrary choices that may not be an appropriate basis for science, but in very many situations, it is hard if not impossible to impose a unique objective choice. Ideally, at some point there is no evidence. At this point, an "informationless prior" is chosen, and then any incoming evidence can be processed using Bayesian updating. However, general agreement regarding how to choose informationless priors does not exist, and there are issues and paradoxes with them (Kass and Wasserman 1996). Furthermore, much evidence comes in forms that an initially chosen model cannot easily incorporate. Objective probabilities might be seen as desirable, but the subjectivists can state that they are an unachievable ideal in most situations. Berger (2006), in a defense of objective Bayesianism, admits that full objectivity cannot be achieved, particularly when invoking existing information that does not come in an appropriately formalized way, for example, knowledge about logically impossible parameter values or observations. The term "objective Bayesianism" in his view refers mainly to priors that reflect a lack of subjective information. These can be useful also for subjectivists, as a "reference." Howson and Urbach (2006) on the other hand state that the hope for objective priors is misplaced, but that the probability axioms provide an objective basis for logical reasoning with uncertainties. They refer to Cox (1946), who showed that probability calculus including Bayesian updating is implied by a certain set of axioms for such logical reasoning, regardless of the prior. This is largely in line with the subjectivists.

The controversy between subjectivist and objectivist proponents of epistemic probability highlights a more general issue of statistics and even science as a whole, namely the tension between the ideal of objectivity, and the impossibility to achieve it, in its idealized form, in practice. Gelman and Hennig (2017) argue that instead of the ultimately futile demand of objectivity, it is more constructive to aim at a list of virtues that constitute aspects of objectivity, namely transparency, enabling consensus, impartiality, stability, and correspondence with observable reality; acknowledging that there are also virtues connected to subjectivity, namely context-dependence; and acknowledging multiple perspectives. Regarding epistemic probabilities, the objectivist focus is on enabling consensus and impartiality, whereas the subjectivist focus is on context-dependence and potentially multiple perspectives. In order to convince others and potentially a whole scientific community of their analysis, subjectivists need to motivate and justify their prior choices transparently just as well as the objectivists, despite acknowledging that others may legitimately choose another prior.

A general issue with epistemic probabilities is that the prior probability assignments determine the set of potential updates. This means in particular that certain prior choices that are in conflict with later observed data can never be corrected, at least not within the Bayesian framework. A Bayesian agent needs to explicitly assign

nonzero probability to whatever seems possible to them, because otherwise it will remain modeled as "impossible" forever. For example, if in a Bayesian analysis the prior involves the assumption that certain future events are exchangeable, meaning that probabilities do not depend on the order of outcomes, any posterior obtained by Bayesian updating from data will still fulfill this assumption, even if the data indicate that the assumption may not be appropriate. This does not seem to be a reasonable point of view of an epistemic agent. Consider an example regarding binary sequences. Even if initially it may seem an epistemic agent that all possible sequences in the future with, say, 500 ones and 500 zeroes are equally likely, it seems advisable to question her own assumption and potentially to change her mind in some cases. Imagine that 100 ones in a row are observed, then 150 zeroes, and then a few more ones, say 15. This seems to show strong evidence of positive dependence between neighboring outcomes, and most would now think that the outcome "one" should be far more likely in the next go, but having committed themselves to exchangeability, the epistemic agent is forced to ignore this.

It may be demanded, for this reason, that priors should not assume exchangeability. Furthermore, a similar case can be made against most regularity constraints that may be involved in non-exchangeable models. In consequence, the choice of priors would be far more complicated if not practically impossible, and much of the mathematical and algorithmic Bayesian machinery for computing posterior distributions, i.e., the probabilities resulting from updating the prior with the data, could no longer be used. Note also that a famous argument in favor of Bayesian epistemic probability states that the prior choice "wears out," i.e., the posterior distribution will ultimately be dominated by the data and will, in particular, converge toward a "true aleatory probability" of an event in case that this exists. This is often stated to suggest that epistemic probability is just as useful as aleatory probability when it comes to correspondence to observed reality, despite locating probabilities in the agent rather than in reality, but the argument assumes exchangeability, among other things (even though assumptions can be relaxed a bit (see Diaconis and Skyrms 2018, Ch. 6, 9)).

Arguably, this means that pretty much all prior assignments of epistemic probability that are done in practice are "wrong" in the sense that they do not really reflect the full belief or state of information. On top of this, it is well known that human agents are often biased when it comes to specifying probabilities and assessing the implications of their own choices (Kahneman et al. 1982).

Ultimately the same that has been stated for the aleatory interpretation already can also be said for the epistemic interpretation of probability. Epistemic probabilities, be they subjective or supposedly objective, should not be taken as a "really true" reflection of the epistemic state of the agent. They are models, and as such, they idealize and simplify. The later section on "epistemic-probability-as-model" discusses the consequences of explicitly acknowledging the model status of epistemic probabilities.

2.1.3 Postscript on the Controversy About Interpretations of Probability

A lot of work (de Finetti 1974; Jaynes 2003; Howson and Urbach 2006; Diaconis and Skyrms 2018) suggests that epistemic probability should be used universally,

and aleatory probability is flawed and/or superfluous (because of the result mentioned above that under certain prior assignments aleatory probabilities, if they exist, can be recovered by epistemic inference given enough data).

In particular, de Finetti (1974) stated that

> Probability does not exist.

This refers to the existence of objective aleatory probabilities in the world and was meant as an argument that the epistemic interpretation of probability is the only legitimate one. However, I have argued above that the existence of "true" epistemic probabilities is just as dubious. Furthermore, the assumptions that allow aleatory probabilities to be emulated in the epistemic framework may be convenient and in widespread use, but are not necessarily convincing. There seems to be a tendency among authors who favor epistemic probability to elaborate very clearly the deviation from reality of the aleatory concept taken literally, but to deny that the same issue exists for epistemic probability. If the latter is acknowledged, one may wonder whether it is worthwhile to model an epistemic agent rather than reality itself, in cases in which researchers want to make statements about observer-independent reality in the first place.

Senn (2011) raises the issue that Bayesian analyses in practice rarely are in line with how epistemic probability should ideally be handled, particularly when it comes to specifying the prior, and suggests (with arguments similar to mine above) that this may often be impossible. As other authors (e.g., Carnap (1950); Cosmides and Tooby (1996); Gillies (2000)), he acknowledges that both epistemic and aleatory probabilities may be needed.

Defense of aleatory probability and criticism of epistemic probability can also be found in the literature (e.g., Mayo (2018)), but there is more general acknowledgement that aleatory probability is not suitable for all applications (particularly if there is nothing that can be convincingly thought of as repetition) and that there is a role for epistemic probability, if (as some authors think) limited.

I do not think that the adoption of one interpretation of probability in one situation should preclude a statistician from using another interpretation in another situation. A statistician can be a frequentist when analyzing a randomized trial to compare a new drug with a placebo and adopt an epistemic approach when computing a probability that an accused is really the murderer, and in this sense she can be a pluralist. However, if in a single analysis the implied interpretation of probability is not clear, results in terms of probability do not have a clear meaning.

An interesting historical note is that a distinction between aleatory and epistemic probabilities was mentioned for the first time only around 1840 (Hacking 1975), more than a century after the first systematic treatment of probabilities by Bernoulli (1713). Problems associated with games of chance were among the first sources of probability considerations and, originally fair betting, classical probability (i.e., based on counting possibilities that were thought of as equiprobably), and expected frequencies seem to have been thought of as synonymous (in fact the first versions of the law of large numbers were taken as some kind of proof of the

correspondence between classical probability and limiting relative frequencies). There had already been considerations of situations that could hardly be reduced to counting equiprobable possibilities, and Bayes (1763) did not require equiprobability anymore, but his work seems to allude to both epistemic and aleatory ideas. Laplace (1814) defines probabilities more explicitly as epistemic, but his treatment of measurement error distributions looks rather aleatory, and no explicit distinction can be found in his work.

In any case it is not an accident that apparently different concepts such as epistemic and aleatory probabilities come with the same name and can be handled with the same calculus, as they draw from the same sources. This may feed the idea that only one interpretation should be needed, which exists particularly in the epistemic camp.

2.2 Approaches to Statistical Inference

In much literature, it is suggested that adopting either aleatory or epistemic interpretation of probability implies how to do statistical inference. Indeed many (though not all) versions of the epistemic interpretation imply Bayesian inference, whereas classical techniques as hypothesis tests and confidence sets have been devised with an aleatory probability interpretation in mind. There are exceptions to these associations though, and I believe that it clarifies the discussion to distinguish between interpretations of probability and approaches to statistical inference. In particular, there is much criticism of the logic implied by hypothesis tests and confidence intervals that does not concern the aleatory probability interpretation as such, and Bayesian inference is often applied having implicitly or explicitly an aleatory interpretation in mind.

These two approaches are the main focus here, but there are some others, as discussed further.

2.2.1 Compatibility Logic

Hypothesis tests and confidence sets concern parameters of statistical models, or, in the nonparametric case, certain classes of models that are of interest in a real situation. A model parameter can, for example, refer to a physical constant that is assumed to be measured with a random error. Comparing the outcome of a therapy on an ordinal well-being scale to a placebo therapy, a nonparametric set of distributions of interest may model the distribution of results in the therapy group as the same, or alternatively as systematically larger than in the placebo group. In the following, parametric inference will be discussed.

Data are assumed to have been generated according to such a model allowing for an often infinite set of parameters, and it is assumed that there is one true value of it. Inference about this true value is made based on with which parameter values data look incompatible, i.e., are in a suitable region with low probability. This region is usually defined by a statistic that formalizes a "distance" of the data to what is expected given a certain parameter value. If the probability ("p-value") is very low

that a dataset generated from the model with the parameter value in question is as far as or farther away from this expectation than the observed data, then the data are deemed incompatible with the parameter value. In that case, a test will reject a prespecified parameter value (or a set of such values) of interest. A confidence set will collect all compatible parameter values. Test and confidence sets have been criticized for simplifying binary decisions regarding compatibility, and in fact thresholding probabilities to make such decisions can only be arbitrary. *p*-values give continuous information about the degree of incompatibility of the data with the model.

Tests and confidence intervals have been very controversially discussed recently. The centrality of the concept of compatibility can be seen in the 2016 ASA (American Statistical Association) Statement on p-values (Wasserstein and Lazar (2016)), which has a single positive message on p-values, besides a number of negative ones:

> p-values can indicate how incompatible the data are with a specified statistical model.

It is very important to understand that being "compatible" does not imply truth. Particularly, alternative models are not ruled out by any means. There is always an infinite variety of models and usually also parameter values compatible with any dataset. Much misinterpretation of tests and confidence sets ignores this. Confidence sets formalize uncertainty in the sense that they show a range of compatible parameters, but on top of the uncertainty within the assumed model, there is model uncertainty that needs to be addressed in different ways.

Compatibility as defined here is not absolute, but relative to the involved test statistic. A model may be compatible with data in some but not other respects. Data used for a simple linear regression, for example, can be compatible with a model that has a regression slope zero, using the standard t-statistic measuring how far away from zero the estimated slope is, but this may be due to nonlinearity, and a linearity test may reject that same model. Compatibility and incompatibility apply to specific aspects of a model (potentially with a fixed parameter value) rather than to the model as a whole.

It has often been stated that the rejection of a null hypothesis by a statistical test is a "statistical falsification" in the sense of Popper (1959a). Mayo (2018) draws this connection explicitly. Popper's work on falsification does not involve probabilities, and consequently it does not allow for a type I error probability, i.e., a probability that a correct model is rejected. It can be seen as problematic that a probability model can be deemed incompatible based on an event the possibility of which was essential part of the model. This particularly leads to problems with multiple testing; a large enough number of tests will reject a true model with a large probability, even if this probability is small for every single test. However, in case of imprecise measurements modeled as involving random errors, erroneous falsification of theories due to random variation is certainly a possibility. Troubles stemming from the possibility of "falsifying" a true model in the model world reflect a corresponding possibility in the real world and seem as such not inappropriate as extension of Popper's original ideas (in fact early work on statistical tests preceded Popper's work, e.g., Fisher (1922)).

Furthermore, compatibility statements regarding models do not require any "belief" that a true aleatory probability distribution exists or even follows the model assumptions of a test or confidence set. The model is a thought construct, and the thought construct can be seen as reasonable and helpful if the data are compatible (there may be further requirements), even acknowledging that the model is not true (the same point has been made by Greenland and Rafi (2019)). There are pitfalls though; a very large dataset can allow so precise statements that a parameter value might be deemed incompatible even though it is, in terms of its real-world implications, so close to compatible values that it can be seen as more or less equivalent. A parameter might be "rejected" that implies that a certain therapy does not improve on a placebo, even if another parameter is still compatible with the data according to which the improvement is very weak and virtually useless.

Compatibility logic is normally applied together with aleatory probability, but an epistemic agent may as well be interested if her model is compatible with the observed data. This has been operationalized by posterior predictive checks (Box 1980; Gelman et al. 1996) that basically test whether the observed data are in line with the epistemic predictive distribution, once more relative to a chosen test statistic.

2.2.2 Inverse Probability Logic

Bayesian inverse probability logic is the major alternative to compatibility logic regarding the assessment of probability models in the light of the data. To fix terminology, in a standard Bayesian analysis, there is usually a sampling model, i.e., a distribution of the data given a parameter, and a prior distribution of the parameter. Both of these together are chosen prior to the analysis and can therefore be called "prior distribution" (as done by, e.g., de Finetti (1974)), even though in much literature this term is used for what I call "parameter prior." The term "inverse" comes from turning the sampling model of the data given the parameter into a posterior distribution of the parameter given the data with help of the parameter prior. This parameter posterior then also allows to compute predictive distributions for future observations.

Inverse probability logic produces a probability distribution over parameters (or models; in the following I will only mention parameters). Whereas assessing a parameter as compatible with the data does not exclude or reduce the compatibility of other parameters, having a probability distribution implies that parameters compete for probability mass. A larger probability of certain regions of the parameter space implies a lower probability elsewhere. The probability axioms, whether interpreted in an epistemic or in an aleatory manner, imply that there is only one truth (only one of two disjunct events can obtain), even though not known with certainty.

Often posterior distributions are interpreted as distributing probabilities about where to find the true parameter value. The idea of a true parameter value is a traditional frequentist one. De Finetti (1974) argued that posteriors should be interpreted regarding observable quantities such as future observations and not regarding unobservables such as true parameter values that may well not exist. The parameters for him are helpful devices to summarize prior and posterior

assessments, but betting (as crucial for the traditional subjectivist Bayesian approach) should concern observables, so that bets can ultimately be decided. However, according to Diaconis and Skyrms (2018), de Finetti's Theorem means that for a subjectivist, belief in exchangeability or a suitable generalization of it implies belief in the existence of limiting relative frequencies and, therefore, a limiting probability distribution that can be parameterized. Applied Bayesians sometimes argue that even though true aleatory distributions might not exist, in many cases the parameter of interest can be interpreted as a meaningful and potentially objectively existing quantity such as a physical constant that can only be measured with an error treated as random, giving rise to epistemic uncertainty.

2.2.3 Compatibility Logic vs. Inverse Probability Logic

There are advantages and disadvantages of both approaches. Many Bayesians such as Diaconis and Skyrms (2018) have pointed out that p-values and confidence levels are regularly misinterpreted as probabilities regarding the true parameter, because these should be the ultimate quantities of interest in statistical inference, or so it is claimed. Inverse probability logic deals with combining different inferences such as multiple testing, which creates trouble for standard compatibility logic approaches, in a unified and coherent way. Frequentists are not only interested in compatibility, but also in estimation; finding a best model amounts to a competition between models. A Bayesian can argue that in this case a probability distribution over parameters provides more differentiated and appropriate information about how the parameters compare and to what extent one parameter value is more likely than others. Using confidence distributions (Xie and Singh (2013)), which define a probability distribution over the parameters based on the confidence levels at which parameters are still in an appropriately defined confidence set, frequentists involving compatibility logic can give more detailed information about how parameters compare as well, but Bayesians hold that a proper probability distribution is more intuitive and less prone to misinterpretation. Confidence distributions are strongly connected to fiducial probabilities, which Fisher (1936) defined in order to make probability statements about parameters without requiring a prior. This implies some kind of inverse probability logic, even though Fisher distanced himself from the Bayesians. Modern work on fiducial inference (Hannig et al. 2016) uses fiducial distributions of parameters as inferential tool allowing for compatibility statements rather than as actual epistemic distribution alternative to the Bayesian approach.

By allowing many models to be compatible with the data at the same time, compatibility logic is more obviously in line with the attitude that models are idealizations and not really true. Davies (1995) argued that if many models are valid approximations for the same real situation, inverse probability logic is inappropriate, because if, for example, $\mathcal{N}(0,1)$ is a reasonable approximation of the truth ($\mathcal{N}$ denoting the Gaussian or normal distribution; the two numbers in brackets are its mean and standard deviation), $\mathcal{N}(10^{-10}, 1)$ is a reasonable approximation as well, whereas according to inverse probability logic any two models compete for a part of the unit probability mass.

Furthermore, it may seem unfair to criticize tests and confidence intervals based on misinterpretations. Arguably many users do not only want to know the probability for certain parameter values to be true, which indeed tempts them to misinterpret confidence levels and *p*-values. Arguably they also want this probability to be objective and independent of prior probability assessments, which to make up they have a hard time. This combination is not licensed by any properly understood philosophy of statistics, and ultimately statisticians need to accept that their job is often not to give the users what they want, but rather to defy wrong expectations.

The role of the prior distribution in inverse probability logic is a major distinction between the two approaches. Bayesians argue that the prior is a good and very useful vehicle to incorporate prior information. Actually, prior information enters frequentist modeling as well (see the later discussion of frequentism-as-model), but the Bayesian prior is still an additional tool on top of the options that frequentists have to involve information. However, the requirement to set up a prior can also be seen as a major problem with inverse probability logic, given that prior information does not normally come in the form of prior probabilities and that it is actually in most cases very difficult to translate existing information into the required form. It is not an accident that a very large number of applied Bayesian publications come with no or very scarce subject matter justification of the prior, and in most cases the prior information is very clearly compatible with many different potential priors, with comprehensive sensitivity analysis rarely done. If the sample size is large enough for the prior to lose most of its influence, one may wonder why to bother having one. The question whether there is prior information that is meant to have an impact on the analysis and can be encoded convincingly in the form of a prior distribution is a key issue for deciding whether inverse probability or compatibility logic will be more promising in a given application of statistics.

2.2.4 Prediction Quality

Given the problems connecting aleatory and epistemic probabilities to any objectively existing truth, a pragmatic stance may hold that inference about "true parameters" is not of interest in its own right. Rather, probability modeling is worthwhile to the extent that it enables the user to deal with uncertainty about the future and, more precisely, prediction of future observations. This point of view is dominant in the machine learning community and becomes more popular also in the statistical community, following Breiman (2001), who pointed out that traditional statistical modeling (be it aleatory or epistemic) often produces an inferior prediction performance compared to approaches that aim more directly at optimizing prediction quality. Such approaches may not even involve any probability modeling, or only in such a convoluted way that clear interpretations regarding the underlying workings of reality leading to the predictions are hardly possible. Prediction quality can be assessed using data-driven techniques such as cross-validation and bootstrap that apparently do not refer to specific probability models. A worry is that performance achieved on specific training, test, and validation data may not necessarily generalize to future data. Probability models, usually nonparametric and interpreted in an aleatory manner, are used to theoretically underwrite and investigate prediction

algorithms as well as validation techniques (e.g., Schölkopf and Smola (2002); Bates et al. (2021)).

I agree with Breiman that probability modeling is certainly not mandatory, which runs counter to the naive idea that finding the true model is the ultimate aim of statistics. On the other hand, Breiman (2001) and much work from the machine learning community seem to reduce aims of modeling to prediction quality as all-dominating issue, which neglects the role of models for communication and building understanding (see the Sect. 2.3), even though it is probably valid to state that prediction quality is very often at least implied by the aim of analysis. Recently, this issue has been acknowledged also in the machine learning community, and there is a raising number of publications on the interpretability of the outcomes of machine learning algorithms (Rudin et al. 2022).

Probability models allow for a quantification of uncertainty that is often desired in prediction problems. Bayesian approaches deliver such uncertainty quantification automatically, of course relying on the appropriateness of the models. This is harder for machine learning techniques that are not based on probability models, but work exists, e.g., Lakshminarayanan et al. (2017).

Also there are doubts to what extent prediction quality for future events can be reliably assessed. For example, there is the possibility that the process of interest in the future may change, and a transparent model with solid subject matter justification may be more easily adapted, as Hand (2006) argues. Cross-validation and other methods for assessing prediction quality imply independently and identically distributed (i.i.d.) repetition, which may be problematic.

2.2.5 Other Approaches

Many further approaches to statistical inference exist. Technically, parameter estimation, i.e., finding a best guess, does not fall into any of the earlier listed categories. Estimation can be of interest regarding both aleatory and epistemic probabilities; in the latter case particularly where the parameter is identified with a not directly observable quantity that is assumed as existing and meaningful, e.g., in measurement problems with measurement error. Estimators are usually solutions of optimality problems, although there are also qualitative criteria for estimators such as consistency, or robustness against model misspecification. Statisticians often insist that estimators should come with an indication of their uncertainty, which usually then requires either inverse probability or confidence sets (which may involve nonparametric bootstrap techniques).

Some authors (Hacking 1965; Edwards 1972) advocated the use of the likelihood for assessing the support that data lend to certain models, without involving prior distributions. Likelihoods are hard to compare particularly over models with different complexities, but information theoretic approaches such as Akaike's Information Criterion can be used for such comparisons (Burnham and Anderson 2002).

A rich literature exists regarding imprecise probabilities, which combine modeling uncertainty about the occurrence of an event A with the strength of knowledge regarding A. Lower and upper probabilities are defined, with the interpretation that generally weak knowledge is expressed by a big difference between the two. This can be interpreted in an epistemic or aleatory manner, referring either to uncertainty

of an agent, or to upper and lower bounds of probabilities in a set of aleatory probability models (Walley 1991). The latter is related to robust statistics, which aims at good frequentist properties of estimators, tests, and confidence sets given a nominal model, and stability in a suitable neighboring class of models. Dempster-Shafer belief functions (Shafer 1976) are another variant of considering upper and lower plausibility indications. Shafer and Vovk (2019) propose new foundations of probability and inference based on specific betting games.

Less formally, visual and exploratory data analysis also deserves a mention, providing sometimes valuable alternatives to model-based inference. This may be better to appreciate from a philosophical position that does not grant mathematical formalism a generally superior access to reality.

2.3 Mathematical Models and Reality

I wrote Hennig (2010) mainly out of the conviction that the debate about the foundations of statistics often suffers from the lack of a general account of mathematical models and their relation to reality.

On the frequentist side often a rather naive connection between the models and reality is postulated, which is then easily criticized by advocates of epistemic probability, implying that because a naive realist idea of frequentist probabilities is not convincing, probability should better be about human uncertainty rather than directly about the reality of interest. However, modeling human uncertainty is still modeling, and similarly naive ideas of how such models relate to "real" human uncertainty are problematic in similar ways.

Inspired by radical and social constructivist philosophy (von Glasersfeld 1995; Gergen 1999), I have argued that mathematical models are thought constructs and means of communication about reality. I have distinguished "observer-independent (or objective) reality," "personal reality" (the view of reality constructed by an individual observer and basis for her actions), and "social reality" (the view of reality constructed by communication between observers). Taking a constructivist perspective, I have argued that observer-independent reality is not accessible directly to human observers and that, if we want to talk about reality in a meaningful way, it makes sense to refer to personal and social reality, which are accessible by the individual, a social group, respectively, rather than only to observer-independent reality. Observer-independent reality manifests itself primarily in the generally shared experience that neither an individual observer nor a social system can construct their reality however they want; we all face resistance from reality. This resonates with Chang (2012)'s "Active Scientific Realism" (see also Chang 2022):

> I take reality as whatever is not subject to one's will, and knowledge as an ability to act without being frustrated by resistance from reality. This perspective allows an optimistic rendition of the pessimistic induction, which celebrates the fact that we can be successful in science without even knowing the truth. The standard realist argument from success to truth is shown to be ill-defined and flawed.

In Hennig (2010), I interpret mathematical models as a particular form of social reality, based on the idea that mathematics is a particular form of communication that aims at being free of ambiguity and that enables absolute agreement by means of proofs. Science is seen as a social endeavor aiming at general agreement about aspects of the world in free exchange, for which unambiguous mathematical communication should be obviously useful. This comes to the price that mathematics needs to unify potentially diverging personal and social observations and constructions. There is no guarantee that by doing so mathematical models come closer to observer-independent reality; in fact, this view sees the domain of mathematics as distinct from the domain of observer-independent reality. The connection is that the constructs of personal and social reality are affected by "perturbation" (or, as Chang puts it, "resistance") from observer-independent reality, and it can be hoped that such perturbation, if observed in sufficiently related ways by different individuals and social systems, can be represented in mathematical modeling, which then allows to analyze the represented reality using the machinery of mathematics and logic. There is also repercussion of communication, including mathematics, on social and personal constructions of reality. Mathematical modeling has an effect on the world view and dealings with the world of social systems and individuals. We can hope for this effect to be beneficial, but this may not always be the case, because important subtleties and differences between individual and social realities may be lost in mathematics. See, e.g., the criticism of the unreflected use of quantification in psychology (Tafreshi et al. 2016) and a more general exposition of the role and history of quantification (Porter 1996).

According to constructivism, it should not be hoped that mathematical models represent reality "correctly," but they can have many uses anyway. They can represent important aspects of the modeler's perception of reality. Accordingly, a major benefit that they can have is to communicate the modeler's view unambiguously and in this way to support agreement (or potentially "agreement to disagree"). They can explore different scenarios, reduce complexity, help decision making, and enable predictions (that can be checked against observed reality). Sometimes the best way to learn from a model is to understand in which way it fails.

Another important benefit is the stimulation of creativity and method development. A standard way to solve a data analytic problem is to set up a probability model and to derive inference methods that are in some formal sense justified or even optimal given that model. This does not rely on the truth of the model, but of course if the model is inappropriate, results can be misleading. Constructivism does not advocate that "anything goes"; the modeler needs to convince themselves and her community that the model is a good basis for inference, which can involve both checking against observations and explaining how existing knowledge and thought is related to the model. Rather than licensing an arbitrary use of models, the focus is on the responsibility of the modeler to explain and defend her modeling choices. Widely accepted mathematical models in science have been discussed, questioned, defended, and possibly updated, and have been found to be in agreement with observations in lots of situations.

The constructivism I adhere to may be these days rather unpopular in philosophy, and what Chang refers to as "standard realism" in his quote above has won some ground. However, given the rather tedious controversy that philosophers have about

the objective "existence" of long run frequentist or single-event chances and propensities (see Eagle (2019)), it seems as attractive as ever to treat them as a thought construct and to look at how they are used and how they relate to observations in order to circumvent the enormous amount of problems that come with postulating the objective "existence" of such a thing.

I acknowledge that there is a lot of philosophical work on models in science that is not naïvely realistic, and concerned in more detail with how modeling actually works, see Frigg and Nguyen (2020). Much of this is compatible with the view taken here, as also a constructivist view implies that models represent reality, reality referring here to the perceived reality of the modeler and possibly her social system.

2.3.1 Reality, Observations, and Operations

In order to make a convincing case for a proposed model, it needs to be connected with reality or, more precisely, with the reality perceptions of the people in the community at which the model is addressed, at an individual and social level. Von Mises, Reichenbach (another contributor to the foundations of frequentism), de Finetti, and Ramsey were all influenced by logical empiricist ideas and by the operationalist view of measurement (Bridgman 1927; Creath 2021; Gillies 2000; Galavotti 2005) when proposing their foundations of aleatory and subjectivist epistemic probability, respectively. They built their concepts on well-defined evaluation operations referring to observations and tried to avoid metaphysical concepts (even though von Mises' limiting relative frequency has been charged as metaphysical). Von Mises defined probabilities as what is measured, with increasing precision, by observed relative frequencies; de Finetti detailed the betting operations necessary for eliciting prior belief and declared that the resulting bets should concern future observations rather than unobservable parameters.

Measurement is central to the philosophy of mathematical models outlined above, as measurement is the transformation of informal perceptions to mathematical objects that can then be handled by mathematical models and methodology.

Logical empiricism and operationalism have been criticized in various ways and are no longer very popular (Creath 2021; Chang 2021), but Chang (2021) argues that operationalism is still relevant regarding central issues in the philosophy of science, and Van Fraassen (1980) proposed a more modern version of empiricism, sharing its anti-metaphysical (sometimes branded "anti-realist") commitment. From my constructivist perspective, early empiricists and operationalists took a too extreme and reductionist point of view by denying the meaning of thought constructs that could not directly be tied to operations and observations. Operations and observations rely themselves on theories. It is important to acknowledge that measurement operations and outcomes are not an objective "given" and that the distinction between a measurement and what is measured is an elementary part of scientific reasoning. Scientists need to argue the validity of their measurement operations regarding what they want to achieve, and observations can be criticized meaningfully as potentially erroneous. This does in my view not refer to the inaccessible observer-independent reality, but rather to the thought constructs of the scientists and their community.

However, I agree with Chang and Van Fraassen that the focus on observations and operations is generally helpful for clarifying meaning, validity, and implications of

scientific concepts. Observations and operations do not have absolute authority and need to be negotiated and agreed, but they seem much better suited to enable clear negotiations and agreement (or clear disagreement) than reference to an unobservable "truth," Particularly regarding epistemic probability, betting schemes give a much clearer idea what it means to state that "the probability of an event is 0.4" than referring to the rather abstract setup of Cox's Theorem as motivation why reasoning about plausibilities can be formalized by probabilities. For frequentism, von Mises's concept of the "Kollektiv" clarifies that aleatory probabilities need to be defined relative to a "reference class" of experiments that qualify to be counted, which is often ignored in practical data analysis but can be a source of trouble (Hajek 2009).

In this vein, the contributions of von Mises, de Finetti, and others can be re-appreciated despite the criticism that they attracted when interpreting their work as attempt to convince the community of the "truth" or "objectivity" of these concepts. Without this ambition, what they achieved is a thorough elaboration of the (partly problematic) implications and the operational and empirical meaning of the corresponding probability interpretations. My position is not that models can be arbitrarily chosen, but rather that the modeler needs to be clear about how the involved probabilities are to be understood and to what extent they can be empirically tested, or used in empirical work. This will ultimately contribute to transparent communication and to stability and reliability of the outcomes.

3 Frequentism-as-Model

The frequentist (aleatory) interpretation of probability and frequentist inference such as hypothesis tests and confidence intervals have been strongly criticized recently (e.g., Hajek (2009); Diaconis and Skyrms (2018); Wasserstein et al. (2019)). In applied statistics, they are still in very widespread use, and in theoretical statistics, the number of still appearing new works based on frequentist principles is probably not lower than that of any competing approach to statistics.

Even defenders of frequentist statistics such as Mayo (2018) admit that frequentist inference is often misinterpreted, while arguing that such misinterpretation is a major source of unfair criticism of frequentism. By and large I agree with this. I will argue that what I call "frequentism-as-model" avoids many issues that critics have raised and allows for a better understanding of how results of frequentist inference can be interpreted.

Here are some influences and important ideas from the literature. I already mentioned the "long run propensity" interpretation of probability by Gillies (2000, Ch. 7). Although his outlook is more traditionally realist than mine, I see this as an insightful interpretation of how frequentist statisticians actually use their models.

Tukey (1997) re-interpreted the role of frequentist models in statistical inference as "challenges" that procedures have to face in order to show that they are worthwhile in a given situation. He recommended using

> bouquets of alternative challenges

to investigate how well a procedure may work in a real situation, including worst cases, rather than finding an optimal procedure for a single model. He wrote

> (more honest foundations of data analysis) have to include not assuming that we always know what in fact we never know – the exact probability structure involved (. . .) almost nothing is harder than verifying a stochastic assumption, something I find hard to believe has ever been done in even a single instance.

Many different models can be compatible with the same situation, and it is often misleading to base an analysis on just one model.

Davies (2014)'s view of statistical models is similar:

> The problem is how to relate a given data set and a given model. Models in statistics are, with some exceptions, ad hoc, although not arbitrary, and so should be treated consistently as approximations and not as truth. I believe there is a true but unknown amount of copper in a sample of water, but I do not believe that there is a true but unknown parameter value. Nor am I prepared to behave as if there were a 'true but unknown parameter value', here put in inverted commas as statisticians often do to demonstrate that they do not actually believe that there is such a thing. Moreover the model has to be an approximation to the data and not to some 'true but unknown generating mechanism'. There may well be some physical truth behind the data but this will be many orders of magnitude more complex than anything that can be reasonably modelled by a probability measure. Furthermore there will be a different truth behind every single observation. (. . .) The definition of approximation used in this book is that a model is an adequate approximation to a data set if 'typical' data generated under the model 'look like' the real data.

Again this implies that many different models can be adequate approximations of the same data and that the job of a model is not to be true.

A difference between Davies's and my own view is that I think that "treating reality *as if* it behaves as the model says" (temporarily, and with skepticism) is a valid and helpful description of the handling of models, whereas Davies thinks it is enough to define the probability models' ability to approximate data mathematically, and no further interpretation is required. Davies and Dümbgen (2022) give an example for a nonstandard use of probability models that uses them as calibration device rather than "assuming" them to be real in any way.

An aspect of the work of both Tukey and Davies is an emphasis on procedures for data analysis rather than models. The latter may be used to assess and potentially define or inspire procedures, but play just an auxiliary role, and are often not required. Tukey (1993) wrote

> (. . .) once we have ceased to give a model's truth a special role, we cannot allow it to "prescribe" a procedure. What we really need to do is to choose a procedure, something we can be helped in by a knowledge of the behavior of alternative procedures when various models (i.e., various challenges) apply (. . .)

I sympathize with this attitude, even though the present chapter on models is not the right place to discuss it in detail. In my impression, Tukey and Davies treat the models as data generating processes, and as such they are interpreted as aleatory.

I will first define what I mean by frequentism-as-model. Then, in order to understand its implications, the role of i.i.d. models and subject matter information is discussed. Reasons why frequentism-as-model can be useful despite the separation between reality and model are given. I will then treat statistical inference based on frequentism-as-model, including the role of model assumptions, robustness and stability, and the key concept of "interpretative equivalence." The last subsection concerns the use of inverse probability logic with aleatory probabilities in the spirit of frequentism-as-model.

3.1 Frequentism-as-Model as Interpretation of Probability

Frequentism-as-model is a version of the aleatory interpretation of probability and can be seen as a flavor of frequentism in the sense that a probability of an event A refers to the limiting relative frequency for observing A imagining an idealized infinite repetition of a random experiment with possible outcome A. This comes with problems, as discussed earlier.

Von Mises and most other frequentists claimed that their interpretation is applicable to experiments allowing for lots of (idealized infinitely many, idealized identical) repetitions, but in fact in standard frequentist probability modeling, such repetitions are modeled as i.i.d., meaning that a whole sequence of repetitions is modeled by a single probability model, modeling probabilities not only for the outcomes of a single replicate but for combinations of outcomes of some or all replicates. Central results of probability theory such as the laws of large numbers and the central limit theorem apply to such models. Applying the traditional frequentist interpretation of probability to them would require whole independent and potentially infinite sequences to be repeated, which of course is impossible in reality.

Frequentism-as-model deals with the issues in two ways. Firstly, it emphasizes that probability is a model and as such fundamentally different from observed reality. Adopting frequentism-as-model means to think about an experiment or a situation *as if* it were generated by a frequentist process, temporarily, without implying that this really is the case. This means that it is not required to make a case that the experiment is really infinitely or even very often repeatable and will really lead to the implied relative frequencies. Particularly, this means that all available observations can be modeled as i.i.d. without having to postulate that the whole sequence of observations can be infinitely or even just once repeated. Frequentism-as-model does not imply a belief in objective randomness and is also compatible with determinism. Obviously, insisting on the fundamental difference between model and reality in this way raises the question how we can use such a model to learn something useful about reality, which I will address further. Von Mises and other frequentists already acknowledged that frequentist probabilities are idealizations. To me it seems, however, that in traditional frequentism this is only a response to critics and that otherwise it does not have consequences regarding data analyses and their interpretations.

Secondly, whereas it is not clear how to connect the limits of traditional frequentist infinite sequences to an observed finite amount of real data as any limit

is invariant against arbitrary changes of any finite beginning of a sequence, i.i.d. models, as well as models with other fully specified dependence and non-identity structures, make probability statements about finite sequences of observations, and these can be checked against the actual observations. It can be found out if and in which sense the observed sequence would have been "typical" according to the specified model. In fact, whereas we may not be able to observe another real-data sequence of the same length, and surely not arbitrarily many, we are able to generate an almost arbitrary number of repetitions of sequences from the model involving just the light idealization that we would need a perfect random number generator. Even without a random number generator, in many situations, probability theory can tell us what to expect if the model holds. This resonates with Gillies's long run propensity interpretation of probability, where probabilities are not defined referring to infinite sequences, but rather as tendencies to observe in finite experiments a "typical" (i.e., large probability) outcome as specified by the model.

An issue with this is the definition of "typical." For example, assuming an i.i.d Bernoulli model, a sequence that has 50 zeroes, then 50 ones, then 50 zeroes, than 50 ones again, and so on (called 50-50-sequence in the following), has the same probability as a randomly looking sequence of zeroes and ones that gives us no intuitive reason to doubt the i.i.d. assumption. On what basis can we claim that the i.i.d. model is adequate (to use Davies's terminology) for the latter sequence but not for the 50-50-sequence? This requires subjective researcher input. The researcher needs to decide about the specific way, or ways, in which a sequence has to be typical according to the model in order for the model to be "adequate." For example, the researcher may decide that the model is only useful for data in which the lengths of "runs" of zeroes or ones in a row are not longer to what is expected under the model, in which case the model will be ruled out for the 50-50-sequence (which can be formally done using the runs test, Lehmann (1986), p. 176), whereas the irregular sequence will count as typical. A reason for such a decision may be that the researcher thinks that sequences with long runs of the same outcome are better modeled by models involving positive dependence between the individual binary experiments and that, under such models, it can be shown that the method of analysis the researcher would want to apply to an i.i.d. Bernoulli sequence will be misleading. This could, for example, be a confidence interval for the probability of observing a one. Keeping in mind the fundamental difference between model and reality, the researcher in this situation does not make a decision about which model she believes is in fact true. For such a belief, the subjective decision to distinguish between two sequences of the same individual probability may look questionable. The actual decision is rather about case-dependent criteria regarding in terms of what models they want to think when analyzing the data, informed by the aim of data analysis as well as the characteristics of potential alternative models, and knowledge about the nature of the data and potential reasons for dependence. Note though that if the researcher uses the runs test as decision rule, she will never be able to observe a 50–50-sequence whenever she uses the i.i.d. Bernoulli model, under which such sequences should actually be possible. This is an instance of the "misspecification paradox"; see Sect. 3.4.3.

Probability theory offers ways to help the researcher in making such decisions, by, for example, addressing questions of the form "If indeed the model is as assumed, how likely is it to decide against it; or if a different model is true, how likely is it to not detect it and wrongly stick to the original one; and how bad would the consequences of such an erroneous decision be in terms of the probability of getting a misleading result of the final analysis?" The researcher may also decide to adopt a more robust final method of analysis in order to deal appropriately with a larger number of models between which the data cannot distinguish.

By always keeping in mind that reality is only treated temporarily *as if* generated by a certain model, not ruling out the possibility that it could be different (for which we may consider different models), and even taking this possibility into account when making further data analytic decisions, frequentism-as-model takes the fundamental difference between model and reality much more seriously into account than a standard frequentist analysis, in which a model is used and normally no longer questioned after some potential initial checks. The latter leads to interpretations of the final results that often seem to naively imply that the model is true, even if the researcher using such an approach may well admit, when asked explicitly, that reality actually differs from the model.

3.2 The Role of i.i.d. Models and Subject-Matter Knowledge

Thinking about reality *as if* it were generated by a certain probability model has implications. A critical discussion of these implications is a way to decide about whether or not to adopt a certain model, temporarily, and on top of this, it bears the potential to learn about the real situation. If a sequence is thought of as generated by an i.i.d. process, it means that the individual experiments are treated as identical and independent. De Finetti made the point that whatever can be distinguished is not identical. Treating experiments as identical in frequentism-as-model does not mean that the researcher believes that they are really identical, and neither do they have to be really identical in order to license the application of such a model. Rather it implies that the differences between the individual experiments are temporarily ignored or, equivalently, treated as irrelevant. Analogously, using an independence model does not mean that the researcher believes that experiments are really independent in reality, but rather that she assesses potential sources of dependence as irrelevant to what she wants to do and how she wants to interpret the result. In this way, i.i.d. repetitions are constructed by the researcher. Of course, depending on what kind and strength of dependence can be found in reality, this may be inappropriate. On such grounds, the model can be criticized based on subject-matter knowledge and may be revised. This allows for a discussion about whether the model is appropriate, on top of possible checks against the data, which may have a low power detecting certain deviations from an i.i.d. model.

I.i.d. models, and their Bayesian counterpart, exchangeability models, play an important role in frequentism-as-model as well as in applied statistics in general. Of course, many non-i.i.d. models are used such as regression where the response

distribution is non-identical depending on the explanatory variables, and models for time series or spatial dependence. Even those models will normally have an i.i.d. element, such as i.i.d. residuals or innovations, be it conditional in a Bayesian setup. This is not an accident. Treating experiments as identical and independent (or having regular and fully specified dependence or non-identity structures that will usually involve an i.i.d. element) specifies how an observation from one experiment can be used for learning about another, which is the core aim of statistics. Statistics relies on models that allow us to use different observations to accumulate information. This particularly means that the statistician will need to make decisions to ignore certain potential irregular differences or dependencies in order to be able to do her job to aggregate information, regardless of whether her position is frequentism-as-model, traditional frequentism, or an epistemic Bayesian approach. Obviously, i.i.d. models do not necessarily lead to convincing results, and ultimately, it is a matter of experience and practical success in what situations the use of these models is appropriate. Note in particular that it is possible with a sufficiently large amount of data to distinguish, with large probability, i.i.d. data from data with a regular dependence structure such as ARIMA. It is however not possible to distinguish i.i.d. data from arbitrarily irregular structures of dependence or non-identity. A model that states that the first observation is random but conditionally on it all further observations are fixed with probability one can never be ruled out based on the data alone, and subject-matter arguments are required to make a reasonably regular model plausible.

At the stage of analysis, both checking of adequacy based on the data and understanding and discussion of the subject matter background are of crucial importance. The charge of an ignorance of subject-matter information that Bayesians often raise against frequentists does not affect frequentism-as-model. On the flipside, frequentism-as-model obviously relies on subjective decisions of the researchers, so that a statistician holding it cannot proudly claim that analyses are fully objective, as some frequentists and objective Bayesians like to do, which is questionable anyway (Gelman and Hennig (2017)).

As an example for subject-matter arguments, in a much-cited and influential study that prompted a Lancet editorial (Lancet (2005)) with the title "The end of homeopathy," Shang et al. (2005) carried out a meta-analysis of eight studies comparing homeopathy with a placebo using a standard meta-analysis model with a random study effect assumed i.i.d. (note that this implies dependence between the observations within the same study). They found that there is no evidence that the odds ratio between "homeopathy works" and "placebo works" is different from one and concluded (not inappropriately) that

> this finding is compatible with the notion that the clinical effects of homeopathy are placebo effects.

Here are two implications of the i.i.d. model for the random study effect. Firstly, modeling it as identically distributed implies that the differences between studies are attributed to random variation, which basically means that knowledge of known

differences between the studies is ignored for modeling. This particularly includes differences between different modes of applying homeopathy. For example, there were only two studies used in the meta-analysis in which homeopathy was applied in the classical way with individual repertorization, which is seen as the only proper way of applying homeopathy by many homeopaths. Modeling the study effect of these studies as coming from the same distribution as all the other study effects may be justifiable if there is an a priori belief that homeopathy basically is a placebo and the differences between application modes are irrelevant, but it is not suitable for convincing skeptical supporters of classical homeopathy who would be willing to accept a fair study.

Secondly, an expected value of 0 of the random effect is not assumed for every single study, but overall studies, with a potentially arbitrary large between-studies variance. This implies that the effective sample size for estimating the odds ratio is not the number of individual patients treated in all studies (several thousands), but the number of studies, $n = 8$, and $n = 2$ for classical homeopathy only. The authors may use this to justify their decision to not make a modeling difference between different modes of applying homeopathy. The low number of studies was selected by Shang et al. (2005) by a study quality criterion. The power of the resulting test is therefore very low, and consequently, the confidence interval that the authors give for the odds ratio is very wide. This argument applies to meta-analyses with a random effect generally; in the literature one can sometimes find the informal remark that such analyses require a large number of studies; see Kulinskaya et al. (2008). On top of that, it could be discussed whether there may be reasons for assuming systematic bias over all studies, which in the model would amount to a nonzero expectation of the random effect.

Obviously, $n = 8$ is not sufficient to check the i.i.d. assumption for the random study effect at any reasonable power. Rather than having any connection to an observable "truth," the random effect is a convenient modeling device allowing for potential individual study effects to be captured by a single parameter. A low number of parameters is, according to statistical theory, useful with a small n. This comes at the price of precluding the possibility to involve specific information about differences between the individual trials. This implication is usually ignored.

Given this, it looks very dubious that the Lancet (2005)'s issue editorial concluded:

> Surely the time has passed for selective analyses, biased reports, or further investment in research to perpetuate the homeopathy versus allopathy debate.

Regarding the purely statistical evidence, the meta-analysis could as well be used to argue that there are not yet enough high-quality studies.

In principle such discussions can also take place regarding the traditional frequentist use of models. However, frequentism-as-model reframes these discussions in a helpful way. It makes us aware of the implicit meaning of the model assumptions, which can be used to discuss them. Moreover, it emphasizes that what has to be decided is not the truth of the model, but rather a balance between the capacity of the model to enable learning from the existing observations about future

observations or underlying mechanisms on one hand and on the other hand taking into account all kinds of peculiarities that may be present in the real situation of interest, but that may be hard to incorporate in such a model despite potentially having a more or less strong impact on the results.

A key aspect is that rather than thinking in binary terms about whether a model is true or not, frequentism-as-model implies that the connection between observed reality and models can be assessed gradually as more or less close. It is neither impossible nor inadmissible to conceive a situation as a random experiment that cannot or only a very limited number of times be repeated and to use a model in the sense of frequentism-as-model for it. This would imply to *think of* the situation as hypothetically repeatable, and of certain outcomes having a certain tendency, or, in standard philosophical terms, propensity to happen, which would materialize in case of repetition, but not in reality.

Therefore, frequentism-as-model does not bar single-case probabilities as von Mises's flavor of frequentism does. However, it is more difficult for the person who puts up such a model to convincingly justify it compared to a situation in which there are what is interpreted as "replicates." Convincing justification is central due to the central role of communication and agreement for science in the philosophy outlined above. Whatever the model is used for, it must be taken into account that hypothesized values of the single-case probability cannot be checked against data. This changes if the experiment is embedded in a set of experiments that are not directly seen as repetitions of each other, but for which an assumption is made that their results are put together from systematic components and an error term, and the latter is interpreted as i.i.d. repetition. This is actually done in standard frequentist regression analyses, in which the explanatory variable or vector $\mathbf{x}$ is often assumed fixed. For a given value or vector of values of the explanatory variable(s) $\mathbf{x}$, a distribution for the response y is implied, despite the fact that the random experiment can in reality not be repeated for any given $\mathbf{x}$ in situations in which the researcher cannot control the $\mathbf{x}$. Insisting on repeatability for the existence of traditional frequentist probabilities would imply that nothing real corresponds to the distribution of y for fixed $\mathbf{x}$, and there is no way to check any probability model. The unobservable i.i.d. error term constructs repeatability artificially, as in this way observations with different $\mathbf{x}$ can be interpreted as involving repeated realizations of the error term. I have not seen this mentioned anywhere. From a frequentism-as-model perspective, this needs to be acknowledged, and dependent on the situation it may be seen as appropriate or inappropriate, once more using information from the data and about the subject matter background, but there is nothing essentially wrong or particularly suspicious about it, apart from the fact that it turns out that our possibilities to test model assumptions are quite generally more limited than many might think (see Sect. 3.4.3).

3.3 How Is Frequentism-as-Model Useful?

From the discussion of mathematical models and reality, it follows that the separation between reality and model is a general feature of mathematical models, not an

exclusive one of frequentism-as-model, although frequentism-as-model acknowledges it explicitly. The question "how is frequentism-as-model useful, and how is it connected to reality?" is therefore connected with the general question how mathematical models can be useful, even if "wrong" in Box's terms. The way to use mathematical models is obviously to take the mathematical objects that are involved in the model as representations of either perceived or theoretically implied aspects of reality and then to use this to interpret the results of using the models.

In order for the model to be useful, does not reality have to be "somehow" like the model? According to the constructivist view presented earlier, reality is accessible only through personal perception and communication, so the best we can hope for is that the model can correspond to how we perceive, communicate, and think about reality. Regarding frequentism-as-model, this concerns in the first place the concept of i.i.d. repetition as already discussed above. I.i.d. repetition is a thought construct and not an objective reality; however, even apart from probability modeling, it is easy to see how much of our worldview even before any science relies on the idea of repetition, be it the cycles of day and night and the seasons, or be it the expectation, out of experience, of roughly the same behavior or even roughly the same distribution of behaviors when observing any kind of recurring process as diverse as what a baby needs to do to attract the attention of the parents, look, size, and edibility of plants of the same species, or any specific industrial production process. Objections against the truth of "i.i.d" can be easily constructed for observations in all of these examples, yet analyzing them in terms of i.i.d. models often gives us insight, new ideas, and practical competence to deal with these processes, be it with additional ingredients such as explanatory variables, regular dependence structures, or seasonal components. Ultimately, the success of probability modeling has to be evaluated empirically, relative to researchers' aims, and obviously the result will sometimes, but not always, be positive. I remain agnostic regarding to what extent positive results confirm that "objective reality really is like that," to which there ultimately is no answer beyond what occurs in personal and social reality.

A major general reason for using probability models is that they allow us to quantify random variation. It is not an accident that probability theory is a relatively young branch of mathematics. Unlike most historically older mathematical modeling, probability modeling is essentially not only about what was, is, or will be observed, but also about what could have been observed but was not and/or will not be observed. The latter does not and will not exist as observation. Connecting this to observations is tricky and, in my view, a major reason why probability models are so controversial and problematic. However, they allow us to deal with a concept that was hardly acknowledged when probability theory emerged and became hugely influential, namely, the distinction between a meaningful pattern and meaningless variation.

What can be done in order to support useful and avoid misleading results of probability modeling interpreted as frequentism-as-model? Below are some questions that need to be addressed. These questions are not very surprising, and statisticians, be they traditional frequentists, Bayesians, or something else, may think that they address these anyway. What makes frequentism-as-model different is that a standard approach would be to take these issues into account when setting up and justifying the model, and then all further analysis and interpretation is done

conditionally on the model being true. In frequentism-as-model, there is no such thing as a true model, meaning that the issues below need to be kept in mind, and they still play a role when running model-based analyses and interpreting the results.

1. What is the aim of modeling? Probability models are used in different ways, and this is important for how to set them up. Hand (1994) emphasized the importance of clarifying the research question for statistical analysis, with several examples illustrating how much of a difference this can make, regarding modeling and analysis, but also in earlier stages such as the planning of experiments. Although the aim of modeling is not always ignored in traditional frequentist or Bayesian analysis, there is a general tendency to think that the ultimate aim is always to find the true model, and if this (or at least a model as "close" as possible to it) is found, everything "relevant" that can be known is known. This is fundamentally different from the attitude implied by frequentism-as-model.

   Cox (1990) lists three different classes of modeling aims, namely, "substantive models," which model (often causal) mechanisms that the researcher is interested in, "empirical models," which try to aid inference about relations between variables such as effect sizes, without making an attempt at reconstructing how the relations work in any detail, and "indirect models," where models are not directly connected with a real situation. This encompasses the use of models for deriving or comparing methodology, but also, in a real situation but only indirectly serving the main aim of analysis, issues such as the imputation of missing values. The classes may be mixed or intermediate in some specific situations.

   This has methodological consequences. Substantive models may have aspects that are there for representing the researcher's view but may refer to unobservables, in which case they cannot or in the best case very indirectly be tested against the data. A substantive model may even be there to communicate a researcher's view without the ambition to fit any data. It may at times represent scenarios that are seen as best or worst cases, intentionally not modeling what is seen as most realistic. Parsimony may be a strong concern if the model is used to communicate an idea, a weaker concern if the model is used for prediction, and no concern at all if the model is used to simulate data for exploring potential future variation in a complex system. In some cases, the major use of the model is learning from discovering its lack of fit and the exploration of reasons.

   At first sight, it seems central for empirical models to fit the data. However, for such models, the specific modeling aim is important, because deviations of the data from what would be typical for the model are only a problem to the extent that they raise the danger of misleading results, which depends on what kind of result the researcher is after, e.g., modeling integer number data by a Gaussian distribution is not normally a problem if only inference about means is required, at least not as long as the i.i.d. assumption is implied and the distributional shape is not strongly skew or with large outliers, both of which can happen with supposedly continuous data as well.

   A major indirect use of models is the investigation of properties of inference methods by theory or simulation. For example, maximum likelihood (ML)

estimators can be seen as inspired by probability models that are interpreted in a frequentism-as-model sense: "Imagine a real situation as modelled, then the ML estimator makes the data most likely." The major aim of modeling there is to find a good method for estimation. Even many Bayesians use models with an implicit frequentist interpretation in methodological work in order to investigate the quality of their methods in a situation with a constructed known truth. It could be argued that in order for such work to be applicable to objective reality, objective reality has to be as the model specifies, but if we accept that "all models are wrong" in objective reality, there is no better alternative than studying the behavior of method under a variety of such models. Simulations and theory will seem more relevant if the used models seem "realistic," but as long as the aim is not to address a very specific application, models used in this way are not checked against data. This only can happen when the resulting methods are applied.

Furthermore, for some modeling aims, there are methods that can more or less directly measure how well the aim is fulfilled. A major example is cross-validation for prediction quality. If prediction is the major modeling aim, good cross-validation results can be seen as dominating other concerns such as fit of the existing data or correspondence with subject matter knowledge.

Another example for direct measurement of what is of interest is the objective function of *k*-means clustering (for details, see Hennig et al. (2015)), which directly measures the quality of the approximation of any data point by the closest cluster centroid (more generally, often loss functions can be constructed that formalize the aim of analysis). If achieving a good performance in this respect is the aim of analysis (e.g., if clustering is used for data set size reduction before some other analysis, and all clustered objects are replaced by the cluster centroid in a final analysis), *k*-means clustering is a suitable method even in situations that are very different from the model for which *k*-means is ML, namely Gaussian distributions with same spherical covariance matrix in all clusters but different cluster means. Statisticians have argued that *k*-means often does not work well if this assumption is violated (e.g., Vermunt (2011) in a discussion of Steinley and Brusco (2011)), but this relies on the view that reconstructing the true model is required, which may deviate from what is needed in practice.

2. Is the model compatible with the data? I will discuss this in more detail in the subsection on statistical inference.
3. How does the model relate to subject matter knowledge? The model should be informed by perceptions and ideas (subject matter knowledge, which is not necessarily "objective") regarding the real process to be modeled, such as specific reasons for dependence, non-identity, or also for or against particular distributional shapes such as symmetry. Just to give an example, dependence by having the same teacher and communication between students makes the use of an i.i.d. model for analyzing exam results for students from the same class or even school suspicious, and it can be controversially discussed to what extent introducing dependence only in form of an additive random effect addresses this appropriately.
4. How stable are conclusions against modeling differently? The ultimate answer to the question how we can be sure that a model is appropriate for the situation we

want to analyze is that we cannot be. Breiman (2001) mentioned the "multiplicity of good models" in line with Tukey (1997) and Davies (2014), and different "good" models may lead to contradicting conclusions. On top of that, research hypotheses may be operationalized in different ways, using different measurements, different data collection, and so on. There is no way to be sure of a scientific claim backed up by a statistical result based on the naive idea that the model is true and the method is optimal. In order to arrive at reliable conclusions, science will need to establish the stability of the conclusions against different ways of operationalizing the problem. This is basically the same way in which we as individual human beings arrive at a stable concept of the world, as far as it concerns us; after lots of experiences, looking at something from different angles in different situations, using different senses, communicating with others about it, etc., we start to rely on our "understanding" of something. In the same way, every single analysis only gives us a very restricted view of a problem and does not suffice to secure stability; see the discussion of "interpretative equivalence" in Sect. 3.4.1. Currently, there is talk of a "reproducibility crisis" in a number of disciplines (Fidler and Wilcox (2018)). I think that a major reason for this is that no single analysis can establish stability, which is all too conveniently ignored, given that researchers and their funders like to tout big meaningful results with limited effort. Even if researchers who try to reproduce other researchers' work have the intention to take the very same steps of analysis described in the original work that they try to reproduce, more often than not there are subtle differences that were not reported, for example, data-dependent selection of a methodology that the reproducer then uses unconditionally. Any single analysis will depend on researchers' decisions that are rarely fully documented, could often be replaced by other decisions that are not in any way obviously worse, and may have a strong impact on the result. Having something confirmed by as large as possible number of analyses investigating the same research hypothesis of interest in different ways is the royal road to increase the reliability of scientific results. In this I agree with the spirit of Mayo (2018)'s "severity," and it also resonates with her "piecemeal testing"; a scientific claim is the more reliable; the harder researchers have tried to falsify it and failed. Frequentism-as-model surely does not license claims that anything substantial about the world can been proved by rejecting a single straw man null hypothesis.

A further "use" of the consciousness and acknowledgement of the essential difference between model and reality may be a better awareness that probability modeling is not mandatory; data can be often analyzed descriptively or visually without the need to compute p-values or posterior probabilities, and in some situations, quantification itself can be regarded with more skepticism (Tafreshi et al. (2016) and Chang (2022)).

3.4 Frequentism-as-Model for Statistical Inference

Adopting frequentism-as-model as interpretation of probability does not imply that classical methods of frequentist inference, tests, confidence intervals, or estimators

have to be used. It may also be combined with Bayesian inference as discussed later. However, the classical methods of statistical inference have valid frequentism-as-model interpretations, and I believe that understanding these interpretations properly will help to apply the methods in a meaningful and useful way. Therefore, I disagree with recent calls to abandon significance testing or even frequentist inference as a whole (Wasserstein et al. (2019)).

3.4.1 Interpretative Equivalence, Stability, and Robustness

The question how stable our conclusions are as raised above does not only depend on models, methods, and the data, but also on the conclusions that are drawn from them, i.e., the interpretation of the results by the researcher. A helpful concept to clarify things is "interpretative equivalence." I call two models "interpretatively equivalent" with respect to a researcher's aim if their subject-matter interpretation of what they are interested in is the same regardless of which of the two models is true. For example, if a researcher is interested in testing whether a certain treatment improves blood pressure based on paired data before and after treatment, she will in all likelihood draw the same conclusion, namely that the treatment overall does not change the blood pressure, if the distribution of differences between after and before treatment is symmetric about zero, be it a Gaussian or a t_2-distribution, for example. For her research aim, the precise shape of the distribution is irrelevant. Comparing two models with expectation zero, one of which is symmetric whereas the other one is not, this is not so clear; the treatment changes the shape of the distribution, and whether this can be seen as an improvement may depend on the precise nature of the change. For example, consider the model

$$0.99\mathcal{N}\left(\mu^*,\ \sigma^2\right) + 0.01^*\delta_{100}, \tag{1}$$

δ_x being the one-point distribution in x. The researcher may think of δ_{100}-distribution as modeling erroneous observations, in which case $\mu^* = 0$ makes the model interpretatively equivalent to $\mathcal{N}(0,\ \sigma^2)$, whereas for $\mu^* = -\frac{1}{0.99}$, despite expectation zero, the researcher will interpret an average effect of lowering the blood pressure, which the model implies for a subpopulation of 99% of people.

In fact, the term "interpretative equivalence" implies an oversimplification, as models can be more or less interpretatively similar, and it is not always possible or helpful to make a binary distinction between "interpretative equivalence" and "interpretative difference," but I will stick to this distinction here for ease of discussion.

The importance of interpretative equivalence is that it allows to discuss what deviations of a temporarily assumed model should be handled in which way. If conclusions are drawn from a method involving certain model assumptions, it would be desirable, and conclusions can be seen as stable, if the probability would be roughly the same that the researcher arrives at the same conclusion from the same data if data are actually generated by an interpretatively equivalent model other than the assumed one. If this is not the case, it would be of interest if the models can be told apart with good probability by the data, in which case the data can be used to

decide on which one of these models to base a data analysis. This also applies to the decision between a specific parametric and a more general but potentially less precise nonparametric approach.

The concept also clarifies the issue that tests on large samples reject point null hypotheses too easily. Considering a $\mu = 0$ null hypothesis, a model with $\mu \neq 0$ but a very small absolute value will lead to a rejection of $\mu = 0$ with a large probability for large n. This is a problem if and only if models with, say, $|\mu| \leq \varepsilon, \varepsilon > 0$ are considered interpretatively equivalent to the model with $\mu = 0$, in other words, if a difference as small as ε is considered irrelevant from a subject matter point of view. If this can be specified, the question whether values of μ with $|\mu| \leq \varepsilon$ are in the corresponding confidence interval, or what severity the test achieves ruling out $|\mu| \leq \varepsilon$, see Mayo (2018), is more relevant than whether a test of $\mu = 0$ is significant. Note that in a real situation it will hardly be possible to specify a precise borderline ε, and one could think that things are rather continuous than binary; however, due to the discreteness of language, in many situations at least certain nonzero differences will be called irrelevant.

Being concerned about interpretative equivalence of models is an entry point for robust methods, which are designed for dealing with the possibility that a nominal model is violated in ways that are hard to diagnose but may make a difference regarding analysis. Robustness theory (e.g., Hampel et al. (1986); Huber and Ronchetti (2009)) is about limiting changes in results under small changes of the modeled processes. An issue with standard robustness theory is that it is often implied that "contamination" of a distribution should not have an influence of the results, whereas in practice the contamination may actually be meaningful. To decide this is a matter of assessing interpretative equivalence. Frequentism-as-model acknowledges that desirable behavior of a statistical method is not just something "objective" but depends on how we interpret and assign meaning to differences between distributions. Robustness is helpful where the reduced sensitivity of robust methods to certain changes in the data or model takes effect if the changes are indeed interpreted as meaningless relative to the aim of analysis; for example, there needs to be a decision whether in model (1) what orresponds to the quantity of interest is rather the mean of the distribution, or rather the μ^*. In some applications, it is inappropriate to use a method of which the results may not change much when replacing up to half of the data, namely, where the resulting processes are considered as interpretatively very different, but in any case comparing the results of such a method with a more "sensitive" non-robust one may allow for a more differentiated perception of what is going on than does every single method on its own.

3.4.2 Significance Tests and Frequentist Inference

Statistical hypothesis tests have become very controversial (e.g., Wasserstein et al. (2019)), but the interpretation of tests from the position of frequentism-as-model is rather straightforward. They address to what extent models are compatible with the data in the sense formalized by the test statistic. For simplicity, I mostly call models "compatible" or "incompatible" with data, but in fact compatibility is gradual, as expressed by p-values.

Obviously, a non-rejection cannot be an indication that the model is in fact true, but it means the absence of evidence in the data that reality is different in the way implied by the test statistic, making it impossible to claim such evidence. Sometimes tests, particularly two-sided tests, are criticized because "point null hypotheses are usually scientifically implausible and hence only a straw man" (e.g., Rice et al. (2020)), but then a parametric model allowing for any parameter value cannot be "really true" anyway, so that for the same reason for which the point null hypothesis (H_0) is "implausible," the whole parametric family is implausible as well, but that does not necessarily stop inference about it from being informative and useful. What a test can do is neither to confirm H_0 as true, nor to allow to infer any specific alternative in case of rejection. A two-sided test should be run if compatibility of the data with H_0 is a possibility of interest; even then it may not be the method of choice if the sample size is too large, see the earlier discussion. Recall that tests are often chosen according to Neyman-Pearson logic (Lehmann 1986). This means that they are meant to maximize the power, i.e., to minimize the probability for non-rejection given a specific alternative hypothesis and given a fixed value for the probability to reject a true H_0. This is often read as being only meaningful if either the nominal H_0 or the specific alternative is true. Instead, I see this reasoning as a rather clever idea to motivate test construction in a real situation, using mathematical modeling. A reasonable formal criterion is optimized in the model world, leading to a procedure that can be applied in the real world, which differs from the model world. It is important to ask to what extent the differences between the real world and the model world have the potential to mislead the procedure, but this can only be assessed case by case. For sure it cannot be required that the real situation satisfies the formal model optimality. Demanding this would be a category error.

Often significance tests are presented implying that a rejection of the H_0 is meaningful whereas a non-rejection is not. Above I have explained the meaning of a non-rejection in frequentism-as-model; the meaning of rejection is a more complex issue. Obviously, rejection of the H_0 does not imply that there is evidence in favor of any particular model that is not part of the H_0. On the positive side, a rejection of the H_0 gives information about the "direction" of deviation from the H_0, which can and mostly should be substantiated using confidence sets of compatible parameter values, and particularly data visualization for exploring how this plays out without relying on the specified model.

Consider a one-sample t-test of the H_0: $\mu = 0$ regarding $\mathcal{N}(\mu,\ \sigma^2)$ against $\mu > 0$. The test statistic T is the difference between the sample mean and $\mu = 0$ standardized by the sample standard deviation. Sticking to model-based thinking while not implying that $\mathcal{N}(\mu,\ \sigma^2)$ is true, rejection of the H_0 can be interpreted as providing evidence in favor of any distribution of the two samples for which a larger value of T is observed with larger probability than under H_0, compared with the H_0. We do not only have evidence against H_0; we also learn that the problem with H_0 is that $\mu = 0$ is most likely too low, which is informative.

In many situations in which the one-sample t-test is used, the user is interested in testing $\mu = 0$ or rather its interpretative meaning, but not in the distributional shape $\mathcal{N}(\mu,\ \sigma^2)$, which just enables them to run a test of $\mu = 0$. If in fact there were a true

distribution, which of course we can consider, in the "as if"-model world, which is not $\mathcal{N}(\mu, \sigma^2)$ with any specific μ or σ^2, it is not clear in a straightforward manner what would correspond to μ. It may be the expected value, but in a model such as (1) it may well be seen as the μ^* that governs 99% of the observations. In any case, there are distributions that could be considered as interpretatively equivalent to the actual H_0. Any distribution symmetric about zero is in most applications of t-tests interpretatively equivalent to the H_0, meaning that if indeed a distribution different from $\mathcal{N}(\mu, \sigma^2)$ but still symmetric about $\mu = 0$ were true, it would be desirable that the probability to reject H_0 would be as low as if H_0 were true.

One can then ask how likely it is to reject the H_0 under a model that is not formally part of the H_0, but interpretatively equivalent. For the one-sample t-test, assuming existing variances, many distributions interpretatively equivalent to $\mathcal{N}(\mu, \sigma^2)$ are asymptotically equivalent as well, and results in Cressie (1980) and some own simulations indicate that it is very hard if not impossible even in finite samples to generate an error probability of more than 7% for rejecting an interpretatively true H_0 with a nominal level of 5%, even if the underlying distribution is skew and μ is taken to be the expected value, meaning that testing at a slightly smaller nominal level than the maximum error probability that we want to achieve will still allow for the intended interpretation.

However, the situation becomes much worse under some other deviations from the model assumptions, particularly positive dependence between observations, which increases the variation of T and may lead to significant T and increased type I error probability very easily, also in situations that are interpretatively equivalent to the H_0. Consider an example in which the expected change of the turnover generated by a salesperson after attending a sales seminar is of interest in order to evaluate the quality of the instructor. If all salespersons in the sample attend the sales seminar together, they may learn something useful from talking with each other about sales strategies, even if what the instructor does itself is useless.

What is required in order to achieve a reliable conclusion is just what was discussed in the section on the use of models. The general question to address is whether a rejection of H_0 could have been caused by something interpretatively equivalent to the H_0, in which case the conclusion could not be relied upon. The questions to ask are as follows: (1) is there any evidence in the data that such a thing may have happened, (2) is there any subject matter knowledge that suggests this (e.g., salespersons may have learnt from each other rather than from the seminar), (3) does the meaning of the test statistic correspond to what is of interest, and (4) is it feasible to run further analyses, with the same or other data, that can confirm the conclusion? (4) is important because even the best efforts to use (1) and (2) will not be able to remove all doubt. Models are always conceivable that can cause trouble but cannot be distinguished from the nominal model based on the data, and thinking about the subject matter may miss something important. (3) is in my view a very important issue that is not usually appreciated (but see Hand (1994)). Tests are usually derived using optimality considerations under the nominal model, but this does not imply that they are optimal for distinguishing the "interpretative H_0" from the "interpretative alternative." In many cases at least, they make some good sense,

but a model like (1) may lead them astray. The full interpretative H_0 and the interpretative alternative will normally be too complex to derive any optimal test from them, but the form of the test statistic itself suggests what kinds of distributions the test actually distinguishes. This should be in line with what is interpreted as the difference of interest between H_0 and the alternative. At least under a point H_0, the distribution of any test statistic can be simulated (if the H_0 is a set of distributions, parametric bootstrap can be used, if potentially involving a certain bias). Assuming that rejection happens for large values of the test statistic, it implicitly defines the interpretative H_0 and the interpretative alternative distinguished by the test as the set of distributions for which the test statistic is expected low and the set of distributions for which it is expected larger, respectively. In many situations, a nonstandard test statistic may be better suited than what is optimal under a simple nominal model (see Hennig and Lin (2015) for an example).

Bayesians often argue against frequentist inference by stating that the probabilities that characterize the performance of frequentist inference methods such as test error and confidence set coverage probabilities are pre-data probabilities and that they do not tell the researcher about the probability for their inferences to be true after having seen the data. One example is that a 95% confidence interval for the mean of a Gaussian distribution in a situation in which the mean is constrained to be larger than zero may consist of negative values only, meaning that after having seen the data the researcher can be sure that the true value is not in the confidence interval. This is a problem if the coverage probability of the confidence interval is indeed interpreted as a probability for the true parameter value to be in the confidence interval, which is a misinterpretation; the coverage probability is a performance characteristic of the confidence interval pre-data, assuming the model. From the point of view of frequentism-as-model, this is not a big problem, because there is no such thing as a true model or a true parameter value, and therefore, a probability for any model to be true is misleading anyway, although it can be given a meaning within a model in which the prior distribution is also interpreted in a frequentism-as-model sense (see Sect. 3.4.4). In practice, if in fact a confidence interval is found that does not contain any admissible value, this means that either the restriction of the parameter space that makes all the values in the confidence interval impossible can be questioned or that a truly atypical sample was observed. Davies (1995) defined "adequacy regions" that are basically confidence sets defined based on several statistics together (such as the mean or median, an extreme value index, and a discrepancy between distributional shapes; appropriately adjusting confidence levels) that can by definition in principle rule out all distributions of an "assumed" parametric family, meaning that no member of the family is compatible with the data given the combination of chosen statistics. Normally confidence intervals are interpreted as giving a set of truth candidate values assuming that the parametric model is true; but if that assumption is dropped from the interpretation and it is just a set of models compatible with the data defined by parameter values within a certain parametric family, it is possible that the whole family is not compatible with the data.

Overall, I suspect that the biggest problem with interpreting standard frequentist inference is that many of the people who use it want to make stronger claims, and

want to have bigger certainty, than the probability setup that they use allows. An example for this is the ubiquity of implicit or explicit claims that the null hypothesis is true in case that it was not rejected by a test. Interpreting the results of classical frequentist inference assuming the truth of the model will generally lead to over-interpretation. According to frequentism-as-model, classical frequentist inference allows compatibility and incompatibility statements of models with data. As far as the models are used to make substantive statements, such compatibility assessment is of course of interest. What exactly can be learnt from this depends on the analyzed situation as well as on what the researcher sees as interpretatively equivalent in that situation. From the point of view of frequentism-as-model, research about the expected variation of results under interpretatively equivalent models would be desirable, acknowledging that interpretative equivalence may mean different things in different applications. Deciding on a parametric model and from then on ignoring that other models can be compatible with the data as well will easily lead to overinterpretation.

3.4.3 Model Assumptions

A standard statement regarding statistical methods is that these are based on model assumptions and that the model assumptions have to be fulfilled for a method to be applied. This is misleading. Model assumptions cannot be fulfilled in reality, because models are thought constructs and operate on a domain different from observer-independent reality. For this reason, they cannot even be approximately true, in a well-defined sense, because no distance between the unformalized "underlying real truth" and the model can be defined, although, following Davies, the approximation notion can be well defined comparing observed data to a model.

What is the role of model assumptions then? There are theorems that grant a certain performance of the method, sometimes optimal, sometimes just good in a certain sense, under the model assumptions. The model assumptions are not required for applying the method, but for securing the performance achieved in theory. The theory can be helpful to choose a method, and some theory leads to the development of methods, but the theoretical performance can never be granted in reality. This does not mean that the performance will be bad whenever the model assumptions are not fulfilled. In fact, some aspects of the model assumptions are usually almost totally irrelevant for the performance, such as the application of methods derived from models for continuous data to data that is rounded to, say, two decimal places. Interpretative equivalence is an important concept also in this respect, because optimally methods would not only distinguish what is deemed relevant to distinguish by the researcher under the model assumptions, e.g., a certain H_0 and its nominal alternative, but they would lead to largely the same results for interpretatively equivalent distributions that do not fulfill the model assumptions. As far as this is the case, the corresponding model assumption is irrelevant.

It makes sense, at first sight, to think that the method will be appropriate if the assumed model is a good model, i.e., if reality looks very much like it. This itself can be modeled, meaning that one can look at the performance of a method in a situation in which the assumed method does not hold, but a somewhat similar model, which

can be formalized using dissimilarity measures between distributions. This has been considered in robust statistics (Hampel et al. (1986); Huber and Ronchetti (2009), "qualitative robustness" in particular) with the unsettling result that the performance of some classical statistical methods can decline strongly in arbitrarily small neighborhoods of the assumed model. As a consequence, more robust methods have been developed, i.e., methods with a more stable performance in close neighborhoods. This is surely valuable progress, but on one hand, it does not change the fact that models can be set up that cannot be rejected by any amount of data and that can annihilate the performance of any method, e.g., using irregular dependence and/or non-identity structures, so full safety cannot even be had in the modeled world, let alone the real one. On the other hand, the situation is not quite as hopeless as this may suggest. Usually, bad results about standard methods are worst case results, very often regarding extreme outliers, and it is often plausible, from checks, data visualization, or subject matter considerations, that the worst case does not occur. To argue against detrimental dependence or non-identity structures is much harder, and the best that can be done in this respect is looking for conceivable reasons for trouble, using a suitable method if no such reason comes to mind, and then hope that the world will behave when acting based on the result. Science makes mistakes and is hopefully open-minded enough to correct itself in case of bad outcomes.

Mayo (2018, Sec. 4.8–4.11) and others argue that model assumptions can and should be tested. Whereas the truth of the model cannot be secured, much can indeed be found out about whether a model is adequate for a purpose. However, model checking has a number of issues. The first one is that if a certain model assumption turns out to be compatible with the data, it does not mean that other models that may lead to different results are ruled out. Misspecification testing cannot secure robustness of results against models that cannot be excluded.

A second issue is that if a method is used conditionally on passing a model misspecification test for checking a model assumption, the distribution of the data that eventually go into the method becomes conditional on passing, and this will normally violate the model assumptions, even if they were not violated before. Particularly, it will make observations dependent even if they were not dependent before, because if, for example, $n - 1$ observations are on the borderline for passing the misspecification test, the nth observation has to fit well for passing. I called this "goodness-of-fit or misspecification paradox" in Hennig (2007). In many situations (but not always), this will not change error probabilities associated with the model-based method strongly, meaning that in case the model was true before misspecification testing, not much harm is done.

On the other hand, in case that the model assumptions are violated in a problematic way, the distribution conditionally under passing a misspecification test will often not make the method work better, and sometimes even worse than before testing; keep in mind that just because the misspecification test does not reject the model assumption, it does not mean that it is fulfilled. Shamsudheen and Hennig (2019) reviewed work investigating the actual performance of procedures that involve a misspecification test for one or more model assumptions before running a method that is based on these model assumptions, looking at data that originally

fulfilled or did not fulfill the model assumption. Occasionally, a combined procedure was investigated in which, in case of the violation of a model assumption, a method with lighter assumptions is used. The philosophy of such work, which is in line with frequentism-as-model, is that the key question is not whether the model assumptions are really fulfilled, but what the performance of such combined procedures is in several situations, compared to both the model-based and the less model-based (often nonparametric) test. The results are mixed, depending on the specific combinations of tests, and surprisingly many authors advise against misspecification testing based on their results, e.g., Fay and Proschan (2010):

> The choice between t- and Wilcoxon-Mann-Whitney decision rules should not be based on a test of normality.

Whereas formally requiring lighter model assumptions, the use of nonparametric methods only pays off if the probability to arrive at a conclusion that is interpretatively in line with a modeled truth is better than for a competing parametric method for most models compatible with data and existing knowledge and traded off potentially against the expected sizes of "interpretative differences," as far as these can be specified. This is not always the case.

Shamsudheen and Hennig (2019) showed a theoretical result that presents combined procedures in a somewhat more positive light. They looked at the overall performance of combined methods in a setup where datasets could be, with a certain probability λ, generated by the assumed model, and with probability $1 - \lambda$ by a distribution that could cause trouble for the model-based method (this probability could be taken as rather idealized aleatory one considering many studies of a similar kind). Under certain assumptions for the involved methods, they showed that for a range of values of λ, the combined procedure beats both involved tests, the model-based one and the one not requiring the specific model assumption, regarding power, even if not winning for $\lambda = 0$ and $\lambda = 1$, which is what authors of previous work had investigated.

The surprisingly pessimistic assessment of misspecification testing by authors who investigated its effect may be due to the fact that most available misspecification tests test the model assumption against alternatives that are either easy to handle or very general, whereas little effort has been spent on developing tests that rule out specific violations of the model assumptions that are known to affect the performance of the model-based method strongly, i.e., leading to different conclusions for interpretatively equivalent models, or same conclusions for models that are interpretatively very different. Such tests would be specifically connected to the model-based method with which they are meant to be combined and to the assessment of interpretative equivalence.

Furthermore, as already mentioned, not everything can be tested on data. For example, many conceivable dependence structures do not lead to patterns that can be used to reject independence. For example, it may occasionally but not regularly happen that one observation determines or changes the distribution of the next one. Think of psychological tests in which sometimes a test person discusses the test with

another participant who has not yet been tested and where such communication can have a strong influence on the result.

Frequentism-as-model could inspire work that looks at performance of methods involving model assumptions and misspecification testing under all kinds of models that seem realistic, including Bayesian combinations of different models with different probabilities. Generally, regarding methodological research, a researcher adhering to frequentism-as-model will always be interested in the performance of methods that are supposedly model-based under situations in which the model assumptions are violated, knowing that model assumptions can never be relied upon and that looking at other models is the only way to investigate what happens then. This is in the tradition of robust statistics, but with less focus on worst cases and more focus on interpretative equivalence for deciding what outcome would actually be desirable. The cases that are really the worst ones are hopeless under any approach, and even the best statistics cannot always save the day.

3.4.4 Frequentism-as-Model and Falsificationist Bayes

Epistemic probabilities model a personal or "objective" degree of belief, not the data generating process as such, and therefore, they cannot be checked against and falsified by the data. See Dawid (1982b) for a discussion of "calibration," i.e., agreement or potential mismatch between predictions based on epistemic Bayesian probabilities and what is actually observed. Gelman and Shalizi (2013) argued that Bayesian statistics should allow for checking the model against the data and interpret Bayesian models as modeling data generating processes rather than epistemic uncertainty. This is in line with a lot of applied Bayesian work in which the posterior distribution of the parameter is interpreted as encoding probabilities for a certain parameter being true descriptors of the underlying data generating process. This allows to check the model against the data and potentially to revise it, even though this violates the coherence requirement, which is taken as essential by most advocates of epistemic Bayesian interpretations. Gelman and Hennig (2017) called the connection of inverse probability logic and model checks "falsificationist Bayes."

My interpretation of it is that probabilities in falsificationist Bayes are interpreted in the same manner as in frequentism-as-model. The parametric model is handled *as if* it describes the data-generating process but can be dropped or modified if falsified by the data. The involved interpretation of probabilities is consistently aleatory if the parameter prior is interpreted as a model of a parameter-generating process in the same way. Gelman and Shalizi (2013) stated that the prior distribution may encode "*a priori* knowledge" or a "subjective degree of belief." This seems to mix up an epistemic interpretation of the parameter prior with an aleatory interpretation of the parametric model, and it is hard to justify using them in the same calculus. I believe that it would be better to refer to the parameter prior as an idealistic model of a process that generates parameters for different situations that are based on the same information, i.e., to interpret it in a frequentism-as-model way. This is in line with the fact that Gelman in presentations sometimes informally refers to the parameter prior as a distribution over parameters realistic in a distribution of different situations of similar kind in which datasets can be drawn. This is a very idealistic concept, and it is

probably hard to connect the setup of parameter generation precisely to real observations. The modeling will normally indeed rely more on belief and informal knowledge than on observation of replicates of what is supposed to be parameter generation, but an arbitrary amount of data can be generated from the fully specified model and can be compared with the observed data. Testing the parameter prior is hard. In a standard simple Bayesian setup, it is assumed that only one (possibly multidimensional) parameter value generated all observed data, so the effective sample size for checking the parameter prior is smaller than one, because the single parameter is not even precisely observed. Therefore, sensitivity against prior specification will always be a concern, but see the earlier discussion of single-case probabilities. In any case, the parametric model can be tested in frequentist ways. In case the parameter prior encodes valuable information about the parameter that can most suitably be encoded in this way, Bayesian reasoning based on such a model is clearly useful and open to self-correction by falsificationist compatibility logic. As for model assumptions testing followed by traditional frequentism methods (Shamsudheen and Hennig (2019)), it may be of interest to analyze the behavior of Bayesian reasoning conditionally on model checking in case of fulfilled and not fulfilled model assumptions.

A benefit of such an interpretation could be that the prior no longer either has to be claimed to be objective or to model a specific person. It is a not necessarily unique researcher's suggestion how to imagine the parameter-generating process based on a certain amount of information and can as such be compared with alternatives and potentially rejected, if not by the data, then by open discussion. As earlier, stability against different prior choices compatible with the same information can be investigated. Models may be set up to formalize not only most realistic processes but also, depending on the application, worst or best case scenarios in order to explore what range of possibilities this generates.

Alternatively, the sampling model may be interpreted in a frequentist manner, and the parameter prior may not be of interest in its own right, but rather be used as a tool to achieve inference with good frequentist properties such as confidence coverage or small estimator mean squared error (Bayarri and Berger 2004; Wasserman 2006). In this case, the posterior probabilities cannot be interpreted, as the posterior inherits meaning from the prior, and the prior has not been chosen in order to be meaningful. Often, Bayesian methods have better frequentist properties for certain parameter values and worse for others, so that the prior can also be used to improve matters for certain parameter values that are seen as more relevant, to the price of having a worse result in some other cases, being potentially in line with the idea that prior information suggests that certain parameter values are more likely than others.

Falsificationist Bayes combines the inverse probability logic and compatibility logic by applying the former within a Bayesian model, of which the compatibility with the data should also be investigated. Gelman et al. (1996) emphasize that the posterior distribution of the parameter is conditional on the truth of the model, and according to frequentism-as-model, a researcher can interpret results temporarily *as if* this were the case, without ignoring that this is just a thought construct and that many other models are compatible as well. This differs from the epistemic

probability interpretation, where the "truth of the model" is not a matter of mechanisms in the real world, but rather of the degrees of belief of the analyst, and the possibility that the analyst's degrees of belief are not properly reflected by the model is rarely discussed.

Frequentism-as-model allows to interpret the parameter prior in falsificationist Bayes in a way that requires neither to mix epistemic and frequentist meanings of probability nor to demand that the prior corresponds to an in principle infinitely repeatable data-generating process. The Achilles heel of this is that in a standard situation, based on a single realization that is not even directly observable, the potential to check the parameter prior against the data is very weak. The prior still needs to be convincingly defended in other ways, and sensitivity analysis is certainly desirable.

4 Epistemic Probability-as-Model

As for aleatory probability, it is also possible to use epistemic probability in a way that explicitly takes into account that models are tools for thought rather than referring to any trut and be it a truth concerning a subjective agent.

This chapter had the main focus on frequentism-as-model, and I will only make short remarks on epistemic probability-as-model. Some of the discussion regarding frequentism-as-model also applies to epistemic probability-as-model, such as regarding the role of the exchangeability assumption, which is analogous to the role of i.i.d. in frequentism as discussed earlier. Considerations regarding interpretative equivalence and robustness are also relevant.

4.1 Epistemic Idealization

As the idea of limiting relative frequencies, the axioms of epistemic probability are idealizations, and as such epistemic probability models are, as models, essentially different from reality, which here is the reality of agents reasoning under uncertainty. Adopting such a model amounts to adopting an idealization, and the "as-model" approach taken here states that this should not be forgotten. In fact, idealization is conceded in many places (e.g., Howson and Urbach (2006)), but as in frequentist analyses, results in practice are often interpreted as if idealization has not happened (e.g., probabilities that a certain parameter lies in a suitably chosen set may be portrayed without stating relative to which choices this has been computed, or without much justification of these choices).

De Finetti's (and others') arguments regarding coherent betting require linear utility of money. Leaving this issue aside, the involved betting regarding completely specified distributions is hardly ever done in practice; if this happens at all (e.g., in some financial applications), human agents with specific points of view bet against other human agents, and taking into account knowledge about the opponent or more generally human behavior may influence the offered bets. Several authors (Jaynes 2003;

Howson and Urbach 2006) prefer the derivation of the probability axioms from desiderata for rational reasoning about plausibility under uncertainty as in Cox (1946)'s Theorem to the betting approach, but also this involves idealization (i.e., the assumption that such plausibilities always can be expressed by bounded real numbers; any two events can be compared on a one-dimensional scale, and a number of other not necessarily intuitive requirements; see Van Horn (2003)), and it does not give an operational meaning to the probabilities chosen in any specific situation.

There are two levels at which idealization takes place. The first one is the choice of priors. It has already been mentioned that prior choices in practice will necessarily be simplified by not taking everything into account that could possibly happen. Furthermore, there are different principles for designing informationless priors that in a given situation may lead to different choices and different results (Kass and Wasserman 1996). The second level is the justification of Bayesian (or other) updating as a supposedly objective way to process probability statements given new data, whether or not the priors are taken as objective. However, this second level can hardly be considered independently of the prior choice, as modifying an ill-chosen prior may require a deviation from Bayesian updating and coherence. See Van Horn (2003) for a comprehensive discussion of other possible objections to the desiderata of Cox's Theorem.

4.2 Flexible Handling of Priors

Many pragmatic Bayesians have been well aware for a long time of the problems of all too dogmatically following the axioms of epistemic probability, and many recommendations exist that deviate from these, so that many practical implications of epistemic probability-as-model are not new. For example, Bernardo and Smith (2000) wrote:

> In this work, we shall proceed on the basis of a prescriptive theory which assumes precise quantification, but then pragmatically acknowledges that, in practice, all this should be taken with a large pinch of salt and a great deal of systematic sensitivity analysis.

More suggestions and references can be found in Gelman et al. (2013), particularly in Chap. 6.

Dropping the requirement to find a "true" prior, it is possible to explore a range of priors. For example, Spiegelhalter et al. (1994) propose to look at a "skeptical," an informationless, and an "enthusiastic" prior in randomized trials, in order to see clearly how posterior results are affected by different attitudes expressed in the prior. Sensitivity analysis looking at different priors that are seen as encoding (more or less) the same prior information is sometimes used. It is also possible to choose a prior that intentionally only uses certain prior information (which may be uncontroversial) while not accounting for other information that may be controversial among stakeholders, to allow for better agreement. See Dawid (1982a) on intersubjective choices of epistemic probabilities.

Maybe the biggest problem with the coherence requirement for epistemic probabilities is that it does not allow the user to deviate from the prior choices other than by Bayesian updating, as abovementioned. Pragmatic Bayesians know that it is practically impossible to specify prior probabilities for everything that can possibly happen. In case of a conflict between prior and data (to be discovered using compatibility logic, temporarily), it is often seen as more appropriate to change the model (see, e.g., Gelman et al. 2013, Ch. 6) even if this violates the axioms of epistemic probability. According to the betting logic proposed by Ramsey and de Finetti, this will allow an opponent to choose bets that incur sure loss for the user who chooses to change their model. However of course, the betting setup is itself an idealization, and in much applied data analysis, bets based on epistemic probabilities do not really happen. It may therefore seem harmless to "reject" earlier prior choices (Bernardo and Smith 2000, Ch. 6) back this up by utility considerations (incurring sure loss may be milder than exposing oneself to higher losses due to an inappropriate model choice), but they admit that rejecting a model cannot be fit into the Bayesian framework unless alternative models are already specified. Another reason to change priors is miscalibration, i.e., bad prediction results (Dawid 1982b).

It should not be ignored that if the data analyst is willing to violate the axioms for epistemic probability, these axioms can no longer be used to sell the Bayesian approach as coherent and unified. All Bayesian posterior probabilities are functions of the prior. If the prior is changed conditionally on the data, the interpretation of the posterior is questionable. A way to still justify the resulting posterior probabilities is to argue that a prior may have been specified in advance that involves both the original and the changed model, and given the incompatible data, the posterior probability for the original model should be very small, so that posterior probabilities from the new changed prior are very close to the posterior probabilities had the analyst specified a prior comprising all possibilities from the outset. It could be objected, though, that also even further models could have been considered (which could have been chosen in case the original model would have been rejected for different reasons), and as this was in fact not done, it cannot be known what implications this would have had. This can be taken as a reason to not change the prior based on the data too lightly.

The topic here is the use of epistemic probabilities in statistical data analysis. Philosophers interested in a general formal logic of plausibility will use epistemic probabilities somewhat differently, even if they follow the same Bayesian formalism with reference to Cox's Theorem. Jaynes (2003) motivates his introduction to Bayesian probability theory with equipping a robot with the formal tools to do automated reasoning. A robot cannot be expected to take axioms and their implications "with a large pinch of salt," as a human statistician can, and such an attitude is probably not to most philosophers' tastes either. A robot can be taught handling of epistemic probabilities, but not (at least not currently) epistemic probabilities-as-model, flexibly distancing itself from the absoluteness of a formal calculus and violating (or re-adjusting) it for a variety of good reasons that may not all be obvious in advance.

In Gelman and Hennig (2017), we have argued that it is worthwhile in science to aim at aspects of objectivity such as transparency, consensus, and impartiality.

Following a consistent formal system is surely attractive in these respects, but there is always an irreducible tension between these aims and the context-dependence of reasoning and the recognition of multiple perspectives. We should be prepared to question and at least temporarily suspend any consistent formal system if required, acknowledging it as a model, an idealization with limitations. A major issue with artificial intelligence (AI) (like Jaynes's robot) is that AI has to rely on formal models and cannot question them, or only in the framework of a bigger formal model.

4.3 How Different Are Epistemic Probability-as-Model and Frequentism-as-Model?

In frequentism-as-model, an agent adopts a probability model temporarily, acknowledging its essential difference from reality, which means that she considers the modeled experiment as if it has a tendency to give rise to the corresponding relative frequencies under repetition. In epistemic probability-as-model, an agent adopts a probability model temporarily, acknowledging its essential difference from reality, which means that she considers the uncertainties in the modeled experiment as if, where she bets on future observations, she would do this according to the model.

Involving exchangeability (which of course is questionable) in the epistemic model actually implies that relative frequencies are expected to converge, and using a frequentist model could then be justified just as well, although a Bayesian may want to keep the prior, at least if it encodes relevant information that would otherwise be lost. It has also been recommended in various places (Gelman et al. 2013, Ch. 1) to think about a situation as repeatable and to consider expected relative frequencies when setting up Bayesian priors. In fact, Bayesians often think of the sampling model part of the prior as modeling an aleatory mechanism (possibly idealized, in an "as-model" manner), and often posterior probabilities regarding a parameter are interpreted as if this were about a "true" parameter value defined within an aleatory sampling model.

Taking also into account that epistemic and aleatory probabilities were historically not distinguished, frequentism-as-model and epistemic probability-as-model are indeed strongly related. It will however contribute to the clarity of communication to specify, when doing analyses, explicitly what the involved probabilities are supposed to mean. Does the modeler model a data generating mechanism in the world, and do probabilities refer to the outcomes of it? Or do probabilities refer to the agent's uncertainty? I have elaborated that this is not an issue of belief in the existence of objective aleatory probabilities, which is not more or less problematic than belief in a general epistemic calculus formalizing rational handling of uncertainty and in specific prior choices, even if the latter only refer to the agent herself. Modeling does not require belief in the truth of a model; a model has to be justified from its use.

Aleatory models can in principle, by bold idealization, even be applied to situations that are essentially non-repeatable and may not even allow for repeatable residual or innovation terms and the like. However, anchoring such applications in

observations and defending them convincingly may be hard if not impossible, and a modeler has an easier task for sure justifying the use of epistemic probabilities.

On the other hand, many sequences of experiments are treated in probability modeling as if they behave like aleatory processes, and results are interpreted in this way, even if used as sampling model in a Bayesian prior. It seems to be more direct to me in such cases to talk about models for data-generating processes in reality, rather than about models for how an agent thinks about data-generating processes in reality, and therefore I often prefer the aleatory interpretation, not ruling out using Bayesian calculus.

5 Conclusion

It may seem to be my core message that models are models and as such different from reality. This is of course commonplace, and agreed by many if not all statisticians, although it rarely influences applied statistical analyses or even discussions about the foundations of statistics.

Here are some less obvious implications:

- The usual way of talking about model assumptions, namely that they "have to be fulfilled," is misleading. The aim of model assumption checking is not to make sure that they are fulfilled, but rather to rule out issues that misguide the interpretation of the results. Combining model assumption checking and analyses chosen conditionally on the model checking results can itself be modeled and analyzed, and depending on what exactly is done, it may or may not turn out to work well.
- There are always lots of models compatible with the data. Some of these can be favored or excluded by plausibility considerations, prior information, or the data, but some irregular ones have to be excluded simply because inference would be hopeless if they were correct.
- Model assessment based on the data involves decisions about "in what way to look," i.e., what model deviations are relevant. Whether a model is compatible with the data cannot be decided independently of such considerations.
- Choosing a model implies decisions to ignore certain aspects of reality, e.g., differences between the conditions under which observations modeled as i.i.d. were gathered. These decisions should be transparent and open for discussion.
- Consideration of interpretative equivalence, i.e., what different models would be interpreted in the same or different way regarding the subject matter, is important in order to investigate robustness and stability, i.e., to what extent different models compatible with the data would lead to results on the same data that have a different meaning.
- Frequentism-as-model is compatible with both compatibility and inverse probability logic. A key to decide which one to prefer is to ask whether the parameter prior distribution required for inverse probability logic can be used to add

valuable information in a convincing way. The parameter prior itself cannot normally be checked against the data with satisfactory power. Compatibility logic can also be used for epistemic-probability-as-model; a model may be dropped that turns out to be incompatible with the observations, even though this violates coherence.

Acknowledgments I thank Laurie Davies, Andrew Gelman, Donald Gillies, Sander Greenland, David Hand, Johannes Hüsing, and Keith O'Rourke for helpful comments on an earlier version of this chapter.

1 Introduction

The ancient problem of the relationship of the continuous to the discrete, since its discovery by the Greeks, has posed a range of immensely fruitful challenges to both philosophical and mathematical thought, leading to a variety of mathematical and conceptual innovations whose positive development actively continues today. In this brief section introduction, I selectively outline some significant moments at which this problem has provided important historical occasions for concrete mathematical innovation as well as closely linked philosophical insights, before introducing the particular contributions of the section authors to historical and contemporary research and practice into the nature and structure of the continuum, the construction of real numbers, the foundations of analysis, and the logical, set-theoretical, and computational underpinnings of the structure of continuously valued numbers in the most general sense, in both constructive and nonconstructivist contexts.

Ancient sources credit the discovery of what we would today call the "irrationality" of the square roots of some integers to a Pythagorean of the early fifth century BC, perhaps Hippasus of Metapontum, and also relate the (probably apocryphal) story of his having been drowned at sea as punishment for making public secret Pythagorean doctrines. From the beginning, what dominates the attention of the Greeks in this discovery is not simply the numerical fact of the nonexistence of any ratio of integers a/b corresponding to the irrational quantities, but (rather more basically) the geometric *incommensurabilty* that is exhibited by (for example) the diagonal of the unit square in relation to its sides (Heath 1921). That the diagonal is incommensurable with the side in this sense means that there can be no common unit length l, no matter how small, that can "measure" both in the sense that both lengths can be expressed as integer multiples of it. There is some evidence (von Fritz 1945) that the first discovery of the mutual incommensurability of lengths was not that of the incommensurability of the diagonal of the square, but rather that of the incommensurability of the pentagon with its side, for which there is a directly geometrical demonstration. However this may be, for the case of the diagonal of the unit square (which was independently known to have the length root $\sqrt{2}$, either by the Pythagorean theorem or by the independent demonstration, given by Plato in the *Meno*, of the possibility of constructing a square of area 2 on the diagonal of the unit square), a primarily numerical proof by contradiction is recorded in an appendix to book 10 of Euclid's *Elements* (although the proof is probably a later addition, not included by Euclid himself, and is omitted from Heath's translation) (Euclid 1908).

Several historians of Greek mathematics, especially in the early twentieth century, have seen this discovery of the incommensurable and hence of the impossibility of understanding all magnitudes in terms of ratios of whole numbers as representing a fundamental crisis in the history of Greek mathematics and as thereby leading to increasingly radical attempts to remedy it (see Hesse and Scholz 1928; Becker 1933; Saito 2004). Whether or not this is the case, the rapid efforts of Greek mathematicians to classify the irrational magnitudes evidently figure prominently in Plato's own thinking about the nature of knowledge and (in particular) the possibility of clarifying the reality of infinite continuous variation through the discovery of

discrete *forms* or *eide* associated with specific discursive definitions. Here, Plato appears to make reference to the project of determining types of quantities capable of classifying this reality of infinite variation, most evidently shown in the infinite multiplicity of types of number or quantity, into discrete identities or groups. The early development of these methods of classification is due primarily to the mathematicians Theaetetus and Theodorus, both associates of Socrates and Plato and connected to his school, and book ten of Euclid's *Elements,* which is devoted to incommensurable and commensurable magnitudes, appears largely to summarize their results (the connection is attested by Pappus: see Sayre 1983, p. 108). Near the beginning of Plato's dialogue *Theaetetus* (147d, ff.) which is primarily concerned with the definition and nature of knowledge, a young Theaetetus is presented as in the middle of classifying the initial integers, in part by demonstrating the irrationality of the roots of the nonsquares from 3 through 17. Just as the integers can be classified into different groups according to whether they are "square" (perfect squares) or "oblongs," so the infinite range of variation of a concept such as that of knowledge might be tamed, Socrates suggests, by means of a specification of the *eide* or types among which this infinity is distributed under a single overarching concept (148d).

The suggestion that one might in this way "tame the infinite" through the specification of determinate limits by using the best *mathematical* techniques available at the time also appears to play a role in the later Plato's conception of how rational thought can comprehend the discrete ideal forms of quantities and magnitudes that are naturally in continuous variation. A concern with the problem of continuous variation appears in many different places in Plato's corpus, perhaps most centrally in the late dialogue *Philebus* in connection with the project of making a "division" of whatever exists into the two categories of the "limit" and "unlimited" (16c–17a; 24c–25a). Here, the suggested "method" of rational inquiry is that of looking, in each case of continuous variation (for example, between the hotter and the colder or between the higher and lower pitch), for the unity of forms which operate as limits and assign discrete measure and proportion between the extremes.

Noting the evident connection that this bears to Theaetetus' problem of the classification of the irrational (i.e., incommensurable) magnitudes, Sayre (1983) suggests that Plato's description of the "method" of determining the ideal forms of these magnitudes may draw on a method for approximating irrationals to an arbitrary degree of precision due to Eudoxus of Cnidus, himself a student and associate of Plato's, which several modern writers have compared to the central innovation of the modern project of "constructing" the reals, Dedekind's so-called "cut." The method is implicit in Euclid's definition 5 in book 5 of the *Elements*, which specifies that two magnitudes a/b and c/d (whether rational or irrational) are in the same ratio if and only if, for any m and n, either (i) $ma > nb$ and $mc > nd$; (ii) $ma = nb$ and $mc = nd$, or (iii) $ma < nb$ and $mc < nd$. Given this, the value of a magnitude incommensurable to the unit length can be approximated in rational terms to an arbitrary degree of accuracy. For example, in a geometric illustration that captures the method as it would have been known to Eudoxus and Plato, the magnitude $\sqrt{2}$ can be approximated by imagining two series of points placed at intervals next to each other. The first series are placed at intervals of the unit length, while the second are placed at

intervals of (the length) $\sqrt{2}$. Then it will be the case that the first point of the second column will fall between the first and second points of the first column: the 10th between the 14th and the 15th, the 100th between the 141st and 142nd, and so on. In this way, the decimal expansion of $\sqrt{2}$ is approximated as falling between two ordered sets of quantities expressed in terms of unit measures, essentially dividing the rationals into those above and those below the relevant irrational magnitude.

With respect to devices such as these, it is clear that the mathematics available to Plato at the time of his writing had already progressed very significantly in the direction of what much later would be understood as the "construction" of the real continuum and even the substantive determination of its defining properties (Eudoxus is also responsible, for instance, for the introduction of the "Archemidean" property of the continuum (*Elements* book V, def. 4) whereby for any two magnitudes m, n, there is an integer p such that $pm > n$, according to Archimedes' own testimony). Moreover, it is clear that what underlies the actual philosophical fruitfulness of these constructions, for example, in the case of Plato's own philosophy of forms and their participants, is the way that they offer to address the underlying problem of incommensurability which threatens to cleave the discrete from the continuous, thereby express the most central kinds of access of rational, discursive, and conceptual thought to what Plato envisioned as its taming of a world of infinite continuous variation. In this light, the philosophical relevance of the mathematical techniques for comprehending and constructing the continuous in terms of the discrete do not come so much from their overcoming or solution of this problem as from the ways in which they offer the problem itself to be reinscribed in more logically and philosophically revealing terms. Much the same is the case, in fact, for much of the later history of the development of the differential and integral calculus, the set-theoretical foundation of the real numbers suggested by Weierstrass, Cantor, and Dedekind, and even the foundational work that is still being done today.

Another opportunity for reflection on the way that the problem of the relationship between the discrete and the continuous has simultaneously led to significant innovations of both a philosophical and a mathematical character is afforded by reflection on the fundamental contributions of G. W. F. Leibniz to both domains. By 1686, Leibniz had arrived at what are essentially the fundamental methods of both the integral and differential calculi, appealing (without using the term) to what are essentially infinitesimal quantities including infinitely small but nonzero distances, and conceiving of curves as essentially infilateral polygons (Bell 2022). His work on the calculus together with his reflections on what he saw as the impossibility of understanding the continuous line as an aggregate of points appears decisive in producing his overarching metaphysical picture of *monadism*, according to which all real unities are simple substances amounting to "formal atoms" (Leibniz 1695). This metaphysics of the composition of all real entities, including matter, as aggregates of monads led Leibniz to his conviction of the ideality of space and time: Since (Leibniz supposed) all real unities were either pointlike monads or aggregates thereof, and since space and time, being continua, could not be understood as such aggregates, they must not be realities at all. However, Leibniz holds that bodies are not only divisible but actually divided into real parts, ad infinitum (Leibniz 1686);

more generally the idea of the actual composition of perceived phenomena by parts that are separate to infinity provides support for what has been called his "principle of continuity," which holds (in various different formulations) that there are nowhere any discontinuities or "gaps" in natural phenomena.

Although Leibniz thus denies the ultimate reality of the continuum along with extension in time and space themselves, these claims also lead him positively to understand the distinction between the necessity and contingency of propositions as a result of the mutual *incommensurability* of continuous magnitudes and the specific kind of irreducibility this may be thought to imply in the logical analysis of subject/predicate propositions. Leibniz saw the truth of any such proposition as following from the "containment" of the predicate term within the subject, whether or not we are in a position to perceive the particular containment by means of any finite analysis. In particular, Leibniz argues in a 1689 fragment (Leibniz 1689) that what we understand as "necessary" truths may be seen as those in which the containment of the predicate in the subject concept may be seen as following from basic truths, or statements of identity, by means of at most *finitely* many deductive steps. For contingent truths, by contrast, the containment of the predicate in the subject cannot be shown in any finite number of steps, although Leibniz suggests it may nevertheless be known to God, who can see the *whole* of the infinite series of steps which could alone resolve it. In this respect, Leibniz argues, the analysis (whether finite or infinite) of containment is analogous to determining the ratios of rational as well as irrational numbers. Just as in every truth the predicate is contained in the subject, so in every such ratio a smaller number is "in" a larger one (or an "equal in an equal"). But whereas in certain ratios (i.e., those corresponding to rational numbers) one can analyze the larger without residue into the smaller, or into a common measure of both, in ratios such as that of the side to the diagonal of the square, the incommensurability of the ratio ensures that there can be no common finite measure and the analysis is hence continued "into infinity" (Leibniz 1689, p. 97). Thus, in the case of contingent propositions whose truth we can see only by means of sensory perception, it is impossible for our reasoning to reduce these to identities by a proof of any (finite) number of steps or to see the necessity of the containment of the predicate in the subject. Nevertheless, just as we do nevertheless have some knowledge through geometry of incommensurable magnitudes and even have proofs (Leibniz is, doubtless, thinking of his the methods of his own infinitesimal calculus) about infinite series, so we may suppose that God has (to an even greater extent) knowledge of the necessary truths through an infallible kind of intellectual intuition of the whole that here precedes the infinite series of parts.

For both Plato and Leibniz, the fact of actual incommensurability and the inherent involvement of the problematic of the infinite to which it leads played an essential role in articulating both the possibility and the inherent limits of any project of conceptual or metaphysical discursive analysis of the phenomena of motion, change, and continuous variation that appear to be given to us primarily rather in sensory, intuitive, or temporal forms. Here, the problem for the logic of the analysis of concepts and propositions that is posed by the continuous is not so much that of applying a pregiven logical framework to its structure as that of comprehending how

conceptual terms can grasp or even approximate its structure at all, given the demands that the phenomenon of incommensurability already itself places on the projects of exact measurement, demarcation, and analysis. In these projects as Plato and Leibniz understood them, there is thus nothing like a full-fledged "construction" of the continuum or of the reals in general yet in view. But with the range of developments in the eighteenth, nineteenth, and twentieth centuries in the foundations of analysis which accomplished the "arithmetization" of the reals, the culmination of which was the foundation of the concepts of the calculus by means of the Cauchy-Weierstrass conception of the limit, and the set-theoretical construction of the reals in general by means of Dedekind's "cut," the logical and conceptual problems of foundation surrounding the grasp of linguistic or discursive thought on the structure of the continuum are not only articulated in a new way, but also in a certain sense intensified and displaced onto a new and more radical logical ground.

One underlying form that these problems do take in the altered context provided by these nineteenth- and early twentieth-century developments is evident in Hermann Weyl's 1918 *The Continuum,* which is simultaneously a devastating conceptual critique of the contemporary set-theoretical "foundations" of real analysis and an attempt to build up these foundations positively on a different and more limited ground, more closely related to the basic form in which the continuous is plausibly given in our *intuitive* experience of space and time. The central issue underlying Weyl's critique is that of the apparent *impredicativity* of Dedekind's attempt at set-theoretical definition of real numbers and of the real number continuum. The terminology and issue of predicativity traces originally to Russell, who used "non-predicative" to describe any propositional function which fails to non-circularly determine a class (Feferman 2005). Such a failure generally may occur when the attempted definition of a class fails to exclude a "vicious circle," for example, by including in the purported definition the notion of definability itself. More generally, Russell held that the definition of a class or totality is nonpredicative whenever the class or totality so defined would have to include members that are definable only on the basis of that totality itself. Russell saw impredicativity in this sense as the underlying origin of a number of set-theoretical and semantic paradoxes, including his own (and Zermelo's) paradox of the set of all sets not elements of themselves, and therefore sought to prohibit impredicativity in general by imposing a system of (simple or, later, "ramified") types ensuring that sets and propositional functions can only be formed from those of lower type (Russell 1908).

As Poincaré had already pointed out in 1906, another paradox plausibly having the same form and origin is Richard's paradox concerning the definition of real numbers generally (Poincaré 1906; cited in Feferman 2005, pp. 1–2). Briefly, since it follows from Cantor's proof of the uncountability of the reals that there are more real numbers than there are possible definitions, it is possible to define (by diagonalization) a real number different from any that is definable. The basis of Weyl's critique of the by-then standard definition of the reals by means of Dedekind's cut is, then, that (as Poincaré in fact also points out) this definition renders familiar properties of the real numbers impredicative. For example, Dedekind's device of defining the real numbers as (generally infinite) sets of

rationals renders it impossible to appeal to the greatest lower bound (g.l.b.) and least upper bound properties of bounded sets of real numbers (i.e., the properties that every bounded subset S of **R** has a greatest lower bound and a least upper bound) in general without essential impredicativity (Feferman 2005). For the identification of the g.l.b. and l.u.b. for any such set is possible, given Dedekind's technique, only by presupposing the *completed* totality of Dedekind cuts itself, the vast majority of which are not definable by any definition of finite length.

For Weyl in 1918, this implies that the Dedekind (or more broadly, any simple set-theoretical) device for defining the reals in general is hopelessly flawed from a logical standpoint: in particular, that it assumes without reason that the concept of a "real number" is (what Weyl calls) an "extensionally determinate" one. Such a concept, in Weyl's terminology, is one that determines a set of *existent* objects falling under it and also determines unequivocally, for any given property, *whether* there is or is not any object falling under the concept that has that property (Weyl 1919, pp. 109–110). This kind of determinacy fails, Weyl argues, for the real numbers exactly in the case of determining (for example) the l.u.b. of a set of reals. If a real number is understood as a definite set of rationals, and thus as corresponding to a single "definite property" of rationals, then a set of real numbers corresponds to a property A *of properties* of rational numbers. The least upper bound of a set of reals is itself a real number, and thus (on Dedekind's definition) a set of rational numbers x which possess a certain property P_A, that is, just the property *that there is* a property (of properties) of the kind A belonging to x. But this kind of expression, which requires of the definition of the property P_A that it be formulated in a way that ranges over the *totality* of properties of (i.e., of sets of) rational numbers, is (Weyl says) "*clearly meaningless*" (Weyl 1919, p. 111). For, as the expression "property of rational numbers" is itself not extensionally determinate, we are in no position to use phrases definitively which require us to reason about what exists or does not within the (supposed) totality of all such properties. Alternatively, though, if we do restrict the relevant kind of property to ones falling under an extensionally determinate concept, then P_A will itself be one which is, as a matter of its *sense,* almost certainly outside the range of such extensionally constrained properties. It follows from this, Weyl argues, that if the continuum and its most characteristic properties are to be founded at all, its foundations must be a different kind of predicative one, in particular one that makes no essential appeal to the (fictitious) totality of *all* properties of rational numbers. Such an alternative can be found, Weyl argues, only if one takes the continuum to have its own, distinct formulation in the *intuitive givenness* of continuous phenomena and quantities, and most basically in the phenomenon of time (for more on the positive form that this development takes in *The Continuum* and in Weyl's later work, see John L. Bell's article in this section).

After *The Continuum*, Weyl was increasingly led by these suggestions toward the philosophical conceptions of Husserl and Brouwer, according to which the "givenness" of the continuum to any project of conceptual analysis or foundation must depend on the specific and temporal form of that very givenness in living intuition prior to, and as an essential ongoing constraint on, its conceptual or logical analysis. That this conception of the actual foundation of the continuum in intuition

does not preclude the significant and ongoing development of the implications of *logic* for its (properly mathematical) structure is shown sufficiently by the developments of intutionist logics that modify the principles of classical logic such as those of excluded middle and double negation elimination, and by the vast range of the implications of these which continue to follow on them today. I will not go into these implications in this introduction, though several of the individual section contributions (discussed below) do so. But it is nevertheless worth noting how the problems of the relationship of what is plausibly the structure of conceptual or discursive thought and the logical dictate of the avoidance of vicious paradox there which yields the issue of predicativity and Weyl's critique of the set-theoretical foundations of the real, on these grounds, appear to manifest once more (as in the cases of Plato and Leibniz as well) the deep and practically insoluble implications of the basic and underlying problem of the irreducibility of the scarcely delimitable variability of the continuous as such to the determinacy and discreteness of conceptual or predicative thought itself.

The various historical and topical contributions to the section further develop the implications of these problems of the relationship of the structure of the continuum and its relationship to the discrete, including logical, constructive, abstractive, and computational aspects, for important historical moments in the history of their development as well as cutting-edge developments today.

First, John L. Bell's comprehensive "The Continuum and the Evolution of the Concept of Real Number" offers a wide-ranging survey of the historical development and contemporary specifications of the concepts of real number and continuum. Beginning with ancient mathematics and the Greek discovery of the incommensurable, Bell treats the first introduction of the general concept of a continuous arithmetic (by Stevin in 1585) and then develops the controversial issues historically surrounding the nature and existence of infinitesimals in the nineteenth century. Following this, Bell describes the motivations and achievement of the project of Weierstrass, Cantor, and Dedekind in "arithmetizing" the continuum by analyzing it in terms of the discrete, and the subsequent set-theoretical identification of real numbers as sets of rationals or sets of points, closely accompanied by the extirpation of infinitesimals that was achieved by means of the Cauchy-Weierstrass redefinition of the basic concepts of the calculus in terms of limits. In the third section of his article, Bell discusses the positions of several nineteenth- and twentieth-century dissidents to the emerging consensus around this set-theoretical analysis of the continuum in discrete terms. For these mathematicians and philosophers (including du Bois-Reymond, Poincaré, Brouwer, Weyl, Brentano, and Peirce), the underlying mysteries of the continuum or the ineliminability of its actual givenness in intuition as continuously or temporally real verified that there could be, in principle, no secure foundation of the continuous in the discrete and led to various attempts (drawing on mathematical, philosophical, and phenomenological sources) to base the reality of the continuous (and, in some cases, the infinitesimal) on alternative grounds.

For Brouwer in particular, the continuous was always a matter of the intuitive givenness of continuous magnitudes actually given in a temporally real intuition, and

all mathematical activity involves essentially such "construction" in intuition. As Bell documents in section 4 of his paper, a development of Brouwer's suggestion outside the specific context of the psychology or phenomenology of intuitive givenness – but preserving the importantly "constructivist" idea that a mathematical problem is to be regarded as solved only if an explicit solution can be produced – leads to the influential project of "constructive" mathematics and, with it, to a completely different way of logically founding the continuum. Here, in particular, certain typical regularities of classical logic are abandoned in favor of what has been called "intuitionistic" logic: In particular, existential statements require the production of an instance, and disjunctions can only be affirmed only when one or the other of the disjuncts (or both) is explicitly demonstrated. For this reason, both the classical law of excluded middle and the classical procedure of "strong" *reductio* (relying on double negation elimination to establish positive existential claims) are not assumed to hold in the intuitionist context. This modification has important consequences, some negative and others positive, for the construction of the reals themselves and the conditions of their identification. On the constructivist conception, real numbers themselves are then not arbitrary sets of rationals, but rather definite sequences determined either by an effective rule or indeed by successive "free choices" conceived as, in principle, able to be made by an actual mathematical consciousness existing in time, or an idealization thereof.

In the last two sections of his contribution, Bell discusses some of the radical consequences and new developments that have followed the reintroduction, primarily by Abraham Robinson, of a mathematics of infinitesimal quantities and the attendant creation of the new project of Nonstandard Analysis. On one development of the project, the standard classical real line **R** is supplemented by a new and additional structure called a *nonstandard universe*: Defining properties of the original continuum are preserved while at the same time the new universe admits a wide variety and richness of new objects, including both infinite and infinitesimal numbers. On another and more directly geometrically founded approach, that of *Smooth Infinitesimal Analysis* (SIA), a restriction of functions to those that are "smooth" or arbitrarily many times differentiable allows for the postulation of a set of infinitesimal lengths within the real continuum. The requirement of smoothness and continuity of functions has the consequence that the underlying logic of SIA does not affirm the law of excluded middle, and so is intuitionist, and as a further consequence allows the refutation of the classical set-theoretical Axiom of Choice. Moreover, and even more radically, the identity relation here fails even to be decidable since it is not universally the case for all x, y that either $x = y$ or $x \neq y$. However, as Bell discusses, models of SIA can also be understood category-theoretically as certain topoi, leading to a fascinating connection to the topos-theoretical modeling of set theories in general (including, in the general case, intuitionistic set theory). In the more generalized context of a topos-theoretic universe, a consequence is that there are now various alternative constructions which may serve the role of "the" mathematical continuum: In Bell's own words, here, "the classical view that the linear continuum is a uniquely determined entity gives way to a pluralistic conception under which the continuum has a number of embodiments with essentially different properties" (p. 81, below). Bell's

article concludes with a brief and illuminating contrast of the logical structure and structural consequences of Nonstandard Analysis with those of SIA, and a suggestive consideration of the plausibility of considering SIA in particular as a potent model for real relations and results in classical and quantum physics.

Following Bell's article, the next three contributions to the section develop historically important conceptions and results from the nineteenth century concerning the structure of reals and the achieved mathematics of real analysis. First, Piotr Blasczyk and Marlena Fila's "On Bolzano and Greek Concepts of Continuity" traces the development of the problem and conception of the continuum from its ancient Greek sources, including their treatment in Euclid, through the more mechanical treatment of curves given by Pappus and then by Descartes. In the last part of their contribution, Blasczyk and Fila treat the conceptual innovations and philosophical implications of the 1817 work of the philosopher and mathematician Bernard Bolzano, *Rein analytischer Beweis*. . ., which culminates in his successful proof of (a formulation of) the Intermediate Value Theorem. Elías Fuentes Guillén's contribution, "Bolzano's Theory of Meβbare Zahlen: Insights and Uncertainties Regarding the Number Continuum," then considers the theory of "measurable numbers" introduced by Bolzano in the 1830s. As Guillén shows, Bolzano's thinking about these quantities was closely connected with his thinking about the general concept of numbers, including imaginary and complex ones, and of the infinite. Despite his initial rejection of the reality of infinitesimals, Bolzano's thinking is, Guillén shows, equally determined by his consideration of rational numbers that are capable of increasing or decreasing to an infinite or an infinitely small quantity. Following on these, John K. Dagsvik's article "Abel's approach to Elliptic Integrals: the Addition Theorems" contextualizes and explains the remarkable contributions of the nineteenth-century mathematician Niels Henrik Abel to the theory and analysis of elliptic integrals and functions, in particular developing his so-called "addition theorems" and bringing out the intuitions behind his distinctive approach to these functions as well as those underlying the previous approaches of others.

The last two papers of the section discuss contemporary developments of the continuum and its potential generalizations, including the dramatic logical, proof-theoretical, and computational implications of these recent innovations around the problem of continuous structure. In "The Absolute Arithmetic Continuum and its Geometric Counterpart," Philip Ehrlich employs the surreal numbers discovered by John Horton Conway in the 1970s as a maximally general field (**No**) of "all numbers great and small," including both reals and ordinals as well as infinites and infinitesimals. Ehrlich describes the development of what is essentially a tree of all the elements of **No** ordered recursively by the increasing lexicographic complexity of their canonical "proper names." Ehrlich suggests that this ordered field of surreal numbers may be considered to define a kind of "absolute" arithmetic continuum, above and beyond the ordered field of real numbers (but without the "Archimedean" property that is definitive in **R** itself). In the last two sections of the paper, Ehrlich fascinatingly suggests that a fundamental kind of bridging between the continuity characteristic of geometrical relationships and the discreteness characteristic of numbers may be provided by considering the Cartesian space over the ordered

field of surreal numbers thus structured. Here, indeed, Ehrlich suggests that it is just the properties that the surreal numbers inherit from their recursive unfolding in the simplicity-hierarchical tree that qualifies their elementary continua to define an absolute continuum suitable for use across a broad variety of specific developments of (generally non-Archimedean) continua in diverse fields.

The final chapter of the section, John Stillwell's "Reverse Mathematics," develops the related consequences for the proof-theoretical and computational bases of real analysis of the project that has been called that of "reverse mathematics," that is, the project of (rather than deriving theorems from "given" axioms) considering *which* axioms are needed to prove certain results. As Stillwell discusses, the first historical applications of this kind of project were marked in the consideration of the specific implications of, and consequences of omitting, Euclid's fifth (or "parallel") postulate for geometry; another important example is provided by set-theoretical reflection about the dispensability of the Axiom of Choice. After discussing the proof-theoretic foundations of the important developments of analysis in the nineteenth century as well as Dedekind's construction of the reals, Stillwell describes how the consideration of the proof-theoretic strength of various axioms systems may be related to considerations of the recursive computability of certain proposed derivations by means of certain determinate rules. Following the precise definition of computability achieved by Turing, Gödel, and Church in the 1930s, it is then possible to distinguish rigorously between recursively enumerable and nonenumerable sets of consequences and thus, in a natural way motivated by the computability considerations themselves, to separate "constructive" from "non-constructive" theorems of analysis and related fields. In particular, the addition of a single "recursive comprehension axiom" to the original Peano axioms for natural numbers leads to the extension of arithmetic to what may be considered a wholly constructive development of the reals. Beyond this, however, it is also possible to define further nonconstructive axiom systems of increasing degrees of complexity and to reflect on the extension which thereby becomes possible into more far-flung results of analysis, including those that essentially involve impredicative "constructions" in the sense discussed above.

2 Summary

With these considerations and constructions, the basic and underlying "philosophical" problem of the extent and limits of the actual positive construction of the reals by the finite conceptual methods of discursive thought, as against the apparently much vaster "reality" of the continuum understood as comprising the vast multiplicity of nonpredicative and nonconstructible elements, is brought to a revealing new level of formal and deductive reflective self-consciousness. At the same time, however, the underlying gulf between the powers of rational discursive thought and the generality of the continuum and its structure (or structures) seems to remain unabated and indeed appears likely to continue to provide a decisive and fruitful stimulus simultaneously for both mathematical innovation and philosophical reflection long into the future.

Abstract

This chapter traces the historical and conceptual development of the idea of the continuum and the allied concept of real number. Particular attention is paid to the idea of infinitesimal, which played a key role in the development of the calculus during the seventeenth and eighteenth centuries, and which has undergone a revival in the later twentieth century.

Keywords

Continuum · Real number · Arithmetization · Infinitesimal · Constructive mathematics · Intuitionistic mathematics · Nonstandard analysis · Smooth infinitesimal analysis

1 The Origins of the Real Number Concept

The concept of number has undergone a long evolution, leading to the emergence of several types of "number." The fundamental numbers are, of course, the *natural or whole numbers* 1, 2, 3, ... associated with the process, temporal in nature, of *counting.* Counting is applied to *discrete* collections of well-distinguished objects such as flocks of sheep, piles of stones, etc. Discrete collections are not always exactly divisible into numerically equal parts of a prescribed size. Thus, for example, a flock of 31 sheep, not being divisible into an exact number of pairs or triplets, cannot be exactly "counted by twos," or "counted by threes." Once the unit, in this case "individual sheep" is fixed, it cannot be arbitrarily changed and used to provide an exact count of the flock. This "rigidity of the unit" is a characteristic feature of the use of natural numbers in counting discrete collections. In this sense counting is *absolute.*

Natural numbers can be *compared.* The basic standard of comparison of numbers is, of course, *greater* ($>$) and *less* ($<$). A subtler standard of comparison is *proportionality* or *ratio.* Intuitively, given two numbers $m < n$, the ratio or proportion $m: n$ represents the *relative size* of m to n. In cases where m divides n exactly, $m: n$ can be regarded as a natural number, the number of times m divides n. For example 4: 24 may be identified with the number 6. But when m is not a divisor of n, the ratio $m: n$ cannot be represented by a natural number in this way. Such ratios came to be known as *fractions,* and later as *rational numbers.*

Such is the case for counting. In the case of *measuring,* additional problems arise from the fact that measuring is concerned not with discrete collections ultimately composed of distinct indivisible "atoms," but with *infinitely divisible, continuous entities,* in a word, with *continua.* In the case of discrete collections, like flocks of sheep, we are automatically provided with a natural "intrinsic" unit for counting purposes, so generating a natural number. Frege's brilliant idea of identifying the unit with a property or concept is illuminating here. In the case of a flock of 31 sheep, the number "31" is based, according to Frege, on the "concept-unit" "individual sheep." The "rigidity of the unit" in this case is illustrated by the fact that changing the concept-unit to "pair of sheep" renders it incapable of associating a natural number with the flock. Now because of the unlimited divisibility of continua, no such intrinsic units are, or can be provided. In measuring the length of a straight line, for example, we say that it is so many inches, or centimeters, long. Apart from the fact that these inches or centimeters represent lengths of straight lines, their lengths are entirely arbitrary "units," not determined in any further way by the extent of the given line. Measurement arises from a *comparison* of the length of the given line with the length of the linear unit, inch or centimeter as it may be. Measurement is thus *relative:* in measuring the length of a straight line an *additional* straight line must be specified as a unit of measurement. This fact further complicates the issue of defining the "ratio" of the lengths of straight lines, and divisible magnitudes generally. In the case of discrete collections, ratios are given directly in terms of the numbers of units constituting the collections: thus the ratio of a collection of 31 sheep to 68 sheep is 31: 68. But in the case of divisible magnitudes such as straight

lines, it is not always immediately clear how the "ratio" between them should be defined. Of course, they are straightforward cases in the divisible case such as the following: suppose we are given a straight line L and we construct two straight lines L' and L'' by laying down the given line L 31 and 68 times, respectively. Then the ratio of (the lengths of) L' to L'' is 31: 68. In effect, the situation has been reduced to the discrete case by taking (the length of) L as a common unit. But when the lines L' and L'' are *arbitrary*, what guarantee is there that they are *commensurable,* that is, can a line L be found to play the role of common unit of measure for L' and L'' so enabling the ratio or proportion to be presented numerically? Let us call this the problem of *commensurability.*

Certain ancient cultures such as the Egyptians and Babylonians handled ratios in a pragmatic manner. Treating them as "fractions," which later became known as *rational numbers,* they formulated rules of calculation for them analogous to, if more complicated than, the familiar rules of calculation for natural numbers. While we do not know whether they regarded fractions as being true "numbers," for all practical purposes they treated them as such. And it seems likely that they treated the issue of commensurability, when it arose in practice, in a rough-and-ready way.

As far as we know, in antiquity, only the mathematicians of the Greek school were exercised by the problem of commensurability, which had naturally arisen in their development of geometry – itself, as its name shows, a by-product of the practice of measurement. The Greek mathematicians had a strict conception of number, *arithmos,* defined by Euclid as a multitude composed of units, which resisted expansion to embrace proportions, ratios, or fractions. They accordingly regarded numerical proportions or ratios– that is, proportions or ratios *between* numbers – as being quite distinct from numbers *themselves.* By 500 B.C.E. they, more precisely the Pythagorean School, had developed a theory of numerical proportions.

It was a fundamental principle of the Pythagoreans that the world is explicable in terms of properties of, and relations between, whole numbers – that number, in fact, forms the very essence of the real. In geometry this doctrine led to the sweeping aside of the problem of commensurability by the affirmation of *universal commensurability*. In particular, given any pair of lines, they took it for granted that it is possible to choose a unit of length sufficiently small so as to enable the proportion of the lengths of the lines to be presented as a numerical ratio.

It must then have come as a great shock to the Pythagoreans to find, as they did, that universal commensurability *cannot be upheld*. This followed upon the shattering discovery, probably made by the later Pythagoreans before 410 B.C., that ratios of whole numbers do not suffice to enable the diagonal of a square or a pentagon to be compared in length with its side. They showed that these line segments are *incommensurable*, that is, it is not possible to choose a unit of length sufficiently small so as to enable both lines to be measured by an integral number of the chosen units. Pythagorean philosophy was dealt a devastating blow by this discovery. Their geometry, too, was affected, since the demonstrations of certain basic propositions employed the principle of universal commensurability.

The discovery of incommensurability (which can be seen as an early instance of a failure to reduce the continuous to the discrete) had made it impossible for

proportions between continuous magnitudes to be generally representable as numerical proportions. The response was to detach the general concept of proportion from the idea of numerical proportion and provide it with an axiomatic development independent both of numerical proportion and of commensurability. This is the theory presented in Book V of Euclid's *Elements.* The commentator Proclus attributes the general theory of proportion to Eudoxus of Cnidus (c.400–350 B.C.E.)

In Eudoxus's theory, we are given a collection of *similar magnitudes,* e.g., line segments, or planes, or volumes, or angles, etc., which can be compared in size, together with the notion of *ratio* of similar magnitudes satisfying certain *postulates,* of which the following, expressed in modern terms, are the most important:

P_1. Given any two similar magnitudes, there is an integral multiple of the one which exceeds the other.

This postulate, which is also known as *Archimedes' principle*, has the effect of excluding infinitely small or infinitely large quantities.

The second postulate is in effect a *definition of equality* for ratios:

P_2. The ratio *A:B* of two magnitudes *A, B* is equal to the ratio *C:D* of two other magnitudes *C, D* if and only if for any natural numbers *m, n, mA* is greater than, equal to, or less than *nB* according as *mC* is greater than, equal to, or less than *nD.*

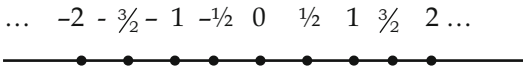
This postulate covers both the cases when A and B are commensurable, and when they are incommensurable. In the former case, numbers p, q can be found to satisfy $pA = qB$. It follows that $pC = qD$ and it is then easily shown that the remaining conditions of the definition are satisfied. In this case equality between the ratios $A{:}B$ and $C{:}D$ is established in a finite number of steps, so the ratios are numerical, and correspond to *rational numbers*.

In the case of *incommensurable* A and B, the content of **P_2** has been interpreted by historians of mathematics as an anticipation of the concept of *irrational number*, and so, by extension, of the general concept of *real number.* There is indeed a strikingly close relationship (Fine 1917) between the idea of the ratio of two incommensurables suggested in **P_2** and that of an irrational number as defined by Dedekind in the nineteenth century (discussed in the next section). The key element in **P_2** is the fact that when A and B are incommensurable the definition of the ratio $A : B$ demands comparing mA and nB for *all* pairs (m, n) of all natural numbers m and $n,$ and thus, implicitly at least, the assembling of these pairs into two separate classes, the class $\{(m, n)\colon mA > nB\}$ and the class $\{(m, n)\colon mA < nB\}$. This separation of pairs of numbers into two classes is, remarkably, identical with the Dedekind cut defining the irrational number which expresses the ratio $A : B$. It follows that the collection of ratios, commensurable and incommensurable, as defined in Euclid Book V, is actually a *subset* of the set $\mathbb{R}$ of real numbers as defined by Dedekind. For this subset to be identifiable with the whole of $\mathbb{R}$ it is necessary to postulate, as Dedekind (and Cantor) did, the existence of a one-to-one correspondence between real numbers and points on a line. This amounts, in the present case, to the assertion that for every Dedekind cut there exists a pair of magnitudes A and B which will yield this cut in the manner just described.

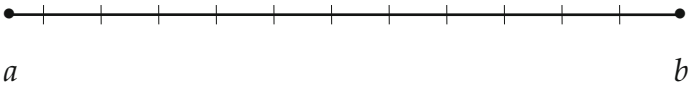
This is not, of course, to claim that Eudoxus or Euclid had literally "anticipated" Dedekiind's definition of irrational or real number. As already observed, they would have rejected the very idea that a numerical ratio could be identified as an actual number. They avoid the fraction and the irrational by basing the theory of proportion upon the equality of ratios instead of ratio itself. Nevertheless, there is no question that the basis of Dedekind's sound definition of the concept of real number millennia later was implicit in notions familiar to Eudoxus and Euclid.

Had incommensurability never been discovered, there would have been no necessity to extend the number system beyond the rational numbers.

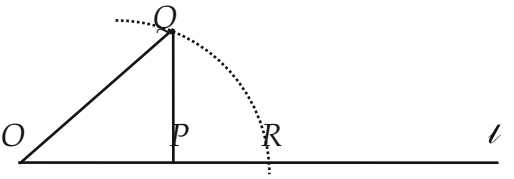
It was only very much later that fractions (along with negative numbers and 0, which, together with the natural numbers, constitute the *integers*) came to be regarded as genuine numbers. This essentially came about in the sixteenth and seventeenth centuries through an expansion of the Greek concept of number as discrete collections of units to numbers conceived as measuring arbitrary quantities such as geometric magnitudes. Numbers came to be associated with *points on a (continuous) line.* In particular the positive rationals (i.e., those of the form m/n with m and n positive integers) appear to the right of the origin 0 and the negative rationals (i.e., those of the form p/q with p negative and q positive) to the left of 0.



Regarding the rationals as points on a line enables the line to be divided as finely as one pleases. For example, to represent all rationals of the form $m/10^9$ as points on the line, we divide the interval (0, 1) of the line between 0 and 1 into a billion equal pieces; similarly for all other intervals (1, 2), (2, 3),. . . and the points of subdivision then correspond to fractions of the form $m/10^9$. Since the denominator of these fractions can be made arbitrarily large, 10^{10}, 10^{100}, or whatever, thereby producing subdivisions of unlimited fineness, it would be natural to suppose that in this way one would capture as points of subdivision *all* the points on the line – in other words, that every point is represented by a *rational* number. Now it is certainly true that rational numbers suffice for all practical purposes of measuring; indeed, the Pythagorean doctrine of universal commensurability essentially elevated this practical fact to a general principle. Moreover, the rational points are *dense* on the line in the sense that they may be found in any interval (a, b), however small, with rational endpoints $a < b$ – we have only to observe that the rational number $(a + b)/2$ lies between a and b. It may be inferred from this fact that each such interval contains *infinitely* many rational points. For if the interval (a, b) contained only finitely many, n say, then we could mark them off as shown below and then any interval between two adjacent points would be free of rational points, contradicting what we have already established.



All this would seem to lend support to the idea that every point on the line is represented by a rational number. But, of course, the Pythagorean discovery of the incommensurability of the side and diagonal of a square shows that this idea is incorrect. If we take two perpendicular lines *OP* and *PQ* of length 1 and use compasses to mark out on the line ℓ a line *OR* of the same length as *OQ* then the incommensurability of *OP* and *OQ*, and hence also *OR,* just means that *R* is not a rational point. In fact, if we designate



the "number" associated with the point *R,* then we have, by the Pythagorean theorem, $r^2 = 1^2 + 1^2 = 2$, so that, replacing *r* by the customary symbol $\sqrt{2}$, we conclude that *no rational number is equal to* $\sqrt{2}$ or that $\sqrt{2}$ is *irrational.* Here the term "irrational" is to be understood in the sense of "that which cannot be expressed as a ratio" as opposed to its more usual (but related) meaning "contrary to reason."

The fact that not every point on the line corresponds to a rational number means that, if the correspondence between points on a continuous line and "numbers" is to be maintained, the system of rational numbers has to be *enlarged still further.* It was essentially this observation, first made by the Dutch mathematician Simon Stevin (1548–1620), that led to the development of the system of *real numbers.* In his *L'Arithmétique* of 1585 Stevin explicitly introduces the idea of extending the discrete arithmetic of the Greeks to a continuous arithmetic. Stevin thinks of numbers as measures, and measures of continuous magnitudes are by their very nature continuous:

> *as well as to continuous water corresponds a continuous wetness*, *so to a continuous magnitude corresponds a continuous number.*

The term "continuous number" would accordingly have been more apposite than the term "real number." But history decreeds otherwise. The term "real number" was introduced in the seventeenth century by Descartes to distinguish them from what had come to be termed "imaginary" numbers – that is, square roots of negative numbers (such as $i = \sqrt{-1}$) arising formally as roots to algebraic equations. These latter were regarded as fictitious, the mere product of imagination. In this respect the term "imaginary" is to be contrasted with the term "irrational."

Stevin's most important innovation was the *decimal representation of real numbers,* which appears (although not of course in modern notation) in his 1585 work *De Thiende* ("the art of tenths"). This still today provides the most familiar way of presenting the continuum arithmetically.

In a major departure from the rational numbers which are given simply by pairs of integers, under the decimal representation each real number takes the form of an *infinite* sequence of integers

$$m.n_0\,n_1\,n_2\ldots.$$

A real number presented in this way is then a rational number precisely when it is *periodic,* i.e., displays a repeating pattern indefinitely after a certain stage. For example,

$$6\,{}^{5}\!/_{8} = 6.6250000\ldots \qquad {}^{3}\!/_{7} = 0.428571\,428571\ldots.$$

It follows that just a *finite* amount of information is needed to represent a rational number as a decimal fraction.

Any *nonperiodic* decimal must then represent an *irrational* number; it is easy to furnish examples of these, for instance, the following decimal containing an increasing number of zeros:

$$0.1010010001000010000001\ldots.$$

Surprisingly, perhaps, no simple rule of this kind exists for constructing the decimal representation of familiar irrational numbers such as $\sqrt{2}$.

The system of *real numbers* can be formally defined to be the set of all finite or infinite (positive or negative) decimals: considered geometrically the real numbers constitute the *geometric continuum* or *real line.* The operations of addition and multiplication can be naturally extended to the real numbers so that, like the rational numbers, they constitute a *field,* which we shall denote by the symbol $\mathbb{R}$. Thus the real numbers resemble the rational numbers insofar as they are subject to the same operational laws. On the other hand, if we regard the integers as the basic ingredients from which the other numbers are constructed, then, as pointed out above, while each rational number can be defined in terms of just two integers, in general a real number requires *infinitely many* integers to define it. The fact that infinite processes play an essential role in the construction of the real numbers places them in sharp contrast with the rationals.

The definition of real numbers as infinite decimals is not entirely satisfactory since, for one thing, there is no compelling mathematical reason to choose the number 10 as a base for them. Moreover, the real numbers are supposed to correspond exactly to points on a line; but how do we know that every such point corresponds to a real number thus defined as a decimal? To establish this it is necessary to show that there are no "gaps" in our set of real numbers, and to define with precision what is to be understood by this assertion. This was carried out in the latter half of the nineteenth century and resulted in the modern theory of real numbers.

The Vexed Issue of Infinitesimals. Closely associated with the concept of an infinitely divisible continuum is that of an *infinitesimal.* According to the *Oxford English Dictionary* the term *infinitesimal* was originally

> *an ordinal, viz. the "infinitieth" in order; but, like other ordinals, also used to name fractions, thus infinitesimal part or infinitesimal came to mean unity divided by infinity* $\left(\frac{1}{\infty}\right)$*, and thus an infinitely small part or quantity.*

An *infinitesimal magnitude* has been, traditionally, somewhat hazily conceived as a continuum "viewed in the small," an "ultimate part" of a continuum. In something like the same sense as a discrete entity is made up of its individual units, its "indivisibles," so, it was maintained, a continuum is "composed" of infinitesimal magnitudes, its ultimate parts. (It is in this sense, for example, that mathematicians of the seventeenth century held that continuous curves are "composed" of infinitesimal straight lines.) Now the "coherence" of a continuum entails that each of its (connected) parts is also a continuum, and, accordingly, divisible. Since individual points are indivisible, it follows that no point can be part of a continuum. Points are, in fact, just *locations* in a continuum. Infinitesimal magnitudes, as parts of continua, cannot, of necessity, be points; they are, in a word, *nonpunctiform.*

Magnitudes are normally taken as being *extensive* quantities, like mass or volume, which are defined over extended regions of space. By contrast, infinitesimal magnitudes have been conceived as *intensive* magnitudes resembling locally defined intensive quantities such as temperature or density. The effect of "distributing" or "integrating" an intensive quantity over an infinitesimal magnitude is to convert the former into an infinitesimal extensive quantity; thus temperature is transformed into infinitesimal heat and density into infinitesimal mass. When the continuum is the trace of a motion, the associated infinitesimal/intensive magnitudes have been identified as *potential* magnitudes – entities which, while not possessing true magnitude themselves, embody a *tendency* to generate magnitude through motion, so manifesting "becoming" as opposed to "being."

An infinitesimal *number* has been conceived as a number so small that, while not coinciding with zero, is in some sense smaller than any finite positive number. An infinitesimal number is, so to speak, "greater than nothing but less than anything" (Pyle 1997, p. 208). An infinitesimal number has been construed as a "number' which fails to satisfy *Archimedes' Principle*, that is, as a nonzero "number" a such that, for any integer n, $n.a$ is less than any finite nonzero number. We have already pointed out that Eudoxus and Euclid explicitly exclude the existence of such "numbers."

The concept of infinitesimal was beset by controversy from its beginnings. The idea makes an early appearance in the mathematics of the Greek atomist philosopher Democritus c. 450 B.C., only to be banished c. 350 B.C. by Eudoxus in what was to become official "Euclidean" mathematics. Taking the form of "indivisibles," infinitesimals resurfaced in the sixteenth and seventeenth centuries and were systematically employed by Kepler, Galileo's student Cavalieri, the Bernoulli clan, and a number of other mathematicians. In the guise of the delightfully named "linelets" and "timelets," infinitesimals played an essential role in Barrow's "method for finding tangents by calculation," which appears in his *Lectiones Geometricae* of 1670. As "evanescent quantities" infinitesimals were instrumental (although later abandoned) in Newton's development of the calculus, and, as "inassignable quantities," in Leibniz's. The Marquis de l'Hôpital, who in 1696 published the first treatise on the differential calculus (entitled *Analyse des Infiniments Petits pour l'Intelligence des Lignes Courbes*), invokes the concept in postulating that "a curved line may be regarded as being made up of infinitely small straight line segments,"

and that "one can take as equal two quantities differing by an infinitely small quantity."

However useful infinitesimals may have been in practice, they could scarcely withstand logical scrutiny. Derided by Berkeley in the eighteenth century as "ghosts of departed quantities," in the nineteenth century execrated by Cantor as "cholera-bacilli" infecting mathematics, and in the twentieth roundly condemned by Bertrand Russell as "unnecessary, erroneous, and self-contradictory," the use of infinitesimals in the calculus and mathematical analysis was believed to have been finally supplanted by the limit concept which took rigorous and final form in the latter half of the nineteenth century. By the beginning of the twentieth century, the concept of infinitesimal had become, in analysis at least, essentially an "unconcept."

Nevertheless, the proscription of infinitesimals did not succeed in extirpating them; they were, rather, driven further underground. Physicists and engineers, for example, never abandoned their use as a heuristic device for the derivation of correct results in the application of the calculus to physical problems. Differential geometers of the stature of Lie and Cartan relied on their use in the formulation of concepts which would later be put on a "rigorous" footing. Even in mathematical analysis they survived in Du Bois-Reymond's "orders of infinity," and, in a mathematically rigorous sense, they lived on in the algebraists' investigations of nonarchimedean fields.

A new phase in the saga of infinitesimals has opened in the past few decades with the refounding on a solid basis of the concept of the infinitesimal in analysis and differential geometry. This has been achieved in two essentially different ways, *Nonstandard Analysis* and *Smooth Infinitesimal Analysis.* These will be discussed in the concluding sections of this survey.

2 The Cantor-Dedekind Theory of Real Numbers and the Arithmetization of the Continuum

By the beginning of the nineteenth century the conception of real numbers as corresponding to points on a line, and so forming a continuum, was firmly established in mathematical practice. But solid definitions of the concept of continuum, and indeed the concept of real number itself, were lacking. Mathematical arguments involving real numbers frequently made appeal to geometric – even spatiotemporal – intuition and the intuitive idea of continuity. (Respectability on the use of spatiotemporal intuition in mathematical arguments had been conferred by the central role such intuition played in Kant's philosophy of mathematics. Kant had claimed that arithmetic and geometry were grounded in the intuition of time and space, respectively. The influence of Kant's philosophy on mathematicians waned after the emergence of non-Euclidean of geometry early on in the nineteenth century.) In addition, the concept of infinitesimal, which had played such an important role in the development of the calculus over the previous two centuries, but whose logical foundations were worryingly shaky, had begun to come under scrutiny.

Cauchy, Bolzano, and Hamilton had all attempted to clarify the concepts of real number, but it was **Karl Weierstrass** (1815–97) who made the first systematic attack on the problem. He was determined to expel spatiotemporal intuition, and the infinitesimal, from the foundations of analysis. To instill complete logical rigor Weierstrass proposed to establish mathematical analysis on the basis of natural number alone – to "arithmetize" it. According to Hobson (1957, p. 22), "the term 'arithmetization' is used to denote the movement which has resulted in placing analysis on a basis free from the idea of measurable quantity, the fractional, negative, and irrational numbers being so defined that they depend ultimately upon the conception of integral number."

In pursuit of this goal Weierstrass had first to formulate a rigorous "arithmetical" definition of real number. He did this by defining a (positive) real number to be a countable set of positive rational numbers for which the sum of any finite subset always remains below some preassigned bound, and then specifying the conditions under which two such "real numbers" are to be considered equal, or strictly less than, one another.

Weierstrass was also concerned to make precise the concept of *continuous function.* The concept of function had by this time been greatly broadened: in 1837 Dirichlet suggested that a variable y should be regarded as a function of the independent variable x if a rule exists according to which, whenever a numerical value of x is given, a unique value of y is determined. (This idea was later to evolve into the set-theoretic definition of function as a set of ordered pairs.) Dirichlet's definition of function as a correspondence, from which all traces of continuity had been purged, made necessary Weierstrass's independent definition of continuous function.

Weierstrass formulated the familiar (ε, δ) definition of continuous function: a function $f(x)$ is continuous at a if for any $\varepsilon > 0$ there is $\delta > 0$ such that $|f(x) - f(a)| < \varepsilon$ for all x with $|x - a| < \delta$. He also proved his famous *approximation theorem for continuous functions:* any continuous function defined on a closed interval of real numbers can be uniformly approximated to by a sequence of polynomials.

The notion of *uniform continuity* for functions was later introduced (in 1870) by Heine: a real valued function f is uniformly continuous if for any $\varepsilon > 0$ there is $\delta > 0$ such that $|f(x) - f(y)| < \varepsilon$ for all x and y in the domain of f with $|x - y| < \delta$. In 1872 Heine proved the important theorem that any continuous real-valued function defined on a closed bounded interval of real numbers is uniformly continuous.

Following Weierstrass's efforts, another attack on the problem of formulating rigorous definitions of continuity and the real numbers was mounted by **Richard Dedekind** (1831–1916). We learn from the introductory remarks to *Continuity and Irrational Numbers* (1872) that Dedekind was inspired to embark on his investigations by his belief that, in presenting the differential calculus, "geometric intuition," while "exceedingly useful from a didactic standpoint," can "make no claim to being scientific." Accordingly he made "the fixed resolve to keep meditating on the question till I should find a purely arithmetic and perfectly rigorous foundation for the principles of infinitesimal analysis." He went on to observe

> *The statement is so frequently made that that the differential calculus deals with continuous magnitude, and yet an explanation of this continuity is nowhere given; even the most rigorous expositions of the differential calculus do not base their proofs upon continuity but, with more or less consciousness of the fact, they either appeal to geometric notions or those suggested by geometry, or upon theorems which are never established in a purely arithmetic manner.*

Dedekind considered the concept of number in general to be a part of *logic,* and not, as Kant had claimed, dependent on spatiotemporal intuition. In the Preface to his later book "*The Nature and Meaning of Numbers*" (*1888*) *he says*

> *In speaking of arithmetic (algebra, analysis) as a part of logic I mean to imply that I consider the number-concept entirely independent of the notions or intuitions of space and time, that I consider it an immediate result from the laws of thought.*

In his investigations of continuity Dedekind focused attention on the question: exactly what is it that distinguishes a continuous domain from a discontinuous one? He seems to have been the first to recognize that the property of density, possessed by the ordered set of rational numbers, is insufficient to guarantee continuity. In *Continuity and Irrational Numbers* he remarks that when the rational numbers are associated to points on a straight line, "there are infinitely many points [on the line] to which no rational number corresponds" (Ewald 1999, p. 770 *et seq*.), so that the rational numbers manifest "a gappiness, incompleteness, discontinuity," in contrast with the straight line's "absence of gaps, completeness, continuity." He goes on:

> *In what then does this continuity consist? Everything must depend on the answer to this question, and only through it shall we obtain a scientific basis for the investigations of all continuous domains. By vague remarks upon the unbroken connection in the smallest parts obviously nothing is gained; the problem is to indicate a precise characteristic of continuity that can serve as the basis for valid deductions. For a long time I pondered over this in vain, but finally I found what I was seeking. This discovery will, perhaps, be differently estimated by different people; but I believe the majority will find its content quite trivial. It consists of the following. In the preceding Section attention was called to the fact that every point p of the straight line produces a separation of the same into two portions such that every point of one portion lies to the left of every point of the other. I find the essence of continuity in the converse, i.e., in the following principle:*
>
> *'If all points of the straight line fall into two classes such that every point of the first class lies to the left of every point of the second class, then there exists one and only one point which produces this division of all points into two classes, this severing of the straight line into two portions.'*

Dedekind regards this principle as being essentially indemonstrable; he ascribes to it, rather, the status of an axiom "by which we attribute to the line its continuity, by which we think continuity into the line." It is not, Dedekind stresses, necessary for *space* to be continuous in this sense, for "many of its properties would remain the same even if it were discontinuous." And in any case, he continues,

> *if we knew for certain that space were discontinuous there would be nothing to prevent us . . . from filling up its gaps in thought and thus making it continuous; this filling up would consist in a creation of new point-individuals and would have to be carried out in accordance with the above principle.*

The filling-up of gaps in the rational numbers through the "creation of new point-individuals" is the key idea underlying Dedekind's construction of the domain of real numbers. He first defines a *cut* to be a partition (A_1, A_2) of the rational numbers such that every member of A_1 is less than every member of A_2. After noting that each rational number corresponds, in an evident way, to a cut, he observes that infinitely many cuts fail to be engendered by rational numbers. The discontinuity or incompleteness of the domain of rational numbers consists precisely in this latter fact. That being the case, he continues,

> *whenever we have a cut (A_1, A_2) produced by no rational number, we create a new number, an irrational number α, which we regard as completely defined by this cut (A_1, A_2); we shall say that the number α corresponds to this cut, or that it produces this cut. From now on, therefore, to every definite cut there corresponds a definite rational or irrational number, and we regard two numbers as different or unequal if and only if they correspond to essentially different cuts.*

It is to be noted that Dedekind does not identify irrational numbers with cuts; rather, each irrational number is newly "created" by a mental act and remains quite distinct from its associated cut.

Dedekind goes on to show how the domain of cuts, and thereby the associated domain of real numbers, can be ordered in such a way as to possess the property of *continuity*, viz.

> *if the system R of all real numbers divides into two classes A_1, A_2 such that every number a_1 of the class A_1 is less than every number a_2 of the class A_2, then there exists one and only one number α by which this separation is produced.*

Dedekind notes that this property of continuity is actually equivalent to two principles basic to the theory of limits; these he states as:

> *If a magnitude grows continually but not beyond all limits it approaches a limiting value*

and

> *if in the variation of a magnitude x we can, for every given positive magnitude δ, assign a corresponding interval within which x changes by less than δ, then x approaches a limiting value.*

Dedekind's definition of real numbers as cuts was to become an essential part of the rigorous analysis of the continuum.

The most visionary "arithmetizer" of all was **Georg Cantor** (1845–1918). Cantor's analysis of the continuum in terms of infinite point sets led to his theory of

transfinite numbers and to the eventual freeing of the concept of set from its geometric origins as a collection of points, so paving the way for the emergence of the concept of general abstract set central to today's mathematics. It is of interest to note that neither Dedekind nor Cantor took real numbers to be actual *sets*. This step was in fact first taken by Bertrand Russell in 1903 in *The Principles of Mathematics* (Russell 1964).

At about the same time that Dedekind published his researches into the nature of the continuous, Cantor formulated his theory of the real numbers. This was presented in the first section of a paper (Cantor 1872) on trigonometric series. Like Weierstrass and Dedekind, Cantor aimed to formulate an adequate definition of the irrational numbers which avoided the presupposition of their prior existence, and he follows them in basing his definition on the rational numbers. Following Cauchy, Cantor calls a sequence $a_1, a_2, \ldots, a_n, \ldots$ of rational numbers a *fundamental sequence* (nowadays called a *Cauchy sequence*) if, for any positive rational ε, there exists an integer N such that, $|a_{n+m} - a_n| < \varepsilon$ for all m and all $n > N$. Any sequence $<a_n>$ satisfying this condition is said to have a *definite limit b*. Dedekind had taken irrational numbers to be "mental objects" associated with cuts, so, analogously, Cantor regards these definite limits as nothing more than *formal symbols* associated with fundamental sequences (Dauben 1979, p. 38).

The domain B of such symbols may be considered an enlargement of the domain A of rational numbers, since each rational number r may be identified with the formal symbol associated with the fundamental sequence $r, r, \ldots, r, \ldots$. Order relations and arithmetical operations are then defined on B: for example, given three such symbols b, b', b'' associated with the fundamental sequences $<a_n>$, $<a'_n>$, $<a''_n>$, the inequality $b < b'$ is taken to signify that, for some $\varepsilon > 0$ and N, $a_n - a'_n > \varepsilon$ for all $n > N$, while the equality $b + b' = b''$ is taken to express the relation $\lim (a_n + a'_n - a''_n) = 0$.

Having imposed an arithmetical structure on the domain B, Cantor is emboldened to refer to its elements as (real) *numbers*. Nevertheless, he still insists that these "numbers" have no existence except as representatives of fundamental sequences: in his theory,

> *the numbers* (*above all lacking general objectivity in themselves*) *appear only as components of theorems which have objectivity, for example, the theorem that the corresponding sequence has the number as limit*. (Dauben 1979, p. 39).

Cantor next considers how real numbers are to be associated with points on the linear continuum. If a given point on the line lies at a distance from the origin O bearing a rational relation to the point at unit distance from that origin, then it can be represented by an element of A. Otherwise, it can be approached by a sequence $a_1, a_2, \ldots a_n, \ldots$ of points each of which corresponds to an element of A. Moreover, the sequence $<a_n>$ can be taken to be a fundamental sequence; Cantor writes:

> *The distance of the point to be determined from the point O* (*the origin*) *is equal to b*, *where b is the number corresponding to the sequence* (Dauben 1979, p. 40).

In this way Cantor shows that each point on the line corresponds to a definite element of *B*. Conversely, each element of *B* should determine a definite point on the line. Realizing that the intuitive nature of the linear continuum precludes a rigorous proof of this property, Cantor simply assumes it as an axiom, just as Dedekind had done in regard to his principle of continuity:

> *Also conversely, to every number there corresponds a definite point of the line, whose coordinate is equal to that number* (Dauben 1979, p. 40).

For Cantor, who began as a number-theorist, and throughout his career cleaved to the discrete, it was numbers, rather than geometric points, that possessed objective significance. Indeed, the isomorphism between the discrete numerical domain *B* and the linear continuum was regarded by Cantor essentially as a device for facilitating the manipulation of numbers.

Cantor and Dedekind had offered different ways of "constructing" the arithmetical continuum of real numbers: the former, using Cauchy sequences of rational numbers, the latter, "cuts" in the rationals. Since each claimed that his system of real numbers corresponded exactly to the points on a geometric line, it would seem to follow that Cantor's and Dedekind's systems of real numbers were essentially "the same," i.e., isomorphic. However, neither provided an explicit proof of this assertion. That the two systems are indeed isomorphic later came to be rigorously proved by showing that they are both *complete ordered fields* and that any two complete ordered fields are isomorphic. An *ordered field* is an algebraic field on which a linear ordering is defined which is compatible with the algebraic operations. *Completeness* is the condition that any bounded subset has a greatest lower bound and a least upper bound (McShane and Botts 1959, Ch. 1). It can be shown that every complete ordered field has the *Archimedean property:* for any $a, b > 0$, there is a natural number n such that $na > b$. This is essentially the condition $\mathbf{P_1}$ laid down in Eudoxus' theory of proportions.

Cantor's arithmetization of the continuum had another important consequence. It had long been recognized that the sets of points of any pair of line segments, even if one of them is infinite in length, can be placed in one-one correspondence. This fact was taken to show that such sets of points have no well-defined "size." But Cantor's identification of the set of points on a linear continuum with a domain of numbers enabled the *sizes* of point sets to be compared in a definite way, using the well-grounded idea of *one-one correspondence between sets of numbers*. Thus, in a letter to Dedekind written in November 1873 Cantor notes that the totality of natural numbers can be put into one-one correspondence with the totality of positive rational numbers, and, more generally, with the totality of finite sequences of natural numbers. It follows that these totalities have the same "size"; they are all *denumerable.* Cantor next raises the question of whether the natural numbers can be placed in one-one correspondence with the totality of all positive *real* numbers (Ewald 1999, p. 844).

He quickly answers his own question in the negative. In letters to Dedekind written during December 1873 Cantor shows that, for any sequence of real numbers, one can define numbers in every interval that are not in the sequence. It follows in

particular that the whole set of real numbers is nondenumerable. Another important consequence concerns the existence of *transcendental numbers*, that is, numbers which are not algebraic in the sense of being the root of an algebraic equation with rational coefficients. In 1844 Liouville had established the transcendentality of any number of the form

$$\frac{a_1}{10} + \frac{a_2}{10^{2!}} + \frac{a_3}{10^{3!}} + \cdots$$

where the a_i are arbitrary integers from 0 to 9 (Kline 1972, p. 981).

In his reply to Cantor's letter of November 1873, Dedekind had observed that the set of algebraic numbers is denumerable; it followed from the nondenumerability of the real numbers that *there must be many transcendental numbers* (in fact nondenumerably many, although Cantor did not make this fact explicit until sometime later).

By this time Cantor had come to regard nondenumerability as a necessary condition for the continuity of a point set, for in a paper of 1874 he asserts:

> *Moreover, the theorem. . .represents the reason why aggregates of real numbers which constitute a so-called continuum (say the totality of real numbers which are* > 0 *and* ≤ 1*), cannot be uniquely correlated with the aggregate (v); thus I found the clear difference between a so-called continuum and an aggregate like the entirety of all real algebraic numbers* (Dauben 1979, p. 53).

Cantor next became concerned with the question of whether the points of spaces of different dimensions – for instance a line and a plane – can be put into one-one correspondence. In a letter to Dedekind of January 1874 he remarks:

> *It still seems to me at the moment that the answer to this question is very difficult – although here too one is so impelled to say no that one would like to hold the proof to be almost superfluous* (Ewald 1999, p. 850).

Nevertheless, 3 years later Cantor, in a dramatic *volte-face*, established the existence of such correspondences between spaces of different dimensions. He showed, in fact, that (the points of) a space of any dimension whatsoever can be put into one-one correspondence with (the points of) a line. This result so startled him that, in a letter to Dedekind of June 1877 he was moved to exclaim: *Je le vois, mais je ne le crois pas* ("I see it, but I don't believe it." (Ewald 1999, p. 860).

Cantor's discovery caused him to question the adequacy of the customary definition of the dimension of a continuum. For it had always been assumed that the determination of a point in an n-dimensional continuous manifold requires *n* independent coordinates, but now Cantor had shown that, in principle at least, the job could be done with just a *single* coordinate. For Cantor this fact was sufficient to justify the claim that

> *. . . all philosophical or mathematical deductions that use that erroneous presupposition are inadmissible. Rather the difference that obtains between structures of different dimensionnumber must be sought in quite other terms than in the number of independent coordinates – the number that was hitherto held to be characteristic* (Ewald 1999, p. 860).

In his reply to Cantor, Dedekind conceded the correctness of Cantor's result, but balked at Cantor's radical inferences therefrom. Dedekind maintained that the dimension-number of a continuous manifold was its "first and most important invariant" and emphasized the issue of continuity:

> *For all authors have clearly made the tacit, completely natural presupposition that in a new determination of the points of a continuous manifold by new coordinates, these coordinates should also (in general) be continuous functions of the old coordinates, so that whatever appears as continuously connected under the first set of coordinates remains continuously connected under the second* (Ewald 1999, p. 863).

Dedekind also noted the extreme discontinuity of the correspondence Cantor had set up between higher dimensional spaces and the line:

> *. . . it seems to me that in your present proof the initial correspondence between the points of the ρ-interval (whose coordinates are all irrational) and the points of the unit interval (also with irrational coordinates) is, in a certain sense (smallness of the alteration), as continuous as possible; but to fill up the gaps, you are compelled to admit, a frightful, dizzying discontinuity in the correspondence, which dissolves everything to atoms, so that every continuously connected part of the one domain appears in its image as thoroughly decomposed and discontinuous* (Ewald 1999, pp. 863–4).

Dedekind avows his belief that no one-one correspondence between spaces of different dimensions can be continuous:

> *If it is possible to establish a reciprocal, one-to-one, and complete correspondence between the points of a continuous manifold A of a dimensions and the points of a continuous manifold B of b dimensions, then this correspondence itself, if a and b are unequal, is necessarily utterly discontinuous* (Ewald 1999, p. 863).

In his reply to Dedekind of July 1877 Cantor clarifies his remarks concerning the dimension of a continuous manifold:

> *. . .I unintentionally gave the appearance of wishing by my proof to oppose altogether the concept of a ρ-fold extended continuous manifold, whereas all my efforts have rather been intended to clarify it and to put it on the correct footing. When I said: "Now it seems to me that all philosophical and mathematical deductions which use that erroneous presupposition –" I meant by this presupposition not "the determinateness of the dimension-number" but rather the determinates of the independent coordinates, whose number is assumed by certain authors to be in all circumstances equal to the number of dimensions. But if one takes the concept of coordinate generally, with no presuppositions about the nature of the intermediate functions, then the number of independent, one-to-one, complete coordinates, as I showed, can be set to any number* (Ewald 1999, p. 863).

Nevertheless he agrees with Dedekind that if "we require that the correspondence be continuous, then only structures with the same number of dimensions can be related to each other one-to-one." (Ewald 1999, p. 863). In that case, an invariant *can* be found in the number of independent coordinates, "which ought to lead to a definition of the dimension-number of a continuous structure" (Ewald 1999, p. 863).

The problem is to correlate that dimension-number, a perfectly definite mathematical object, with something as elusive as an arbitrary continuous correspondence. Cantor writes:

> *However, I do not yet know how difficult this path (to the concept of dimension-number) will prove, because I do not know whether one is able to limit the concept of continuous correspondence in general. But everything in this direction seems to me to depend on the possibility of such a limiting.*
>
> *I believe I see a further difficulty in the fact that this path will probably fail if the structure ceases to be thoroughly continuous; but even in this case one wants to have something corresponding to the dimension-number – all the more so, given how difficult it is to prove that the manifolds that occur in nature are thoroughly continuous* (Ewald 1999, p. 863).

In rendering the continuous discrete, and thereby admitting *arbitrary* correspondences "of [a] frightful, dizzying discontinuity" between geometric objects "dissolved to atoms," Cantor grasps at the same time that he has rendered the intuitive concept of spatial dimension a hostage to fortune.

In 1878 Cantor published a fuller account of his ideas (Cantor 1878). Here he explicitly introduces the concept of the *power (Mächtigkeit)* of a set of points: two sets are said to be of equal power if there exists a one-one correspondence between them. Cantor presents demonstrations of the denumerability of the rationals and the algebraic numbers, remarking that "the sequence of positive whole numbers constitutes. . .the least of all powers which occur among infinite aggregates." (Dauben 1979, p. 59).

The central theme of Cantor's 1878 paper is the study of the powers of continuous n-dimensional spaces. He raises the issue of invariance of dimension and its connection with continuity:

> *Apart from making the assumption, most are silent about how it follows from the course of this research that the correspondence between the elements of the space and the system of values $x_1, x_2, \ldots, x_n$ is a continuous one, so that any infinitely small change of the system $x_1, x_2, \ldots, x_n$ corresponds to an infinitely small change of the corresponding element, and conversely, to every infinitely small change of the element a similar change in the coordinates corresponds. It may be left undecided whether these assumptions are to be considered as sufficient, or whether they are to be extended by more specialized conditions in order to consider the intended conceptual construction of n-dimensional continuous spaces as one ensured against any contradictions, sound in itself* (Dauben 1979, p. 60).

The remarkable result obtained when one no longer insists on continuity in the correspondence between the spatial elements and the system of coordinates is described by Cantor in the following terms:

> *As our research will show, it is even possible to determine uniquely and completely the elements of an n-dimensional continuous space by a single real coordinate t. If no assumptions are made about the kind of correspondence, it then follows that the number of independent, continuous, real coordinates which are used for the unique and complete determination of the elements of an n-dimensional continuous space can be brought to*

any arbitrary number, and thus is not to be regarded as a unique feature of the space (Dauben 1979, p. 60).

Cantor shows how this result can be deduced from the existence of a one-one correspondence between the set of reals and the set of irrationals, and then, by means of an involved argument, constructs such a correspondence.

Cantor seems to have become convinced by this time that the essential nature of a continuum was fully reflected in the properties of sets of points – a conviction which was later to give birth to abstract set theory. In particular a continuum's key properties, Cantor believed, resided in the range of powers of its subsets of points. Since the power of a continuum of any number of dimensions is the same as that of a linear continuum, the essential properties of arbitrary continua were thereby reduced to those of a line. In his investigations of the linear continuum Cantor had found its infinite subsets to possess just two powers, that of the natural numbers and that of the linear continuum itself. This led him to the conviction that these were the only possible powers of such subsets – a thesis later to be enunciated as the *continuum hypothesis*. The question of the truth or falsity of the continuum hypothesis was to become one of the most celebrated problems of set theory. In the twentieth century its independence of the axioms of set theory was established by Kurt Gödel and Paul Cohen.

The problem of establishing the invariance of dimension of spaces under continuous correspondences remained a pressing issue. Soon after the publication of Cantor's 1878 paper, a number of mathematicians, for example, Lüroth, Thomae, Jürgens, and Netto attempted proofs, but all of these suffered from shortcomings which did not escape notice (Dauben 1979, pp. 70–72). In 1879 Cantor himself published a proof which seems to have passed muster at the time, but which also contained flaws that were not detected for another 20 years (Dauben 1979, pp. 72–76).

Satisfied that he had resolved the question of invariance of dimension, Cantor returned to his investigation of the properties of subsets of the linear continuum. The results of his labors are presented in six masterly papers published during 1879–84, *Über unendliche lineare Punktmannigfaltigkeiten* ("On infinite, linear point manifolds"). Remarkable in their richness of ideas, these papers contain the first accounts of Cantor's revolutionary theory of infinite sets and its application to the classification of subsets of the linear continuum. In the third and fifth of these are to be found Cantor's observations on the nature of the continuum.

In the third article, that of 1882, which is concerned with multidimensional spaces, Cantor applies his result on the nondenumerability of the continuum to prove the startling result that continuous motion is possible in discontinuous spaces. To be precise, he shows that, if M is any countable dense subset of the Euclidean plane R^2, (for example, the set of points with both coordinates algebraic real numbers), then any pair of points of the discontinuous space $\mathrm{A} = \mathrm{R}^2 - M$ can be joined by a continuous arc lying entirely within A. In fact, Cantor claims even more:

After all, with the same resources, it would be possible to connect the points…by a continuously running line given by a unique analytic rule and completely contained within the domain A.

(Spaces like A are today called *arcwise connected*.) Cantor points out that the belief in the continuity of space is traditionally based on the evidence of continuous motion, but now it has been shown that continuous motion is possible even in discontinuous spaces. That being the case, the presumed continuity of space is no more than a hypothesis. Indeed, it cannot necessarily be assumed that physical space contains every point given by three real number coordinates. This assumption, he urges,

> *. . .must be regarded as a free act of our constructive mental activity. The hypothesis of the continuity of space is therefore nothing but the assumption, arbitrary in itself, of the complete, one-to-one correspondence between the 3-dimensional purely arithmetic continuum* (*x, y, z*) *and the space underlying the world of phenomena* (Dauben 1979, pp. 72–76).

These facts, so much at variance with received views, confirmed for Cantor once again that geometric intuition was a poor guide to the understanding of the continuum. For such understanding to be attained reliance must instead be placed on arithmetical analysis.

In the fifth paper in the series, the *Grundlagen* of 1883, is to be found a forthright declaration of Cantor's philosophical principles, which leads on to an extensive discussion of the concept of the continuum. Cantor distinguishes between the *intrasubjective* or *immanent* reality and *transsubjective* or *transient* reality of concepts or ideas. The first type of reality, he says, is ascribable to a concept which may be regarded

> *as actual in so far as*, *on the basis of definitions*, *[it] is well distinguished from other parts of our thought and stand[s] to them in determinate relationships*, *and thus modifies the substance of our mind in a determinate way* (Ewald 1999, p. 895).

The second type, transient or transsubjective reality, is ascribable to a concept when it can, or must, be taken

> *as an expression or copy of the events and relationships in the external world which confronts the intellect.*

Cantor now presents the principal tenet of his philosophy, to wit, that the two sorts of reality he has identified invariably occur together,

> *in the sense that a concept designated in the first respect as existent always also possesses*, *in certain*, *even infinitely many ways*, *a transient reality.*

Cantor's thesis is tantamount to the principle that correct thinking is, in its essence, a reflection of the order of Nature (or, perhaps, vice-versa. In a footnote Cantor places his thesis in the context of the history of philosophy. He claims that "it agrees essentially both with the principles of the Platonic system and with an essential tendency of the Spinozistic system" and that it can be found also in Leibniz's philosophy. But philosophy since that time has come, in Cantor's eyes, to deviate from this cardinal principle:

> *Only since the growth of modern empiricism, sensualism, and scepticism, as well as of the Kantian criticism that grows out of them, have people believed that the source of knowledge and certainty is to be found in the senses or in the so-called pure form of intuition of the world of appearances, and that they must confine themselves to these. But in my opinion these elements do not furnish us with any secure knowledge. For this can be obtained only from concepts and ideas that are stimulated by external experience and are essentially formed by inner induction and deduction as something that, as it were, was already in us and is merely awakened and brought to consciousness.*

This linkage between the immanent and transient reality of mathematical concepts – the fact that correct mathematical thinking reflects objective reality – has, in Cantor's view, the important consequence that

> *mathematics, in the development of its ideas has only to take account of the immanent reality of its concepts and has absolutely no obligation to examine their transient reality.*

It follows that

> *mathematics in its development is entirely free and is only bound in the self-evident respect that its concepts must both be consistent with each other and also stand in exact relationships, ordered by definitions, to those concepts which have previously been introduced and are already at hand and established. In particular, in the introduction of new numbers it is only obliged to give definitions of them which will bestow such a determinacy and, in certain circumstances, such a relationship to older numbers that they can in any given instance be precisely distinguished.*

For these reasons Cantor bestows his blessing on rational, irrational, and complex numbers, which "one must regard as being every bit as existent as the finite positive integers"; even Kummer's introduction of "ideal" numbers into number theory meets with his approval. But not infinitesimal numbers, as we shall see.

Cantor begins his examination of the continuum with a tart summary of the controversies that have traditionally surrounded the notion:

> *The concept of the 'continuum' has not only played an important role everywhere in the development of the sciences but has also evoked the greatest differences of opinion and event vehement quarrels. This lies perhaps in the fact that, because the exact and complete definition of the concept has not been bequeathed to the dissentients, the underlying idea has taken on different meanings; but it must also be (and this seems to me the most probable) that the idea of the continuum had not been thought out by the Greeks (who may have been the first to conceive it) with the clarity and completeness which would have been required to exclude the possibility of different opinions among their posterity. Thus we see that Leucippus, Democritus, and Aristotle consider the continuum as a composite which consists ex partibus sine fine divisilibus, but Epicurus and Lucretius construct it out of their atoms considered as finite things. Out of this a great quarrel arose among the philosophers, of whom some followed Aristotle, others Epicurus; still others, in order to remain aloof from this quarrel, declared with Thomas Aquinas that the continuum consisted neither of infinitely many nor of a finite number of parts, but of absolutely no parts. This last opinion seems to me to contain less an explanation of the facts than a tacit confession that one has not got to the bottom of the matter and prefers to get genteely out of its way. Here we see the medieval-scholastic origin of a point of view which we still find represented today, in which the*

> *continuum is thought to be an unanalysable concept, or, as others express themselves, a pure a priori intuition which is scarcely susceptible to a determination through concepts. Every arithmetical attempt at determination of this mysterium is looked on as a forbidden encroachment and repulsed with due vigour. Timid natures thereby get the impression that with the 'continuum' it is not a matter of a mathematically logical concept but rather of religious dogma* (Ewald 1999, p. 903).

It is not Cantor's intention to "conjure up these controversial questions again." Rather, he is concerned to "develop the concept of the continuum as soberly and briefly as possible, and only with regard to the *mathematical* theory of sets." This opens the way, he believes, to the formulation of an exact concept of the continuum – nothing less than a demystification of the *mysterium.* Cantor points out that the idea of the continuum has heretofore merely been presupposed by mathematicians concerned with the analysis of continuous functions and the like and has "not been subjected to any more thorough inspection."

Cantor next repudiates any use of temporal intuition in an exact determination of the continuum:

> *. . .I must explain that in my opinion to bring in the concept of time or the intuition of time in discussing the much more fundamental and more general concept of the continuum is not the correct way to proceed; time is in my opinion a representation, and its clear explanation presupposes the concept of continuity upon which it depends and without whose assistance it cannot be conceived either objectively (as a substance) or subjectively (as the form of an a priori intuition), but is nothing other than a helping and linking concept, through which one ascertains the relation between various different motions that occur in nature and are perceived by us. Such a thing as objective or absolute time never occurs in nature, and therefore time cannot be regarded as the measure of motion; far rather motion as the measure of time – were it not that time, even in the modest role of a subjective necessary a priori form of intuition, has not been able to produce any fruitful, incontestable success, although since Kant the time for this has not been lacking.*

These strictures apply, *pari passu,* to spatial intuition:

> *It is likewise my conviction that with the so-called form of intuition of space one cannot even begin to acquire knowledge of the continuum. For only with the help of a conceptually already completed continuum do space and the structure thought into it receive that content with which they can become the object, not merely of aesthetic contemplation or philosophical cleverness or imprecise comparisons, but of sober and exact mathematical investigations.*

Cantor now embarks on the formulation of a precise arithmetical definition of a continuum. Making reference to the definition of real number he has already provided (i.e., in terms of fundamental sequences), he introduces the n-dimensional arithmetical space G_n as the set of all n-tuples of real numbers $(x_1 \, |x_2| \, \ldots \, |x_n)$, calling each such an *arithmetical point* of G_n. The distance between two such points is given by

$$\sqrt{\left(x_1' - x_1\right)^2 + \left(x_2' - x_2\right)^2 + \ldots \left(x_n' - x_n\right)^2}.$$

Cantor defines an *arithmetical* point-set in G_n to be any "aggregate of points of the points of the space G_n that is given in a lawlike way."

After remarking that he has previously shown that all spaces G_n have the same power as the set of real numbers in the interval (0, 1), and reiterating his conviction that any infinite point set has either the power of the set of natural numbers or that of (0, 1) – the continuum hypothesis – Cantor turns to the definition of the general concept of a continuum within *Gn.* For this he employs the concept of *derivative* or *derived set* of a point set introduced in his 1872 paper on trigonometric series. Cantor had defined the derived set of a point set *P* to be the set of *limit points* of *P,* where a limit point of *P* is a point of *P* with infinitely many points of *P* arbitrarily close to it. A point set is called *perfect* if it coincides with its derived set (in the terminology of general topology, a set is perfect if it is closed and has no isolated points). Cantor observes that this condition does not suffice to characterize a continuum, since perfect sets can be constructed in the linear continuum which are dense in no interval, however small: as an example of such a set he offers the set consisting of all real numbers in (0, 1) whose ternary expansion does not contain a "1." This set later became known as the *Cantor ternary set* or the *Cantor discontinuum.*

Accordingly, an additional condition is needed to define a continuum. Cantor supplies this by introducing the concept of a *connected* set. A point set *T* is connected in Cantor's sense if for any pair of its points *t, t'* and any arbitrarily small number ε there is a finite sequence of points $t_1, t_2, \ldots, t_n$ of *T* for which the distances $\overline{tt_1}, \overline{t_1t_2}, \overline{t_2t_3}, \ldots, \overline{t_nt'}$ are all less than ε. Cantor now observes:

> *all the geometric point-continua known to us fall under this concept of connected pointset, as it easy to see; I believe that in these two predicates 'perfect" and 'connected' I have discovered the necessary and sufficient properties of a point-continuum. I therefore define a point-continuum inside G_n as a perfect-connected set. Here 'perfect' and 'connected' are not merely words but completely general predicates of the continuum; they have been conceptually characterized in the sharpest way by the foregoing definitions* (Ewald 1999, p. 906).

Cantor points out the shortcomings of previous definitions of continuum such as those of Bolzano and Dedekind, and in a note dilates on the merits of his own definition:

> *Observe that this definition of a continuum is free from every reference to that which is called the dimension of a continuous structure; the definition includes also continua that are composed of connected pieces of different dimensions, such as lines, surfaces, solids, etc. . ..I know very well that the word 'continuum' has previously not had a precise meaning in mathematics; so my definition will be judged by some as too narrow, by others as too broad. I trust that that I have succeeded in finding a proper mean between the two.*
>
> *In my opinion, a continuum can only be a perfect and connected structure. So, for example, a straight line segment lacking one or both of its end-points, or a disc whose boundary is excluded, are not complete continua; I call such point-sets semi-continua.*

It will be seen that Cantor has advanced beyond his predecessors in formulating what is in essence a *topological* definition of continuum, one that, while still dependent on metric notions, does not involve an order relation. It is interesting to

compare Cantor's definition with that given in modern general topology. There we find a *continuum* defined as a compact connected subset of a topological space. Now within any *bounded* region of Euclidean space it can be shown that Cantor's continua coincide with continua in the sense of the modern definition. While Cantor lacked the definition of compactness, his requirement that continua be "complete" (which led to his rejecting as continua such noncompact sets as open intervals or discs) is not far away from the idea.

Cantor's analysis of infinite point sets had led him to introduce transfinite numbers (Hallett 1984) and he had come to accept their objective existence as being beyond doubt. But throughout his mathematical career he maintained an unwavering, even dogmatic opposition to infinitesimals, attacking the efforts of mathematicians such as du Bois-Reymond and Veronese to formulate rigorous theories of actual infinitesimals. As far as Cantor was concerned, the infinitesimal was beyond the realm of the possible; infiinitesimals were no more than "castles in the air, or rather just nonsense," to be classed "with circular squares and square circles" (Fisher 1981). His abhorrence of infinitesimals went so deep as to move him to outright vilification, branding them as "cholera-bacilli of mathematics" (Dauben 1979, p. 233).

Cantor believed that the theory of transfinite numbers could be employed to explode the concept of infinitesimal once and for all. Cantor's specific aim was to refute all attempts at introducing infinitesimals through the abandoning of the *Archimedean principle* – i.e., the assertion that for any positive real numbers $a < b$, there is a sufficiently large natural number n such that $na > b$. (Domains in which this principle fails to hold are called *nonarchimedean*). In a paper of 1887, Cantor attempted to demonstrate that the Archimedean property was a necessary consequence of the "concept of linear quantity" and "certain theorems of transfinite number theory," so that the linear continuum could contain no infinitesimals. He concludes that "the so-called Archimedean axiom is not an axiom at all, but a theorem which follows with logical necessity from the concept of linear quantity (Fisher 1981). Cantor's argument (in amended form) seems to have convinced a number of influential mathematicians, including Peano and Russell, of the untenability of infinitesimals.

Cantor's argument relied on the claim that the product of a positive infinitesimal, should such exist, with one of his transfinite numbers could never b finite. But since a proof of this claim was not supplied, Cantor's alleged demonstration that infinitesimals are impossible must be regarded as inconclusive (Fisher 1981). In any case consistent theories of infinitesimals were later constructed (see Sects. 5 and 6 below).

Cantor's rejection of infinitesimals stemmed from his conviction that his own theory of transfinite ordinal and cardinal numbers exhausted the realm of the numerable, so that no further generalization of the concept of number, in particular any which embraced infinitesimals, was admissible. For Cantor, transfinite numbers were grounded in *transient reality*, while infinitesimals and similar chimeras (in his estimation) could not be accorded such a status. Recall Cantor's assertion:

> *In particular, in the introduction of new numbers it is only obliged to give definitions of them which will bestow such a determinacy and, in certain circumstances, such a relationship to older numbers that they can in any given instance be precisely distinguished.*

Accordingly Cantor could not, or would not, grant the infinitesimal an immanent reality which was compatible with "older" numbers – among which he of course included his transfinite numbers – for had he done so he would perforce have had, in accordance with his own principles, to grant the infinitesimal transient reality. This seems to be the reason for Cantor's determination to demonstrate the inconsistency of the infinitesimal with his concept of transfinite number.

It has to be said (Fisher 1981) that concerning infinitesimals Cantor displayed a dogmatic attitude, arguing, in effect, that the admission of infinitesimals was self-contradictory. While Cantor's intolerant attitude toward the infinitesimal is not, strictly speaking, inconsistent with the "freedom" of mathematics he proclaimed, it does seem to reflect his deep-seated conviction (Dauben 1979, pp. 288–91) that his transfinite set theory was the product of "divine inspiration," so that anything in conflict with it must be anathematized.

3 Dissenting Voices: Divergent Conceptions of the Continuum in the Nineteenth and Early Twentieth Centuries

Despite the remarkable success of Weierstrass, Dedekind, and Cantor in constructing the continuum from arithmetical materials, a number of thinkers of the late nineteenth and early twentieth centuries remained opposed, in varying degrees, to the idea of explicating the continuum concept entirely in discrete terms, whether arithmetical or set-theoretic. These include the mathematicians *du Bois-Reymond, Poincaré, Brouwer,* and *Weyl,* and the philosophers *Brentano* and *Peirce.*

Paul du Bois-Reymond (1831–1889), against whose theory of infinities and infinitesimals Cantor fought so hard, was a prominent mathematician of the later nineteenth century who made significant contributions to real analysis, differential equations, mathematical physics, and the foundations of mathematics. While accepting many of the methods of the Dedekind-Cantor school, and indeed embracing the idea of the actual infinite, he rejected its associated philosophy of the continuum on the grounds that it was committed to the reduction of the continuous to the discrete. In 1882 he writes:

> *The conception of space as static and unchanging can never generate the notion of a sharply defined, uniform line from a series of points however dense, for, after all, points are devoid of size, and hence no matter how dense a series of points may be, it can never become an interval, which must always be regarded as the sum of intervals between points* (Ehrlich 1994, p. x).

Du Bois-Reymond took a somewhat mystical view of the continuum, asserting that its true nature, being beyond the limits of human cognition, would forever elude the understanding of mathematicians. This echoes his older brother Emile's famous *ignorabimus* declaration in 1880 concerning "world riddles," certain of which, such as the ultimate nature of matter and force, and the origin of sensations, would always elude explanation.

Nevertheless, Du Bois-Reymond's view of the continuum as a *mysterium* did not prevent him from developing his own theory of the mathematical continuum, a *continuum of functions,* during the 1870s and 1880s. This was introduced in an article of 1870–1871 as the *calculus of infinities.* Here du Bois-Reymond considers "functions ordered according to the limit of their quotients" (this and all subsequent quotations of Du Bois-Reymond are taken from Fisher 1981).

The orderings of functions, in du Bois-Reymond's notation,

$$f(x) \succ \varphi(x), f(x) \approx \varphi(x), f(x) \prec \varphi(x),$$

are defined, respectively, by

$$\lim_{x\to\infty} f(x)/\varphi(x) = \infty, \lim_{x\to\infty} f(x)/\varphi(x) \text{ is finite and } \neq 0, \lim_{x\to\infty} f(x)/\varphi(x) = 0.$$

Thus, for example, $e^x \succ x \succ \log(x)$, $x^p \succ x$ for any $p > 1$, while $cx^r \approx x^r$ for any c and r. When $f(x) \succ \varphi(x)$, $f(x)$ is said to have an "infinity greater than $\varphi(x)$"; when $f(x) \prec \varphi(x)$, $f(x)$ may be thought of (although du Bois-Reymond does not say this explicitly) as being infinitesimal in comparison with $\varphi(x)$. Du Bois-Reymond considers sequences of functions linearly ordered under $\prec$ or $\succ$. Such "scales of infinity" can be caused to become arbitrarily complex by the continued interpolation of new such sequences between terms. Du Bois-Reymond draws an analogy with the ordered set of real numbers:

> *Just as between two functions two functions as close with respect to their infinities as one may want, one can imagine an infinity of others forming a kind of passage from the first function to the second, one can compare the sequence F [a scale of infinity] to the sequence of real numbers, in which one can also pass from one number to a number very little different from it by an infinity of other ones.*

While du Bois-Reymond uses the term "infinities" in connection with his classification of functions, he does not at this point speak of infinite numbers or actual infinities. But in an article of 1875 he drops his reservations on the matter, and boldly begins by asserting:

> *I decided to publish this continuation of my research on functions becoming infinite in German after I overcame my aversion to using the word 'infinite* (unendlich)' *as a substantive, like the French their 'infini'. I even flatter myself that, by this 'infinite* (unendlich)', *I have enriched our mathematical vocabulary in a noteworthy way.*

He goes on to say:

> *In earlier articles I have distinguished the different infinities of functions by their different magnitudes so that they form a domain of quantities (the infinitary) with the stipulation that the infinity of $\varphi(x)$ is to be regarded as larger than that of $\psi(x)$ or equal to it. . .according as the quotient $\varphi(x)/\psi(x)$ is infinite or finite. Thus in the infinitary domain of quantities the quotient enters in place of the difference in the ordinary domain of numbers. Between the two domains there are many analogies. . . I can add further that the most complete symmetry*

exists between functions becoming zero and becoming infinity, in such a way that everywhere the positive numbers correspond in the most striking way to becoming infinity, the negative numbers to becoming zero, zero to remaining finite. Instead of numbers as fixed signs in the domain of numbers, one has in the infinitary domain of quantities an unlimited number of simple functions; the exponential functions, the powers, the logarithmic functions, that likewise form fixed points of comparisons, and between whose arbitrarily close infinities a limitless number of infinities different from each other can be inserted.

In a paper of 1877 du Bois-Reymond compares his system of "infinities" and that of "ordinary" numbers. He introduces the concept of "numerical continuity," an idea which he suggests underlies the introduction of irrational numbers. To illustrate the idea, du Bois-Reymond offers as a metaphor the distribution of the stars on a great circle in the sky. The readily identified brighter stars he compares to rational numbers with small numerators and denominators. Use of telescopes reveals the presence of new stars in any region, however small, but patches of darkness are always found between them. And then

our imagination, or speculation, peoples this as it were asymptotically uniform nothingness which always remains, with matter whose radiation or our observation can no longer make accessible. In our thought, we may believe there is no end, and we admit no empty spot in the sky.

This is analogous to the generation of rational and irrational numbers:

Thus through more precise consideration the rational numbers always approach more closely to one another, yet in our minds gaps are always left between them, which mathematical speculation then fills with the irrationals.

According to du Bois-Reymond this is essentially the way in which "numerical continuity" has arisen. He sees mathematical intuition as assigning equal authenticity to geometric and numerical quantity, but the attainment of complete equality between the two can only be attained through the use of the limit concept in introducing the irrationals. And the insertion of the irrationals between the rationals is an extension of the primitive concept of number to an equally primitive, but more comprehensive, concept of continuous quantity. That being the case, the comparison between numerical and geometric quantities may conceal further subtleties.

One such subtlety is brought to light in connection with continuous families of curves. When these are allowed to increase with growing rapidity their approximative behavior is quite different from that associated with ordinary spatial continuity. Du Bois-Reymond writes:

If we think of two different quickly increasing functions, then all the transitions from one to the other are spatially conceivable and present in our minds. We cannot conceive anywhere a gap between two curves increasing to infinity or in the neighbourhood of one such curve, which could not be filled with curves; on the contrary, each curve is accompanied by curves which proceed arbitrarily close to it, to infinity.

Now, unlike the points on a line segment, the curves which run between two such curves do not form a "simple infinity," that is, they do not depend on just a single parameter. Du Bois-Reymond shows that this infinity is "unlimited" in the sense that it is not n-fold for any finite n. He continues:

> *. . .just as in the ordinary domain of quantities we can only express quantities numerically exactly by means of rational numbers, since the other numbers are not actual numbers but only limits of such numbers: so we can only express infinities with well-defined functions, of which we only have at our disposal up to now those belonging to the family of logarithms, powers, exponential functions.*

Du Bois-Reymond next notes the difference between the approximative behavior of real numbers and that of "infinities" associated with functions. While one can approximate a number, say ½, by many sequences in such a way that any number, however close to ½, will fall between two members of any such sequence, the situation is quite different for the functions associated with infinities. For example, consider the sequence of functions

$$x^{1/2}, x^{2/3}, \ldots, x^{p/p+1}, \ldots.$$

The exponents of the members of this sequence approach 1, but it is not hard to establish the existence of functions whose infinities fall between *all* of the infinities of the members of this sequence and the function x to which the sequence converges in an appropriate sense. For example, $x^{\log\log x/\log\log x+1}$ is readily shown to be such a function.

Du Bois-Reymond next proceeds to demonstrate the generality of this phenomenon:

> *One cannot approximate a given infinity $\lambda(x)$ with any sequence of functions $\varphi_p(x)$, $p = 1, 2, \ldots$ in such a way that one could not always specify a function $\psi(x)$ which satisfies for arbitrarily large values of p $\lambda(x) \gtrless \psi(x) \gtrless \varphi_p(x)$.*

He continues:

> *Now the fact that we can with no conceivable sequence of functions approach without limit a given infinity, certainly has something strange about it. For it would be . . . completely counter to our intuition to suppose that there is necessarily a gap, for example around the line $y = x$. We can always fill this gap in our thoughts with curves which accompany the line $y = x$ to infinity.*

However, he finds here

> *no irreconcilable conflict of the results of different forms of thought, but only one of the idea of a perhaps not very familiar but still not inaccessible spatial behaviour.*

For du Bois-Reymond this only indicates the presence of "a gap between in the analogy between ordinary and infinitary quantities," the manifestation of "a behaviour peculiar to the infinitary domain."

In his book *Die allgemeine Functionentheorie* of 1882 du Bois-Reymond presents his views on the nature and existence of infinitesimals. He begins by stating that in the analysis of "continuous mathematical quantities," one begins with a "geometric quantity" and tries to relate other quantities to it. So the finite decimals are assigned correlates on a segment, that is, "points." This correlation between finite decimals and points is then extended to infinite decimals by a limit process. But the totality of such points can never form a complete segment, since

> *points are just dimensionless, and therefore an arbitrarily dense sequence of points can never become a distance.*

Here we see once again a rejection of the idea that the continuous is reducible to the discrete. Consequently, a geometric segment must contain something other than finite and infinite decimals. These "others," according to du Bois-Reymond, are infinitesimal segments: there are infinitely many of these in any line segment, however short.

Du Bois-Reymond provides just a few rules of calculation for infinitesimal segments, reminiscent of those used by seventeenth and eighteenth mathematicians. To wit:

> *A finite number of infinitely small segments joined to one another do not form a finite segment, but again an infinitely small segment . . . no upper bound can be specified either for the finite or for the infinitely small.*

> *I say two finite segments are equal when there is no* finite *difference between them . . . Two finite quantities whose difference is infinitely small are equal to one another . . .* A *finite quantity does not change if an infinitely small quantity is added to it or taken away from it.*

While we may be incapable of forming a mental image of the *relation* of the infinitesimal to the finite, according to du Bois-Reymond we can visualize the infinitesimal *in itself*, and when we do so we find that it behaves just like the finite:

> *The infinitely small is a mathematical quantity and has all its properties in common with the finite.*

Du Bois-Reymond took a dim view of some mathematicians' conception of infinitesimals as being ordinary magnitudes continually in a state of flux toward zero, remarking sarcastically

> *As long as the book is closed there is perfect repose, but as soon as I open it there commences a race of all the magnitudes which are provided with the letter d towards the zero limit.* (Ehrlich 1994, pp. 9–10.)

The admission of the infinitesimal in relation to the *finite* opens the way to the infinitesimal in relation to the *infinitesimal* (so entailing, reciprocally, the presence of the infinitely large):

> *In this way, there arises a series of types of quantities, whose successive relation always is that a finite number of quantities of one kind never yields a quantity of the preceding kinds.*

Such quantities accordingly form a nonarchimedean domain. Moreover,

> *If within one and the same of these types of quantities, the properties of ordinary mathematical quantities hold, hence the same types of calculation as in the finite, then the comparison of the different types of quantities with each other is the object of the so-called infinitary* calculus. *This calculus reckons with the relations of the infinitely large or infinitely small from type to type, and these types show connections with each other that do not fall under the ordinary concept of equality. The passages of one type into another do not show, for example, the continuity of change of mathematical quantities, although no jump changes result.*

Du Bois-Reymond concludes his musings on the infinitesimal with the observation that there is an imbalance between belief in the infinitely large and belief in the infinitely small. A majority of educated people, he says, will admit an "infinite" (i.e., actual infinite) in space and time, and not just an "unboundedly large" (i.e., potential infinite). But only with difficulty will they accept the infinitely small, despite the fact that it has the same "right to existence" as the infinitely large. In sum,

> *A belief in the infinitely small does not triumph easily. Yet when one thinks boldly and freely, the initial mistrust will soon mellow into a pleasant certainty. . .. Were the sight of the starry sky lacking to mankind; had the race arisen and developed troglodytically in enclosed spaces; had its scholars, instead of wandering through the distant places of the universe telescopically, only looked for the smallest constituents of form and so were used in their thoughts to advancing into the boundless in the direction of the unmeasurably small: who would doubt that then the infinitely small would take the same place in our system of concepts that the infinitely large does now? Moreover, hasn't the attempt in mechanics to go back down to the smallest active elements long ago introduced into science the atom, the embodiment of the infinitely small? And don't as always skilful attempts to make it superfluous for physics face with certainty the same fate as Lagrange's battle against the differential?*

Du Bois-Reymond was, indeed, a doughty champion of the infinitesimal.

In his later years the Austrian philosopher **Franz Brentano** (1838–1917) became preoccupied with the nature of the continuous. Much of Brentano's philosophy has its starting point in Aristotelian doctrine, and his conception of the continuum constitutes no exception. Aristotle's theory of the continuum, it will be recalled, rests upon the assumption that all change is continuous and that continuous variation of quality, of quantity, and of position are inherent features of perception and intuition. Aristotle considered it self-evident that a continuum cannot consist of points. Any pair of unextended points, he observes, are such that they either touch or are totally separated: in the first case, they yield just a single unextended point, in the second there is a definite gap between the points. Aristotle held that any continuum – a continuous path, say, or a temporal duration, or a motion – may be divided ad infinitum into other continua but not into what might be called "discreta" – parts that cannot themselves be further subdivided. Accordingly, paths may be divided into shorter

paths, but not into unextended points; durations into briefer durations but not into unextended instants; motions into smaller motions but not into unextended "stations." Nevertheless, this does not prevent a continuous line from being divided at a point constituting the common border of the line segments it divides. But such points are, according to Aristotle, just *boundaries,* and not to be regarded as actual *parts* of the continuum from which they spring. If two continua have a common boundary, that common border unites them into a single continuum. Such boundaries exist only *potentially,* since they come into being when they are, so to speak, marked out as connecting parts of a continuum; and the parts in their turn are similarly dependent as parts upon the existence of the continuum.

In its fundamentals Brentano's account of the continuous is akin to Aristotle's. Brentano regards continuity as something given in perception, primordial in nature, rather than a mathematical construction. He held that the idea of the continuous is a fundamental notion abstracted from sensible intuition:

> *Thus I affirm that. . . the concept of the continuous is acquired not through combinations of marks taken from different intuitions and experiences, but through abstraction from unitary intuitions. . .Every single one of our intuitions – both those of outer perception as also their accompaniments in inner perception, and therefore also those of memory – bring to appearance what is continuous* (Brentano 1988, p. 6).

Brentano suggests that the continuous is brought to appearance by sensible intuition in three stages. First, sensation presents us with objects having parts that coincide. From such objects the concept of *boundary* is abstracted in turn, and then one grasps that these objects actually *contain* coincident boundaries. Finally, it becomes clear that this is all that is required in order to understand the concept of a continuum.

Continuity is manifested in sensation in a variety of ways. In *visual* sensation, we are presented with *extension*, something possessing length and breadth, and hence with something such that between any two of its parts, provided these are separated, there is a third part. Every sensation possesses a certain *qualitative* continuity in that the object presented in the sensation could have a given manifested quality (color, for example) in a greater or less degree, and between any two degrees of that quality lies still another degree of that quality. Finally, each sensation manifests *temporal* continuity: this is most evident when we perceive something as moving or at rest.

Brentano recognizes that continua have *qualities* which cause them to possess *multiplicity*—a continuum may manifest continuity in several ways simultaneously. This led him to classify continua into *primary* and *secondary:* a secondary continuum being one whose manifestation is dependent upon another continuum. Here is Brentano himself on the matter:

> *Imagine, for example, a coloured surface. Its colour is something from which the geometer abstracts. For him there comes into consideration only the constantly changing manifold of spatial differences. But the colour, too, appears extended with the spatial surface, whether it manifests no specific colour-differences of its own – as in the case of a red colour which fills out a surface uniformly – or whether it varies in its colouring – perhaps in the manner of a*

> *rectangle which begins on one side with red and ends on the other side with blue, progressing uniformly through all colour-differences from violet to pure blue in between. In both cases we have to do with a multiple continuum, and it is the spatial continuum which appears thereby as primary, the colour-continuum as secondary.* A *similar double continuum can also be established in the case of a motion from place to place or of a rest, in which case it is a temporal continuum as such that is primary, the temporally constant or varying place that is the secondary continuum. Even when one considers a boundary of a mathematical body as such, for example a curved or straight line, a double continuity can be distinguished. The one presents itself in the totality of the differences of place that are given in the line, which always grows uniformly, whether in the case of straight, bent, or curved lines, and is that which determines the length of the line. The other resides in the direction of the line, and is either constant or alternating, and may vary continuously, or now more strongly, now less. It is constant in the case of the straight line, changing in the case of the broken line, and continuously varying in every line that is more or less curved. The direction-continuum here is to be compared with the colour-continuum discussed earlier and with the continuum of place in the case of rest or motion of a corporeal point in time. In the double continuum that presents itself to us in the line it is this continuum of directions that is to be referred to as the secondary, the manifold of differences of place as such as the primary continuum* (Brentano 1988, p. 21f).

It is worth mentioning that Brentano's distinction of primary and secondary continua can be neatly represented within *category theory*: to put it succinctly, a *primary continuum* is a *domain,* a *secondary continuum* a *codomain.* We form a category C – the *category of continua* – by taking continua as objects and *correlations* between continua as arrows. Then, given any arrow $f: A \rightarrow B$ in C, the domain A of f may be taken as a "primary" continuum and its codomain B as a "secondary" continuum. In Brentano's example of a colored surface, for instance, the primary continuum A is the given spatial surface, the secondary continuum B is the color spectrum, and the correlation f assigns to each place in A its color as a position in B. In the case of a corporeal point moving in space, the primary continuum A is an interval of time, the secondary continuum B a region of space, and the correlation f assigns to each instant in A the position in B occupied by the corporeal point. Finally, in the case of the varying direction of a curve the primary continuum A is the curve itself, the secondary continuum is the continuum of measures of angles, and the correlation f assigns to each point on the curve the slope of the tangent there: thus f is nothing other than the *first derivative* of the function associated with the curve.

For Brentano the essential feature of a continuum is its inherent capacity to engender boundaries, and the fact that such boundaries can be grasped as coincident. Boundaries themselves possess a quality which Brentano calls *plerosis* ("fullness"). Plerosis is the measure of the number of directions in which the given boundary actually bounds. Thus, for example, within a temporal continuum the endpoint of a past episode or the starting point of a future one bounds in a single direction, while the point marking the end of one episode and the beginning of another may be said to bound doubly. In the case of a spatial continuum there are numerous additional possibilities: here a boundary may bound in all the directions of which it is capable of bounding, or it may bound in only some of these directions. In the former case, the boundary is said to exist in *full plerosis;* in the latter, in *partial plerosis.* Brentano writes:

> *. . .the spatial nature of a point differs according to whether it serves as a limit in all or only in some directions. Thus a point located inside a physical thing serves as a limit in all directions, but a point on a surface or an edge or a vertex serves as a limit in only some direction. And the point in a vertex will differ in accordance with the directions of the edges that meet at the vertex. . . I call these specific distinctions differences of plerosis. Like any manifold variation, plerosis admits of a more and a less. The plerosis of the centre of a cone is more complete than that of a point on its surface; the plerosis of a point on its surface is more complete than that of a point on its edge, or that of its vertex. Even the plerosis of the vertex is the more complete the less the cone is pointed.* (Brentano 1988, p. xvii).

Brentano believed that the concept of plerosis enabled sense to be made of the idea that a boundary possesses "parts," even when the boundary lacks dimensions altogether, as in the case of a point. Thus, while the present or "now" is, according to Brentano, temporally unextended and exists only as a boundary between past and future, it still possesses two "parts" or aspects: it is both the end of the past and the beginning of the future. It is worth mentioning that for Brentano it was not just the "now" that existed only as a boundary; since, like Aristotle he held that "existence" in the strict sense means "existence now," it necessarily followed that existing things exist only as boundaries of what has existed or of what will exist, or both.

Brentano ascribes particular importance to the fact that points in a continuum can *coincide.* On this matter he writes:

> *Various other thorough studies could be* made [on the continuum concept] *such as a study of the impossibility of adjacent points and the* possibility of coincident points, *which have, despite their coincidence, distinctness and full relative independence.* [This] *has been and is misunderstood in many ways. It is commonly believed that if four different-coloured quadrants of a circular area touch each other at its centre, the centre belongs to only one of the coloured surfaces and must be that colour only. Galileo's judgment on the matter was more correct; he expressed his interpretation by saying paradoxically that the centre of the circle has as many parts as its periphery. Here we will only give some indication of these studies by commenting that everything which arises in this connection* follows from the point's relativity as involves a continuum and the fact that it is essential for it to belong to a continuum. *Just as the possibility of the coincidence of different points is connected with that fact, so is the existence of a point in diverse or more or less perfect* plerosis. *All of this is overlooked even today by those who understand the continuum to be an actual infinite multiplicity and who believe that we get the concept not by abstraction from spatial and temporal intuitions but from the combination of fractions between numbers, such as between 0 and* 1 (Brentano 1974, p. 357).

Brentano's doctrines of plerosis and coincidence of points are well illustrated by applying them to the traditional philosophical problem of the initiation of motion: if a thing begins to move, is there a last moment of its being at rest or a first moment of its being in motion? The usual objection to the claim that both moments exist is that, if they did, there would be a time between the two moments, and at that time the thing could be said neither to be at rest nor to be in motion – in violation of the law of excluded middle. Brentano's response would be to say that both moments do exist, but that they *coincide*, so that there are no times between them; the violation of the law of excluded middle is thereby avoided. More exactly, Brentano would assert that

the temporal boundary of the thing's being at rest – the end of its being at rest – is the same as the temporal boundary of the thing's being in motion – the beginning of its being in motion – but the boundary is *twofold* in respect of its plerosis. The boundary is, in fact, in half plerosis at rest and in half plerosis in motion.

Brentano took a dim view of the efforts of mathematicians to construct the continuum from numbers. His attitude varied from rejecting such attempts as inadequate to according them the status of "fictions." In a letter to Husserl drafted in 1905, Brentano asserts that "I regard it as absurd to interpret a continuum as a set of points." This is not surprising given his Aristotelian inclination to take mathematical and physical theories to be genuine descriptions of empirical phenomena rather than idealizations: in his view, if such theories were to be taken as literal descriptions of experience, they would amount to nothing better than "misrepresentations." Indeed, Brentano writes:

> *We must ask those who say that the continuum ultimately consists of points what they mean by a point. Many reply that a point is a cut which divides the continuum into two parts. The answer to this is that a cut cannot be called a thing and therefore cannot be a presentation in the strict and proper sense at all. We have, rather, only presentations of contiguous parts. . . . The spatial point cannot exist or* be conceived of *in isolation. It is just as necessary for it to belong to a spatial continuum as for the moment of time to belong to a temporal continuum* (Brentano 1974, p. 354).

Concerning Poincaré's approach to the continuum (see below) Brentano has this to say:

> *Poincaré . . .follows extreme empiricists in the in the area of sensory psychology and therefore does not believe that there is granted to us an intuition of a continuous space. Poincaré's entire mode of procedure reveals that he also denies that we are in possession of an intuition of a continuous time. We saw how first of all he inserted between 0 and 1 fractions having a whole number as numerator and a whole power of 2 as denominator. In similar fashion, he then inserted all proper fractions whose denominator is a whole power of 3, and then also all those whose denominators are powers of every other whole number. He obtained thereby a series containing all rational fractions which, as he said, already has a certain continuity about it. He then inserted . . . a series of irrational fractions. To these one now adds the series of fractions involving transcendental ratios. . .. Poincaré was prepared to admit that this process will never come to an end. . .. But he believed that he could be satisfied with the insertions already made. And nothing is more self-evident than that we have here a confession that the attempt to obtain a true continuum in this way has broken down* (Brentano 1988, p. 39).

Dedekind's account of the continuum does not fare much better (Brentano 1988, pp. 40–41):

> *Dedekind differs from Poincaré already in the fact that he does not wish to deny that we have an intuition of a continuum – he simply does not want to make any use thereof. . . . Dedekind's and Poincaré's constructions share in common that they fail to recognise the essential character of the continuum, namely that it allows the distinguishing of boundaries, which are nothing in themselves, but yet in conjunction make a contribution to the continuum. Dedekind believes that either the number ½ forms the beginning of the series ½ to 1, so*

> *that the series 0 to ½ would thereby be spared a final member, i.e. an end point which would belong to it, or conversely. But this is not how things are in the case of a true continuum. Rather it is the case that, when one divides a line, every part has a starting point, but in half plerosis. . . .*

Here Brentano appears to be saying that when one divides a closed interval $[a, b]$ at an intermediate point c, one necessarily obtains the closed intervals $[a, c]$, $[c, b]$, with the common point c (in half plerosis). In that case, Brentano probably has regarded a continuous line as indecomposable into disjoint intervals.

He goes on:

> *If a red and a blue surface are in contact with each other then a red and a blue line coincide, each with different plerosis. And if a circular area is made up of three sectors, a red, a blue and a yellow, then the mid-point is a whole which consists to an equal extent of a red, a blue and a yellow part. According to Dedekind this point would belong to just one of the three colour-segments, and we should have to say that it could be separated from this while the segment in question remained otherwise unchanged. Indeed, the whole circular surface would then be conceivable as having been deprived of its mid-point, like Dedekind's number-series from which only the number ½ has fallen away. One sees immediately that this is absurd if one keeps in mind that the true concept of the continuum is obtained through abstraction from an intuition, and thus also that the entire conception has missed its target.*

That Brentano considered "absurd" the idea of removing a single point from a continuum seems to indicate that his continuum has the same "syrupy" property as those of intuitionistic and smooth infinitesimal analysis: see Sects. 4 and 6 below.

In conclusion,

> *One sees that in this entire putative construction of the concept of what is continuous the goal has been entirely missed; for that which is above all else characteristic of a continuum, namely the idea of a boundary in the strict sense* (*to which belongs the possibility of a coincidence of boundaries*), *will be sought after entirely in vain. Thus also the attempt to have the concept of what is continuous spring forth out of the combination of individual marks distilled from intuition is to be rejected as entirely mistaken, and this implies further that what is continuous must be given to us in individual intuition and must therefore have been extracted therefrom* (Brentano 1988, pp. 4f).

Brentano's analysis of the continuum centered on its phenomenological and qualitative aspects, which are by their very nature incapable of reduction to the discrete. Brentano's rejection of the mathematicians' attempts to construct it in discrete terms is thus hardly surprising.

The American philosopher-mathematician **Charles Sanders Peirce**'s (1839–1914) view of the continuum was, in a sense, intermediate between that of Brentano and the arithmetizers. Like Brentano, he held that the cohesiveness of a continuum rules out the possibility of it being a mere collection of discrete individuals, or points, in the usual sense:

> *The very word* continuity *implies that the instants of time or the points of a line are everywhere welded together.*

> [*The*] *continuum does not consist of indivisibles, or points, or instants, and does not contain any except insofar as its continuity is ruptured* (Peirce 1976, p. 925).

And even before Brouwer (see below) Peirce seems to have been aware that a faithful account of the continuum will involve questioning the law of excluded middle:

> *Now if we are to accept the common idea of continuity . . . we must either say that a continuous line contains no points or . . . that the principle of excluded middle does not hold of these points. The principle of excluded middle applies only to an individual . . . but places being mere possibilities without actual existence are not individuals.* (Peirce 1976, p. xvi: the quotation is from a note written in 1903).

But Peirce also held that any continuum harbors an *unboundedly large* collection of points – in his colorful terminology, a *supermultitudinous* collection – what we would today call a *proper class*. Peirce maintained that if "enough" points were to be crowded together by carrying insertion of new points between old to its ultimate limit, they would – through a *logical* "transformation of quantity into quality" – lose their individual identity and become fused into a true continuum. Here are his observations on the matter:

It is substantially proved by Euclid that there is but one assignable quantity which is the limit of a convergent series. That is, if there is an increasing convergent series, A *say, and a decreasing convergent series,* B *say, of which every approximation exceeds every approximation of* A*, and if there is no rational quantity which is at once greater than every approximation of* A *and less than every approximation of* B*, then there is but one surd quantity so intermediate. . .There is one surd quantity and only one for each convergent series, calling two series the same if their approximations all agree after a sufficient number of terms, or if their difference approximates toward zero. But this is only to say that the multitude of surds equals the multitude of denumerable sets of rational numbers which is. . . the primipostnumeral multitude.* [Peirce assumed what amounts to the generalized continuum hypothesis in supposing that each possible infinite set has one of the cardinalities $\aleph_0, 2^{\aleph_0}, 2^{2^{\aleph_0}}, \ldots$. These he termed denumerable, primipostnumeral, secundipostnumeral, etc.]

> *. . .We remark that there is plenty of room to insert a* secundipostnumeral *multitude of quantities between* [*a*] *convergent series and its limit. Any one of those quantities may likewise be separated from its neighbours, and we thus see that between it and its nearest neighbours there is ample room for a* tertiopostnumeral *multitude of other quantities, and so on through the whole denumerable series of postnumeral quantities.*

> *But if we suppose that all such orders of systems of quantities have been inserted, there is no longer any room for inserting any more. For to do so we must select some quantity to be thus isolated in our representation. Now whatever one we take, there will always be quantities of higher order filling up the spaces on the two sides.*

> *We therefore see that such a supermultitudinous collection sticks together by logical necessity. Its constituent individuals are no longer distinct and independent subjects. They*

have no existence – no hypothetical existence – except in their relations to one another. They are not subjects, but phrases expressive of the properties of the continuum.

. . . Supposing a line to be a supermultitudinous collection of points, . . . to sever a line in the middle is to disrupt the logical identity of the point there and make it two points. It is impossible to sever a continuum by separating the connections of the points, for the points only exist by virtue of those connections. The only way to sever a continuum is to burst it, that is, to convert what was one into two (Peirce 1976, p. 95).

There is some resemblance between Peirce's conception of the continuum and John Conway's system of *surreal numbers* (Ehrlich 1994a). Conway's system may be characterized as being an η_α-field for every ordinal α, that is, a real-closed ordered field S which satisfies the condition that, for any pair of subsets X, Y for which every member of X is less than every member of Y, there is an element of S strictly between X and Y.

In their Introduction to Peirce (1992), Ketner and Putnam characterize Peirce's conception of the continuum as "a possibility of repeated division which can never be exhausted in any possible world, not even in a possible world in which one can complete [nondenumerably] infinite processes." (This description would seem to apply equally well to Conway's conception.) It is not hard to show that, between any pair of members of S there is a *proper class* of members of S – in Peirce's terminology, a supermultitudinous collection. Nevertheless, S is still discrete: its elements, while supermultitudinous, remain distinct and unfused (were it not for this fact, Conway would scarcely be justified in calling the members of S "numbers"). On the face of it the discreteness of S would seem to imply that the presence of superabundant quantity in Peirce's sense is not enough to ensure continuity. Of course, Brentano would have dismissed this idea altogether, in view of his critical attitude toward any construction of the continuum by repeated insertion of points.

Peirce's conception of the number continuum is also notable for the presence in it of an abundance of *infinitesimals*, a feature it shares with du Bois-Reymond's nonarchimedean number systems. In defending infinitesimals, Peirce remarks that

It is singular that nobody objects to $\sqrt{-1}$ *as involving any contradiction, nor, since Cantor, are infinitely great quantities much objected to, but still the antique prejudice against infinitely small quantities remains* (Peirce 1976, p. 123).

Peirce held the view that the conception of infinitesimal is suggested by introspection – that the *specious present* is in fact an infinitesimal:

It is difficult to explain the fact of memory and our apparently perceiving the flow of time, unless we suppose immediate consciousness to extend beyond a single instant. Yet if we make such a supposition we fall into grave difficulties, unless we suppose the time of which we are immediately conscious to be strictly infinitesimal (Peirce 1976, p. 124).

We are conscious of the present time, which is an instant, if there be any such thing as an instant. But in the present we are conscious of the flow of time. There is no flow in an instant. Hence, the present is not an instant. (Peirce 1976, p. 925).

Peirce also championed the retention of the infinitesimal concept in the foundations of the calculus, both because of what he saw as the efficiency of infinitesimal methods, and because he regarded infinitesimals as constituting the "glue" causing points on a continuous line to lose their individual identity.

The idea of continuity played a central role in the thought of the great French mathematician **Henri Poincaré** (1854–1912). But sorting out his views on the continuum, concerning which he made numerous scattered remarks, is by no means an easy task. Indeed, there seems to be an inconsistency in his attitude toward the set-theoretical, or arithmetized, continuum. On the one hand, he rejected actual infinity and impredicative definition – both cornerstones of the Cantorian theory of sets which underpins the construction of the arithmetized continuum. And yet in his mathematical work he employs variables ranging over all the points of an interval of the set-theoretical continuum, and he "accepts the standard account of the least upper bound, which is impredicative" (Folina 1992, p. xv). (Impredicativity is a form of circularity: a definition of a term is impredicative if it contains a reference to a totality to which the term under definition belongs. See, e.g., Fraenkel et al. 1973, pp. 193–200.)

Beneath this apparent inconsistency lies his belief that what ultimately underpins mathematics, creating its linkage with objective reality, is *intuition – that* "intuition is what bridges the gap between symbol and reality" (Folina 1992, p. 113).

His view of the continuum, in particular, is informed by this credo. For Poincaré the continuum and the range of points on it is grasped in intuition in something like the Kantian sense, and yet the continuum cannot be treated as a completed mathematical object, as a "mere set." (Folina 1992, p. xvi).

Of the arithmetical continuum Poincaré remarks:

> *The continuum so conceived is only a collection of individuals ranged in a certain order, infinite to one another, it is true, but* exterior *to one another. This is not the ordinary conception, wherein is supposed between the elements of the continuum a sort of intimate bond which makes of them a whole, where the point does not exist before the line, but the line before the point. Of the celebrated formula "the continuum is unity in multiplicity", only the multiplicity remains, the unity has disappeared. The analysts are none the less right in defining the continuum as they do, for they always reason on just this as soon as they pique themselves on their rigor. But this is enough to apprise us that the veritable mathematical continuum is a very different thing from that of the physicists and the metaphysicians.* (Poincaré 1946, pp. 43–44).

But despite Poincaré's apparent acceptance of the arithmetic definition of the continuum, he questions the fact that (as with Dedekind and Cantor's formulations) the (irrational) numbers so produced are mere symbols, detached from their origins in intuition:

> *But to be content with this [fact] would be to forget too far the origin of these symbols; it remains to explain how we have been led to attribute to them a sort of concrete existence, and, besides, does not the difficulty begin even for the fractional numbers themselves? Should we have the notion of these numbers if we had not known a matter that we conceive as infinitely divisible, that is to say, a continuum?* (Poincaré 1946, pp. 45–46).

That being the case, Poincaré asks whether the notion of the mathematical continuum is "simply drawn from experience." To this he responds in the negative, for the reason that our sensations, the "raw data of experience," cannot be brought under an acceptable scheme of measurement:

> *It has been observed, for example, that a weight* A *of 10 grams and a weight B of 11 grams produce identical sensations, that the weight B is just as indistinguishable from a weight C of 12 grams, but that the weight* A *is easily distinguished from the weight C. Thus the raw results of experience may be expressed by the following relations:*

$$A = B, B = C, A < C,$$

which may be regarded as the formula of the physical continuum.

According to Poincaré it is the "intolerable discord with the principle of contradiction" of this formula which has forced the invention of the mathematical continuum. (Actually, the formula ceases to be contradictory if the identity relation $=$ is replaced by a symmetric, reflexive, but *nontransitive* relation $\approx$: here $x \approx y$ is taken to assert that the sensations or perceptions x and y are indistinguishable.) The continuum is then obtained in two stages. First, formerly indistinguishable terms are distinguished and a new term, indistinguishable from both, inserted between them. Repeating this procedure indefinitely gives rise to what Poincaré calls a *first-order continuum*, in essence the rational number line. A second stage now becomes necessary because two first-order continua, for example, the diagonal of a square and its inscribed circle, need not intersect. This second stage, in which are added all possible "boundary" points between first-order continua leads to the second-order or mathematical continuum. Here is how Poincaré describes the process:

> *But conceive of a straight line divided into two rays. Each of these rays will appear to our imagination as a band of a certain breadth; these bands moreover will encroach one on the other, since there must be no interval between them. The common part will appear to us as a point which will always remain when we try to imagine our bands narrower and narrower, so that we admit as an intuitive truth that if a straight line is cut into two rays their common boundary is a point; we recognize here the conception of Dedekind, in which an incommensurable number was regarded as the common boundary of two classes of rational numbers.*
>
> *Such is the origin of the continuum of second order, which is the mathematical continuum so called.*

Poincaré goes on to discuss continua of higher dimensions. To obtain these he considers *aggregates* of sensations. As with single sensations, any given pair of these aggregates may or may not be distinguishable. He remarks that, while these aggregates, which he terms *elements*, are analogous to mathematical points, they are not in fact quite the same thing, for

> *we cannot say that our element is without extension, since we cannot distinguish it from neighbouring elements and it is thus surrounded by a sort of haze. If the astronomical*

> *comparison may be allowed, our 'elements' would be like nebulae, whereas the mathematical points would be like stars* (Poincaré 1946, p. 49).

This leads to a definition of a physical continuum:

> *a system of elements will form a* continuum *if we can pass from any one of them to any other, by a series of consecutive elements such that each is indistinguishable from the preceding. This* linear series *is to the* line *of the mathematician what an isolated* element *was to the point.*

Poincaré defines a *cut* in a physical continuum *C* to be a set of elements removed from it "which for an instant we shall regard as no longer belonging to this continuum." Such a cut may happen to subdivide *C* into several distinct continua, in which case *C* will contain two distinct elements *A* and *B* that must be regarded as belonging to two distinct continua. This becomes necessary

> *because it will be impossible to find a linear series of consecutive elements of C, each of these elements indistinguishable from the preceding, the first being A and the last B,* without one of the elements of this series being indistinguishable from one of the elements of the cut.

On the other hand, it may happen that the cut fails to subdivide the continuum C, in which case it becomes necessary to determine precisely which cuts will subdivide it. Poincaré calls a continuum *one-dimensional* if it can be subdivided by a cut which reduces to a finite number of elements all distinguishable from one another (and so forming neither a continuum nor several continua). When *C* can be subdivided only by cuts which are themselves continua, *C* is said to possess several dimensions:

> *If cuts which are continua of one dimension suffice, we shall say that C has two dimensions; if cuts of two dimensions suffice, we shall say that C has three dimensions, and so on.*

Thus is defined the concept of a multidimensional physical continuum, based on "the very simple fact that two aggregates of sensations are distinguishable or indistinguishable."

Unlike Cantor, Poincaré accepted the infinitesimal, even if he did not regard all of the concept's manifestations as useful. This emerges from his answer to the question: "Is the creative power of the mind exhausted by the creation of the mathematical continuum?" He responds:

> *No; the works of Du Bois-Reymond demonstrate it in a striking way. We know the mathematicians distinguish between infinitesimals and that those of second order are infinitesimal not only in an absolute way, but also in relation to those of first order. It is not difficult to imagine infinitesimals of fractional and even irrational order, and thus we find again that scale of the mathematical continuum which has been dealt with in the preceding pages.*
>
> *Further, there are infinitesimals which are infinitely small in relation to those of the first order, and, on the contrary, infinitely great in relation to those of order 1 + ε, and that*

> *however small ε may be. Here, then, are new terms intercalated in our series . . . I shall say that thus has been created a sort of continuum of the third order.*
>
> *It would be easy to go further, but that would be idle; one would only be imagining symbols without possible application, and no one would think of doing that. The continuum of the third order, to which the consideration of the different orders of infinitesimals leads, is itself not useful enough to have won citizenship, and geometers regard it as a mere curiosity. The mind uses its creative faculty only when experience requires it.*

Poincaré's attitude toward the continuum resembles in certain respects that of the intuitionists (see below): while the continuum exists, and is knowable intuitively, it is not a "completed" set-theoretical object. It is geometric intuition, not set theory, upon which the totality of real numbers is ultimately grounded.

The Dutch mathematician *L. E. J. Brouwer* (1881–1966) is best known as the founder of the philosophy of *(neo)intuitionism*. Brouwer's highly idealist views on mathematics bore some resemblance to Kant's. For Brouwer, mathematical concepts are admissible only if they are adequately grounded in intuition, mathematical theories are significant only if they concern entities which are constructed out of something given immediately in intuition, and mathematical demonstration is a form of construction in intuition. Brouwer's insistence that mathematical proof be constructive in this sense required the jettisoning of certain received principles of classical logic, notably the *law of excluded middle*: the assertion that, for any proposition *p,* either *p* or not *p*. Brouwer maintained, in fact, that the applicability of the law of excluded middle to mathematics

> *was caused historically by the fact that, first, classical logic was abstracted from the mathematics of the subsets of a definite finite set, that, secondly, an a priori existence independent of mathematics was ascribed to the logic, and that, finally, on the basis of this supposed apriority it was unjustifiably applied to the mathematics of infinite sets* (Kneebone 1963, p. 246).

Brouwer held that much of modern mathematics is based on an illicit extension of procedures valid only in the restricted domain of the finite. He therefore embarked on the radical course of jettisoning virtually all of the mathematics of his day – in particular the set-theoretical construction of the continuum – and starting anew, using only concepts and modes of inference that could be given clear intuitive justification. In the process it would become clear precisely what the logical laws are that intuitive, or constructive, mathematical reasoning actually obeys, making possible a comparison of the resulting *intuitionistic,* or *constructive logic* with classical logic. This is not to say that Brouwer was primarily interested in *logic,* far from it: indeed, his distaste for formalization caused him to be quite dismissive of subsequent codifications of intuitionistic logic.

While admitting that the emergence of noneuclidean geometry had discredited Kant's view of space, Brouwer maintained, in opposition to the logicists (whom he called "formalists") that arithmetic, and so all mathematics, must derive from *temporal intuition.* In his own words:

> *Neointuitionism considers the falling apart of moments of life into qualitatively different parts, to be reunited only while remaining separated by time, as the fundamental phenomenon of the human intellect, passing by abstracting from its emotional content into the fundamental phenomenon of mathematical thinking, the intuition of the bare two-oneness. This intuition of two-oneness, the basal intuition of mathematics, creates not only the numbers one and two, but also all finite ordinal numbers, inasmuch as one of the elements of the two-oneness may be thought of as a new two-oneness, which process may be repeated indefinitely; this gives rise still further to the smallest infinite ordinal ω. Finally this basal intuition of mathematics, in which the connected and the separate, the continuous and the discrete are united, gives rise immediately to the intuition of the linear continuum, i.e., of the "between", which is not exhaustible by the interposition of new units and which can therefore never be thought of as a mere collection of units. In this way the apriority of time does not only qualify the properties of arithmetic as synthetic a priori judgments, but it does the same for those of geometry, and not only for elementary two- and three-dimensional geometry, but for non-euclidean and n-dimensional geometries as well. For since Descartes we have learned to reduce all these geometries to arithmetic by means of coordinates.* (Benacerraf and Putnam 1977, p. 80).

Brouwer maintained that it is the awakening of awareness of the temporal continuum in the subject, an event termed by him "The Primordial Happening" or "The Primordial Intuition of Time," that engenders the fundamental concepts and methods of mathematics. In "Mathematics, Science and Language" (1929), he describes how the notion of number – the discrete – emerges from the awareness of the continuous:

> Mathematical Attention *as an act of the will serves the instinct for self-preservation of individual man; it comes into being in two phases;* time awareness *and* causal attention. *The first phase is nothing but the fundamental intellectual phenomenon of the falling apart of a moment of life into two qualitatively different things of which one is experienced as giving away to the other and yet is retained by an act of memory. At the same time this split moment of life is separated from the Ego and moved into a world of its own, the world of perception. Temporal twoity, born from this time awareness, or the two-membered sequence of time phenomena, can itself again be taken as one of the elements of a new twoity, so creating temporal threeity, and so on. In this way, by means of the self-unfolding of the fundamental phenomenon of the intellect, a* time sequence of phenomena is created of arbitrary multiplicity (Mancosu 1998, p. 45)

Brouwer took the elucidation of the continuum as his *raison d'être.* In his early thought he rejected out of hand the set-theoretic account of the continuum in terms of discrete points as put forward by Cantor and Dedekind, asserting that

> *. . .The* continuum as a whole [is] *given to us by intuition; a construction for it, an action which would create from the mathematical intuition 'all' its points as individuals, is inconceivable and impossible.* (Mancosu 1998, p.45)

Later Brouwer was to modify this doctrine. In his mature thought, he radically transformed the concept of point, endowing points with sufficient fluidity to enable them to serve as generators of a "true" continuum. This fluidity was achieved by admitting as "points," not only fully defined discrete numbers such as $\sqrt{2}$, π, *e,* and the like – which have, so to speak, already achieved "being" – but also "numbers"

which are in a perpetual state of becoming in that their the entries in their decimal (or dyadic) expansions are the result of free acts of choice by a subject operating throughout an indefinitely extended time. The resulting *choice sequences* cannot be conceived as finished, completed objects: at any moment only an initial segment of each is known (Fraenkel et al. 1973, pp. 255–261). In this way Brouwer obtained the mathematical continuum in a way compatible with his belief in the primordial intuition of time – that is, as an unfinished, indeed unfinishable entity in a perpetual state of growth, a "medium of free development." In this conception, the mathematical continuum is indeed "constructed," not, however, by initially shattering, as did Cantor and Dedekind, an intuitive continuum into isolated points, but rather by assembling it from a complex of continually changing overlapping parts.

The mathematical continuum as conceived by Brouwer displays a number of features that seem bizarre to the classical eye. For example, in the Brouwerian continuum the usual law of comparability, namely, that for any real numbers *a, b* either $a < b$ or $a = b$ or $a > b$, fails. Even more fundamental is the failure of the law of excluded middle in the form that for any real numbers *a, b,* either $a = b$ or $a \neq b$. The failure of these seemingly unquestionable principles in turn vitiates the proofs of a number of basic results of classical analysis, for example, the Bolzano–Weierstrass theorem, as well as the theorems of monotone convergence, intermediate value, least upper bound, and maximum value for continuous functions. The failure of these important results of classical analysis has caused most mathematicians of the day to shun intuitionistic, and even constructive mathematics. It was not until the 1960s that adequate constructive versions were worked out (see Sect. 4 below).

While the Brouwerian continuum may possess a number of negative features from the standpoint of the classical mathematician, it has the merit of corresponding more closely to the continuum of intuition than does its classical counterpart. Hermann Weyl pointed out a number of respects in which this is so:

> *In accordance with intuition, Brouwer sees the essential character of the continuum, not in the relation between element and set, but in that between part and whole. The continuum falls under the notion of the 'extensive whole', which Husserl characterizes as that "which permits a dismemberment of such a kind that the pieces are by their very nature of the same lowest species as is determined by the undivided whole* (Weyl 1949, p. 52).

Far from being bizarre, the failure of the law of excluded middle for points in the intuitionistic continuum is seen by Weyl as "fitting in well with the character of the intuitive continuum":

> *For there the separateness of two places, upon moving them toward each other, slowly and in vague gradations passes over into indiscernibility. In a continuum, according to Brouwer, there can be only continuous functions.* The continuum is not composed of parts (Weyl 1949, p. 54).

For Brouwer had indeed shown, in 1924, that every function defined on a closed interval of the continuum as he conceived it is uniformly continuous. Now one might be inclined to regard this claim as impossible: is not a counterexample provided by, for example, the function f given by $f(0) = 0, f(x) = \mid x \mid /x$ otherwise? No, because

from the intuitionistic standpoint, this function is not everywhere defined on the interval $[-1, 1]$, being undefined at those arguments x for which it is unknown whether $x = 0$ or $x \neq 0$.

As a consequence, the intuitionistic continuum is *indecomposable* or *cohesive,* that is, *it cannot be split into two nonempty disjoint parts in any way whatsoever.* In contrast with a discrete entity, the cohesive Brouwerian continuum cannot be composed of its parts.

Hermann Weyl (1885–1955), one of most important and versatile mathematicians of the twentieth century, devoted a great deal of thought to the nature of the continuum. In his *Philosophy of Mathematics and Natural Science* he reflects on what he calls the "inwardly infinite" nature of a continuum:

> *The essential character of the continuum is clearly described in this fragment of Anaxagoras: "Among the small there is no smallest, but always something smaller. For what is cannot cease to be no matter how small it is being subdivided." The continuum is not composed of discrete elements which are "separated from one another as though chopped off by a hatchet." Space is infinite not only in the sense that it never comes to an end; but at every place it is, so to speak, inwardly infinite, inasmuch as a point can only be fixed as step-by-step by a process of subdivision which progresses* ad infinitum. *This is in contrast with the resting and complete existence that intuition ascribes to space. The "open" character is communicated by the continuous space and the continuously graded qualities to the things of the external world. A real thing can never be given adequately, its "inner horizon" is unfolded by an infinitely continued process of ever new and more exact experiences; it is, as emphasized by Husserl, a limiting idea in the Kantian sense. For this reason it is impossible to posit the real thing as existing, closed and complete in itself. The continuum problem thus drives one to epistemological idealism. Leibniz, among others, testifies that it was the search for a way out of the "labyrinth of the continuum" which first suggested to him the conception of space and time as orders of phenomena* (Weyl 1949, p. 41).

Weyl identifies three attempts in the history of thought "to conceive of the continuum as Being in itself." These are, respectively, *atomism, the infinitely small,* and *set theory.* In Weyl's view, despite atomism's brilliant success in unraveling the structure of matter, it had failed in that regard as to space, time, and mathematical extension because it "never achieved sufficient contact with reality." As for the infinitely small, it was not so much supplanted as rendered superfluous by the limit concept. Weyl saw the limit concept as providing the necessary link between the microcosm of the infinitely small and the realm of macroscopic objects. Without that link, the fact that the microcosm is governed by "elementary laws" making for ease of calculation, would remain entirely useless in drawing conclusions about the macrocosm (but in this connection see the remarks on the Constancy Principle in Sect. 6).

In the case of set theory Weyl saw the danger in employing it a basis for explicating the continuum as lying in the fact that set theory bestows a finished, completed character on "the places in the continuum, i.e. to the possible sequences or sets of natural numbers." In Weyl's view, this was a double error for, neither the aggregate of sets of natural numbers nor (in general) individual such sets can be considered finished entities. Rather the continuum should be considered as an

essentially incompletable "field of constructive possibilities." To suppose otherwise is to risk running up against set-theoretic paradoxes such as Russell's.

During the period 1918–1921 Weyl wrestled with the problem of providing the continuum with an exact mathematical formulation free of objectionable set-theoretic assumptions. As he saw it in 1918, there is an unbridgeable gap between intuitively given continua (e.g., those of space, time, and motion) on the one hand, and the discrete exact concepts of mathematics (e.g., that of real number) on the other. For Weyl the presence of this gap meant that the construction of the mathematical continuum could not simply be "read off" from intuition. Rather, he believed at this time that the mathematical continuum must be treated as if it were an element of the realm immediately accessible to intuition, and so, in the end, justified in the same way as a physical theory. In Weyl's view, it was not enough that the mathematical theory of the continuum be *consistent*; it must also be *reasonable.*

Das Kontinuum (1918) embodies Weyl's attempt at formulating a theory of the continuum which satisfies the first, and, as far as possible, the second, of these requirements. In the following passages from this work he acknowledges the difficulty of the task:

> *. . . the conceptual world of mathematics is so foreign to what the intuitive continuum presents to us that the demand for coincidence between the two must be dismissed as absurd.*

> *. . . the continuity given to us immediately by intuition* (*in the flow of time and of motion*) *has yet to be grasped mathematically as a totality of discrete "stages" in accordance with that part of its content which can be conceptualized in an exact way.*

> *Exact time- or space-points are not the ultimate, underlying atomic elements of the duration or extension given to us in experience. On the contrary, only reason, which thoroughly penetrates what is experientially given, is able to grasp these exact ideas. And only in the arithmetico-analytic concept of the real number belonging to the purely formal sphere do these ideas crystallize into full definiteness.*

> *When our experience has turned into a real process in a real world and our phenomenal time has spread itself out over this world and assumed a cosmic dimension, we are not satisfied with replacing the continuum by the exact concept of the real number, in spite of the essential and undeniable inexactness arising from what is given.*

However much he may have wished it, in *Das Kontinuum* Weyl did not aim to provide a mathematical formulation of the continuum as it is presented to intuition, which, as the quotations above show, he regarded as an impossibility (at that time at least). Rather, his goal was first to achieve *consistency* by putting the *arithmetical* notion of real number on a firm logical basis, and then to show that the resulting theory is *reasonable* by employing it as the foundation for a plausible account of continuous process in the objective physical world.

Weyl had come to believe that mathematical analysis at the beginning of the twentieth century would not bear logical scrutiny, for its essential concepts and procedures involved vicious circles to such an extent that, as he says, "every cell (so to speak) of this mighty organism is permeated by contradiction." In *Das Kontinuum*

he tries to overcome this by providing analysis with a *predicative* formulation – not, as Russell and Whitehead had attempted in their *Principia Mathematica,* by introducing a hierarchy of logically ramified types, which Weyl seems to have regarded as too complicated – but rather by confining the basic principle of set formation to formulas whose bound variables range over just the initial given entities (numbers). Thus, he restricts analysis to what can be done in terms of natural numbers with the aid of three basic logical operations, together with the operation of substitution and the process of "iteration," i.e., primitive recursion. Weyl recognized that the effect of this restriction would be to render unprovable many of the central results of classical analysis – e.g., Dirichlet's principle that any bounded set of real numbers has a least upper bound – but he was prepared to accept this as part of the price that must be paid for the security of mathematics.

In Sect. 6 of *Das Kontinuum* Weyl presents his conclusions as to the relationship between the intuitive and mathematical continua. He poses the question: Does the mathematical framework he has erected provide an adequate representation of physical or temporal continuity as it is *actually experienced*? He begins his investigation by noting that, according to his theory, if one asks whether a given function is continuous, the answer is not fixed once and for all, but is, rather, dependent on the extent of the domain of real numbers which have been defined up to the point at which the question is posed. Thus the continuity of a function must always remain *provisional*; the possibility always exists that a function deemed continuous *now* may, with the emergence of "new" real numbers, turn out to be discontinuous *in the future.*

To reveal the discrepancy between this formal account of continuity based on real numbers and the properties of an intuitively given continuum, Weyl next considers the experience of seeing a pencil lying on a table before him throughout a certain time interval. The position of the pencil during this interval may be taken as a function of the time, and Weyl takes it as a fact of observation that during the time interval in question this function is continuous and that its values fall within a definite range. And so, he says,

> *This observation entitles me to assert that during a certain period this pencil was on the table; and even if my right to do so is not absolute, it is nevertheless reasonable and well-grounded. It is obviously absurd to suppose that this right can be undermined by "an expansion of our principles of definition" – as if new moments of time, overlooked by my intuition could be added to this interval, moments in which the pencil was, perhaps, in the vicinity of Sirius or who knows where. If the temporal continuum can be represented by a variable which "ranges over" the real numbers, then it appears to be determined thereby how narrowly or widely we must understand the concept "real number" and the decision about this must not be entrusted to* logical *deliberations over principles of definition and the like.*

To drive the point home, Weyl focuses attention on the fundamental continuum of *immediately given phenomenal time*, that is, as he characterizes it,

> *. . . to that constant form of my experiences of consciousness by virtue of which they appear to me to flow by successively.* (*By "experiences" I mean what I experience, exactly as I*

experience it. I do not mean real psychical or even physical processes which occur in a definite psychicsomatic individual, belong to a real world, and, perhaps, correspond to the direct experiences.)

In order to correlate mathematical concepts with phenomenal time in this sense Weyl grants the possibility of introducing a rigidly punctate "now" and of identifying and exhibiting the resulting temporal points. On the collection of these temporal points is defined the relation of *earlier than* as well as a congruence relation of *equality of temporal intervals,* the basic constituents of a simple mathematical theory of time. Now Weyl observes that the discrepancy between phenomenal time and the concept of real number would vanish if the following pair of conditions could be shown to be satisfied:

1. *The immediate expression of the intuitive finding that during a certain period I saw the pencil lying there were construed in such a way that the phrase "during a certain period" was replaced by "in every temporal point which falls within a certain time span OE.* [Weyl goes on to say parenthetically here that he admits "that this no longer reproduces what is intuitively present, but one will have to let it pass, *if it is really legitimate to dissolve a period into temporal points."*]
2. If P is a temporal point, then the domain of rational numbers to which l belongs if and only if there is a time point L earlier than P such that OL = l.OE *can be constructed arithmetically in pure number theory on the basis of our principles of definition, and is therefore a real number in our sense.*

Condition 3 means that, if we take the time span *OE* as a unit, then each temporal point *P* is correlated with a definite real number. In an addendum Weyl also stipulates the converse.

But can temporal intuition itself provide evidence for the truth or falsity of these two conditions? Weyl thinks not. In fact, he states unequivocally that

. . . everything we are demanding here is obvious nonsense: *to* these *questions, the intuition of time provides no answer – just as a man makes no reply to questions which clearly are addressed to him by mistake and, therefore, are unintelligible when addressed to him.*

The grounds for this assertion are by no means immediately evident, but one gathers from the passages following it that Weyl regards the experienced *continuous flow* of phenomenal time as constituting an insuperable barrier to the whole enterprise of representing this continuum in terms of individual points, and even to the characterization of "individual temporal point" itself. As he says,

The view of a flow consisting of points and, therefore, also dissolving into points turns out to be mistaken: precisely what eludes us is the nature of the continuity, the flowing from point to point; in other words, the secret of how the continually enduring present can continually slip away into the receding past. Each one of us, at every moment, directly experiences the true character of this temporal continuity. But, because of the genuine primitiveness of phenomenal time, we cannot put our experiences into words. So we shall content ourselves with the following description. What I am conscious of is for me both a being-now and, in its essence,

> *something which, with its temporal position, slips away. In this way there arises the persisting factual extent, something ever new which endures and changes in consciousness.*

Weyl sums up what he thinks can be affirmed about "objectively presented time" – by which I take it is meant "phenomenal time described in an objective manner" – in the following two assertions, which he claims apply equally, mutatis mutandis, to every intuitively given continuum, in particular, to the continuum of spatial extension:

> 1. *An individual point in it is non-independent,* i.e., *is pure nothingness when taken by itself, and exists only as a "point of transition" (which, of course, can in no way be understood mathematically);*
> 2. *it is due to the essence of time (and not to contingent imperfections in our medium) that a fixed temporal point cannot be exhibited in any way, that always only an approximate, never an exact determination is possible.*

The fact that single points in a true continuum "cannot be exhibited" arises, Weyl continues, from the fact that they are not genuine individuals and so cannot be characterized by their properties. In the physical world they are never defined absolutely, but only in terms of a coordinate system, which, in an arresting metaphor, Weyl describes as "the unavoidable residue of the eradication of the ego." This metaphor, which Weyl was to employ more than once (Weyl 1950, p. 8 and 1949, p. 123) reflects the continuing influence of Husserlian phenomenological doctrine: in this case, the thesis that the existent is given in the first instance as the contents of a consciousness.

By 1919 Weyl had come to embrace Brouwer's views on the intuitive continuum. The latter's influence looms large in Weyl's next paper on the subject, *On the New Foundational Crisis of Mathematics,* written in 1920. Here Weyl identifies two distinct views of the continuum: "atomistic" or "discrete"; and "continuous." In the first of these the continuum is composed of individual real numbers which are well-defined and can be sharply distinguished. Weyl describes his earlier attempt at reconstructing analysis in Das Kontinuum as atomistic in this sense:

> *Existential questions concerning real numbers only become meaningful if we analyze the concept of real number in this extensionally determining and delimiting manner. Through this conceptual restriction, an ensemble of individual points is, so to speak, picked out from the fluid paste of the continuum. The continuum is broken up into isolated elements, and the flowing-into-each other of its parts is replaced by certain conceptual relations between these elements, based on the "larger-smaller" relationship. This is why I speak of the* atomistic *conception of the continuum* (Weyl 1998, p. 91).

Weyl now repudiated atomistic theories of the continuum, including that of *Das Kontinuum*. He writes:

> *In traditional analysis, the continuum appeared as the set of its points; it was considered merely as a special case of the basic logical relationship of* element and set. *Who would not have already noticed that, up to now, there was no place in mathematics for the equally fundamental relationship of* part and whole? *The fact, however,* that it has parts, *is a fundamental property of the continuum; and so* (*in harmony with intuition, so drastically*

> *offended against by today's "atomism"*) *this relationship is taken as the mathematical basis for the continuum by Brouwer's theory. This is the real reason why the method used in delimiting subcontinua and in forming continuous functions starts out from* intervals *and not* points *as the primary elements of construction. Admittedly a set also has parts. Yet what distinguishes the parts of sets in the realm of the "divisible" is the existence of "elements" in the set-theoretical sense, that is, the existence of* parts that themselves do not contain any further parts. *And indeed, every part contains at least one "element". In contrast, it is inherent in the nature of the continuum that every part of it can be further divided without limitation. The concept of a point must be seen as an idea of a limit, "point" is the idea of a* limit *of a division extending* in infinitum. *To represent the continuous connection of the points, traditional analysis, given its shattering of the continuum into isolated points, had to have recourse to the concept of a* neighbourhood. *Yet, because the concept of continuous function remained mathematically sterile in the resulting generality, it became necessary to introduce the possibility of "triangulation" as a restrictive condition* (Weyl 1998, p. 115).

Like Brentano, Weyl knew that to "shatter a continuum into isolated points" would be to eradicate the very feature which characterizes a continuum – the fact that its cohesiveness is inherited by every one of its (connected) parts.

Weyl welcomed Brouwer's construction of the continuum by means of sequences generated by free acts of choice, thus identifying it as a "medium of free Becoming" which "does not dissolve into a set of real numbers as finished entities." Weyl felt that Brouwer's intuitionistic approach had brought him closer than anyone else to bridging that "unbridgeable chasm" between the intuitive and mathematical continua. In particular, he found compelling the fact that the Brouwerian continuum is not the union of two disjoint nonempty parts – that it is *indecomposable* or *cohesive.* "A genuine continuum," Weyl says, "cannot be divided into separate fragments." In 1921 Weyl observed:

> *. . .if we pick out a specific point, say, $x = 0$, on the number line C* (*i.e., on the variable range of a real variable x*), *then one cannot, under any circumstance, claim either coincides with it or is disjoint from it. The point $x = 0$ thus does not at all split the continuum C into two parts $C^-: x < 0$ and $C^+: x > 0$, in the sense that C would consist of the union of C^-, C^+ and the one point 0 . . . If this appears offensive to present-day mathematicians with their atomistic thought habits, it was in earlier times a self-evident view held by everyone: Within a continuum, one can very well generate subcontinua by introducing boundaries; yet it is irrational to claim that the total continuum is made up of the boundaries and the subcontinua. The point is, a genuine continuum is something connected in itself, and it cannot be divided into separate fragments; this conflicts with its nature* (Weyl 1921, p. 111).

In later publications he expresses this more colorfully by quoting Anaxagoras to the effect that a continuum "defies the chopping off of its parts with a hatchet."

There being only minor differences between Weyl's and Brouwer's accounts of the continuum, Weyl abandoned his earlier attempt at the reconstruction of analysis and "joined Brouwer." At the same time, however, Weyl recognized that the resulting gain in intuitive clarity had been bought at a considerable price:

> *Mathematics with Brouwer gains its highest intuitive clarity. He succeeds in developing the beginnings of analysis in a natural manner, all the time preserving the contact with intuition much more closely than had been done before. It cannot be denied, however, that in*

> *advancing to higher and more general theories the inapplicability of the simple laws of classical logic eventually results in an almost unbearable awkwardness. And the mathematician watches with pain the greater part of his towering edifice which he believed to be built of concrete blocks dissolve into mist before his eyes* (Weyl 1949, p. 54).

Although he later practiced intuitionistic mathematics very rarely, Weyl remained an admirer of intuitionism. And the "riddle of the continuum" retained its fascination for him, as is attested to by the observation he made one of his last papers, *Axiomatic and Constructive Procedures in Mathematics*, written in 1954,

> *. . . the constructive transition to the continuum of real numbers is a serious affair. . . and I am bold enough to say that not even to this day are the logical issues involved in that constructive concept completely clarified and settled* (Weyl 1985, p. 17).

4 The Continuum in Constructive and Intuitionistic Mathematics

As we have observed, Brouwer maintained that mathematical activity is a form of construction in intuition. If the philosophically loaded term "in intuition" is removed, we are left simply with the term "construction," a much more concrete term on whose meaning mathematicians have achieved some measure of agreement. This leads to the idea of *constructive mathematics*.

The central principle of constructive mathematics is that a problem is to be regarded as solved only if an explicit solution can, in principle at least, be produced. Thus, for example, "There is an x such that $P(x)$" *means* that, in principle at least, we can explicitly produce an x such that $P(x)$. If the solution to the problem involves parameters, we must be able to present the solution explicitly by means of some *algorithm* or *rule* when given values of the parameters. That is, "for every x there is a y such that $P(x, y)$ *means* that, we possess an explicit method of determining, for any given x, a y for which $P(x, y)$.

The practice of constructive mathematics requires, as Brouwer recognized, the abandoning of certain laws of classical logic. In constructive mathematical reasoning *an existential statement can be considered affirmed only when an instance is produced*, and *a disjunction can be considered affirmed only when an explicit one of the disjuncts is demonstrated*. Consequently, neither the classical law of excluded middle nor the law of strong reductio ad absurdum can be constructively admissible. Hermann Weyl said of nonconstructive existence proofs that "they inform the world that a treasure exists without disclosing its location."

Consider the existential statement *there exists an odd perfect number* (i.e., an odd number equal to the sum of its proper divisors) which we shall write as $\exists nP(n)$. Its contradictory is the statement $\forall n\neg P(n)$. Classically, the law of excluded middle then allows us to affirm the disjunction

$$\exists nP(n) \vee \forall n\neg P(n) \tag{1}$$

Constructively, however, in order to affirm this disjunction we must *either* be in a position to affirm the first disjunct $\exists n P(n)$, i.e., to possess, or have the means of obtaining, an odd perfect number, *or* to affirm the second disjunct $\forall n \neg P(n)$, i.e., to possess a demonstration that no odd number is perfect. Since at the present time mathematicians have neither of these, the disjunction (1), and *a fortiori* the law of excluded middle is not constructively admissible.

The logical principles underlying constructive reasoning have been codified into what is known as *constructiive* or *intuitionistic* logic. Roughly speaking, constructive/intuitionistic logic is the body of arguments of classical logic, which can be established without the use, explicitly or implicitly, of the law of excluded middle.

Intuitionistic logic guides how one should *reason* in constructive mathematics. But how are mathematical objects to be given, or, as we shall say, *specified*, in constructive mathematics? To begin with, everybody knows what it means to specify an *integer*. For example, $7 \bullet 10^4$ is specified, while the number n defined to be 0 if an odd perfect number exists, and 1 if an odd perfect number does not exist, is not specified. The number of primes less than, say, $10^{1000000}$ is specified, in the sense intended here, since we could, *in principle at least*, calculate this number. Constructive mathematics as we shall understand it is not concerned with questions of feasibility, nor in particular with what can actually be computed in real time by actual computers.

In *constructive real analysis* (Bishop and Bridges 1985) a *rational number* may be defined as a pair of integers (a, b) without a common divisor (where $b > 0$ and a may be positive or negative, or a is 0 and b is 1). The usual arithmetic operations on the rationals, together with the operation of taking the absolute value, are then easily supplied with explicit definitions. Accordingly it is clear what it means to specify a rational number.

To specify exactly what is meant by giving a *real number* explicitly is not quite so simple. For a real number is by its nature an infinite object, but one normally regards only finite objects as capable of being given explicitly. This difficulty may be overcome by stipulating that, to be given a real number, we must be given a (finite) *rule* or *explicit procedure* for calculating it to any desired degree of accuracy. Intuitively speaking, to be given a real number r is to be given a method of computing, for each positive integer n, a rational number r_n such that

$$|r - r_n| < \frac{1}{n}.$$

These r_n will then obey the law

$$|r_m - r_n| \leq \frac{1}{m} + \frac{1}{n}.$$

So, given any numbers k, p, we have, setting $n = 2\,k$,

$$\left|r_{n+p} - r_n\right| \leq \frac{1}{n+p} + \frac{1}{n} \leq \frac{2}{n} = \frac{1}{k}.$$

One is thus led to *define* a (constructive) real number to be a sequence of rationals $(r_n) = r_1, r_2, \ldots$ such that, for any k, a number n can be found such that, for all p $\left|r_{n+p} - r_n\right| \leq \frac{1}{k}$.

Here we understand that to be given a *sequence* we must be in possession of a *rule* or explicit method for generating its members. Each rational number α may be regarded as a real number by identifying it with the real number (α, α, …). The set of all real numbers – the *constructive real line* or the *constructive continuum* – will be denoted, as usual, by $\mathbb{R}$. Now of course, for any "given" real number there are a variety of ways of giving explicit approximating sequences for it. Thus it is necessary to define an equivalence relation, "equality on the reals." The correct definition here is: $r =_{\mathbb{R}} s$ if and only if for any k, a number n can be found so that

$$\left|r_{n+p} - s_{n+p}\right| \leq \frac{1}{k} \text{ for all } p.$$

When we say that two real numbers are equal we shall mean that they are equivalent in this sense, and so write simply "=" for "$=_{\mathbb{R}}$". To assert the inequality $r \neq s$ of two real numbers r, s is to assert that the equality $r = s$ leads to a contradiction. Inequality in this sense is constructively weak. In constructive mathematics a stronger notion of inequality, that of *apartness*, is normally used instead. We say that r and s are *apart*, or *distinguishable*, written $r \# s$, if n and k can actually be found so that $\left|r_{n+p} - s_{n+p}\right| > \frac{1}{k}$ for all p. Clearly $r \# s$ implies $r \neq s$, but the converse cannot be affirmed constructively. (In fact the converse is equivalent to *Markov's Principle*, which asserts that, if, for each n, $x_n = 0$ or 1, and if it is contradictory that $x_n = 0$ for all n, then there exists n for which $x_n = 1$. This thesis is accepted by some, but not all schools of constructivism.)

Is it constructively the case that for any real numbers x and y, we have $x = y \vee x \neq y$? The answer is no. For if this assertion were constructively true, then, in particular, we would have a method of deciding whether, for any given rational number r, whether $r = \pi^{\sqrt{2}}$ or not. But at present no such method is known — it is not known, in fact, whether $\pi^{\sqrt{2}}$ is rational or irrational. We can, of course, calculate $\pi^{\sqrt{2}}$ to as many decimal places as we please, and if in actuality it is unequal to a given rational number r, we shall discover this fact after a sufficient amount of calculation. If, however, $\pi^{\sqrt{2}}$ is *equal* to r, even several centuries of computation cannot make this fact certain; we can be sure only that is very close to r. We have no method which will tell us, in finite time, whether $\pi^{\sqrt{2}}$ exactly coincides with r or not. This situation may be summarized by saying that equality on the reals is *not decidable*. (By contrast, equality on the integers or rational numbers is decidable.) Observe that this does *not* mean $\neg(x = y \vee x \neq y)$. We have not actually derived a *contradiction* from the assumption $x = y \vee x \neq y$; we have only given an example showing its implausibility. It is natural to ask whether it can actually be *refuted*. For this it would be necessary to make some assumption concerning the real numbers which contradicts classical mathematics. Certain schools of constructive mathematics are willing to make such assumptions; but the majority of constructivists confine themselves to methods which are also classically correct.

Despite the fact that constructive equality of real numbers is not a decidable relation, it is *balanced* in the sense of satisfying the *law of double negation* $\neg(r \neq s) \Rightarrow r = s$. In fact, we can prove the stronger assertion that $\neg(r \# s) \Rightarrow r = s$. For, given k, we may choose n so that $|r_{n+p} - r_n| \leq \frac{1}{4k}$ and $|s_{n+p} - s_n| \leq \frac{1}{4k}$ for all p. If $|r_n - s_n| \geq \frac{1}{k}$, then we would have $|r_{n+p} - s_{n+p}| \geq \frac{1}{2k}$ for all p, which entails $r \neq s$. If $\neg(r \# s)$, it follows that $|r_n - s_n| < \frac{1}{k}$ and $|r_{n+p} - s_{n+p}| \leq \frac{2}{k}$ for every p. Since for every k we can find n so that this inequality holds for every p, it follows that $r = s$. (From the facts that $\neg(r \# s) \Rightarrow r = s$ it follows easily that $r \neq s \Leftrightarrow \neg\neg(r \# s)$).

One should not, however, conclude from the stability of equality that the law of double negation $\neg\neg A \rightarrow A$ is generally affirmable. That it is not can be seen from the following example. Write the decimal expansion of π and below the decimal expansion $\rho = 0.333\ldots$, terminating it as soon as a sequence of digits 0123456789 has appeared in π. Then if the 9 of the first sequence 0123456789 in π is the k^{th} digit after the decimal point, $\rho = \frac{10^k - 1}{3 \cdot 10^k}$. Now suppose that ρ were not rational; then $\rho = \frac{10^k - 1}{3 \cdot 10^k}$ would be impossible and no sequence 0123456789 could appear in π, so that $\rho = \frac{1}{3}$, which is also impossible. Thus the assumption that ρ is not rational leads to a contradiction; yet we are not warranted to assert that r is rational, for this would mean that we could calculate integers m and n for which $\rho = \frac{m}{n}$. But this evidently requires that we can produce a sequence 0123456789 in π or demonstrate that no such sequence can appear, and at present we can do neither.

Order on the Constructive Real Line. The *order relation* on the reals is given constructively by stipulating that $r < s$ is to mean that we have an explicit lower bound on the distance between r and s. That is,

$$r < s \Leftrightarrow n \text{ and } k \text{ can be found so that } s_{n+p} - r_{n+p} > 1/k \text{ for all } p.$$

It can readily be shown that, for any real numbers x, y such that $x < y$, there is a rational number α such that $x < \alpha < y$.

We observe that $r \# s \Leftrightarrow r < s \vee s < r$. The implication from right to left is clear. Conversely, suppose that $r \# s$. Find n and k so that $|r_{n+p} - s_{n+p}| > \frac{1}{k}$ for every p, and determine $m > n$ so that $|r_m - r_{m+p}| < \frac{1}{4k}$ and $|s_m - s_{m+p}| < \frac{1}{4k}$ for every p. Either $r_m - s_m > \frac{1}{k}$ or $s_m - r_m > \frac{1}{k}$; in the first case $r_{m+p} - s_{m+p} > \frac{1}{2k}$ for every p, whence $s < r$; similarly, in the second case, we obtain $r < s$.

We define $r \leq s$ to mean that $s < r$ is false. Notice that $r \leq s$ is not the same as $r < s$ or $r = s$: in the case of the real number ρ defined above, for instance, clearly $\rho \leq \frac{1}{3}$; but we do not know whether $\rho < \frac{1}{3}$ or $\rho = \frac{1}{3}$. Still, it is true that $r \leq s \wedge s \leq r \Rightarrow r = s$. For the premise is the negation of $r < s \vee s < r$, which, by the above, is equivalent to $\neg r \# s$. But we have already seen that this last implies $r = s$.

There are several common properties of the order relation on real numbers which hold classically but which cannot be established constructively. Consider, for example, the trichotomy law $x < y \vee x = y \vee y < x$. Suppose we had a method enabling us to decide which of the three alternatives holds. Applying it to the case $y = 0$, $x = \pi^{\sqrt{2}} - r$ for rational r would yield an algorithm for determining whether $\pi^{\sqrt{2}} = r$ or not, which we have already observed is an open problem. One can also

demonstrate the failure of the trichotomy law (as well as other classical laws) by the use of "fugitive sequences." Here one picks an unsolved problem of the form $\forall nP(n)$, where P is a decidable property of integers – for example, Goldbach's conjecture that every even number ≥ 4 is the sum of two odd primes. Now one defines a sequence – a "fugitive" sequence – of integers (n_k) by $n_k = 0$ if $2\,k$ is the sum of two primes and $n_k = 1$ otherwise. Let r be the real number defined by $r_k = 0$ if $n_k = 0$ for all $j \leq k$, and $r_k = 1/m$ otherwise, where m is the least positive integer such that $n_m = 1$. It is then easy to check that $r \geq 0$ and $r = 0$ if and only if Goldbach's conjecture holds. Accordingly the correctness of the trichotomy law would imply that we could resolve Goldbach's conjecture. Of course, Goldbach's conjecture might be resolved in the future, in which case we would merely choose another unsolved problem of a similar form to define our fugitive sequence.

A similar argument shows that the law $r \leq s \vee s \leq r$ also fails constructively: define the real number s by $s_k = 0$ if $n_k = 0$ for all $j \leq k$; $s_k = 1/m$ if m is the least positive integer such that $n_m = 1$, and m is even; $s_k = -1/m$ if m is the least positive integer such that $n_m = 1$, and m is odd. Then $s \leq 0$ (resp. $0 \leq s$) would mean that there is no number of the form $2 \cdot 2\,k$ (resp. $2 \cdot (2\,k + 1)$) which is not the sum of two primes. Since neither claim is at present known to be correct, we cannot assert the disjunction $s \leq 0 \vee 0 \leq s$.

In constructive analysis there is a convenient substitute for trichotomy known as the *comparison principle*. This is the assertion

$$r < t \Rightarrow r < s \vee s < t.$$

Its validity can be established in a manner similar to the foregoing.

Albebraic Operations on the Constructive Reals. The fundamental operations $+$, $-$, $\cdot$, $^{-1}$ and $|\cdot|$ are defined for real numbers as one would expect, viz.

- $r + s$ is the sequence $(r_n + s_n)$
- $r - s$ is the sequence $(r_n - s_n)$
- $r \cdot s$ or rs is the sequence $(r_n s_n)$
- if $r \# 0$, r^{-1} is the sequence (t_n), where $t_n = {r_n}^{-1}$ if $t_n \neq 0$ and $t_n = 0$ if $r_n = 0$
- $|\,r\,|$ is the sequence $(|r_n|)$

It is then easily shown that $rs \# 0 \Leftrightarrow r \# 0 \wedge s \# 0$. For if $r \# 0 \wedge s \# 0$, we can find k and n such that $|r_{n+p}| > \frac{1}{k}$ and $|s_{n+p}| > \frac{1}{k}$ for every p, so that $|r_{n+p}s_{n+p}| > \frac{1}{k^2}$ for every p, and $rs \# 0$. Conversely, if $rs \# 0$, then we can find k and n so that

$$|r_{n+p}s_{n+p}| > \frac{1}{k}, |r_{n+p} - r_n| < 1, |s_{n+p} - s_n| < 1$$

for every p. It follows that

$$|r_{n+p}| > \frac{1}{k}(|s_n| + 1) \text{ and } |s_{n+p}| > \frac{1}{k}(|r_n| + 1)$$

for every p, whence $r \# 0 \wedge s \# 0$.

But it is not constructively true that, if $rs = 0$, then $r = 0$ or $s = 0$! To see this, use the following prescription to define two real numbers r and s. If in the first n decimals of π no sequence 0123456789 occurs, put $r_n = s_n = 2^{-n}$; if a sequence of this kind does occur in the first n decimals, suppose the 9 in the first such sequence is the k^{th} digit. If k is odd, put $r_n = 2^{-k}$, $s_n = 2^{-n}$; if k is even, put $r_n = 2^{-n}$, $s_n = 2^{-k}$. Then we are unable to decide whether $r = 0$ or $s = 0$. But $rs = 0$. For in the first case above r_n $s_n = 2^{-2n}$; in the second r_n $s_n = 2^{-k-n}$. In either case $|r_n s_n| < \frac{1}{m}$ for $n > m$, so that $rs = 0$.

Convergence of Sequences and Completeness of the Constructive Reals. As usual, a sequence (a_n) of real numbers is said to *converge* to a real number b, or to have *limit* s if, given any natural number k, a natural number n can be found so that for every natural number p,

$$\left|b - a_{n+p}\right| < 2^{-k}.$$

As in classical analysis, a constructive necessary and condition that a sequence (a_n) of real numbers be convergent is that it be a *Cauchy* sequence, that is, if, given any natural number k, a natural number n can be found so that for every natural number p,

$$\left|a_{n+p} - a_n\right| < 2^{-k}.$$

However, some classical theorems concerning convergent sequences are no longer valid constructively. For example, a bounded momotone sequence need no longer be convergent. A simple counterexample is provided by the sequence (a_n) defined as follows: $a_n = 1–2^{-n}$ if among the first n digits in the decimal expansion of π no sequence 0123456789 occurs, while $a_n = 2–2^{-n}$ if among these n digits such a sequence does occur. Since it is not known whether the limit of this sequence, if it exists, is 1 or 2, we cannot claim that that this limit exists as a well-defined real number.

In classical analysis $\mathbb{R}$ is *complete* in the sense that every nonempty set of real numbers that is bounded above has a supremum. As it stands, this assertion is constructively incorrect. For consider the set A of members $\{x_1, x_2, \ldots\}$ of any fugitive sequence of 0 s and 1 s. Clearly A is bounded above, and its supremum would be either 0 or 1. If we knew which, we would also know whether $x_n = 0$ for all n, and the sequence would no longer be fugitive.

Nevertheless, the completeness of $\mathbb{R}$ can be salvaged by defining suprema and infima somewhat more delicately than is customary in classical mathematics. A nonempty set A of real numbers is *bounded above* if there exists a real number b, called an *upper bound* for A, such that $x \leq b$ for all $x \in A$. A real number b is called a *supremum*, or *least upper bound*, of A if it is an upper bound for A and if for each $\varepsilon > 0$ there exists $x \in A$ with $x > b - \varepsilon$. We say that A is *bounded below* if there exists a real number b, called a *lower bound* for A, such that $b \leq x$ for all $x \in A$. A real number b is called an *infimum*, or *greatest lower bound*, of A if it is a lower bound for

A and if for each $\varepsilon > 0$ there exists $x \in A$ with $x < b + \varepsilon$. The supremum (respectively, infimum) of A, is unique if it exists and is written sup A (respectively, inf A).

Let us prove the *constructive least upper bound principle*.

Theorem Let A be a nonempty set of real numbers that is bounded above. Then sup A exists if and only if for all $x, y \in \mathbb{R}$ with $x < y$, either y is an upper bound for A or there exists $a \in A$ with $x < a$.

Proof If sup A exists and $x < y$, then either sup $A < y$ or $x <$ sup A; in the latter case we can find $a \in A$ with sup A – (sup $A - x$) $< a$, and hence $x < a$. Thus the stated condition is necessary.

Conversely, suppose the stated condition holds. Let a_1 be an element of A and choose an upper bound b_1 for A with $b_1 > a_1$. We construct recursively a sequence (a_n) in A and (b_n) of upper bounds for A such that, for each $n \geq 0$,

(i) $a_n \leq a_{n+1} \leq b_{n+1} \leq b_n$

and

(ii) $b_{n+1} - a_{n+1} \leq \frac{3}{4}(b_n - a_n)$.

Having found $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$, if $a_n + \frac{3}{4}(b_n - a_n)$ is an upper bound for A, put $b_{n+1} = a_n + \frac{3}{4}(b_n - a_n)$ and $a_{n+1} = a_n$; while if there exists $a \in A$ with $a > a_n + \frac{3}{4}(b_n - a_n)$, we set $a_{n+1} = a$ and $b_{n+1} = b_n$. This completes the recursive construction.

From (i) and (ii) we have

$$0 \leq b_n - a_n \leq (\tfrac{3}{4})^{n-1}(b_1 - a_1).$$

It follows that the sequences (a_n) and (b_n) converge to a common limit 1 with $a_n \leq 1 \leq b_n$ for $n \geq 1$. Since each b_n is an upper bound for A, so is 1. On the other hand, given $\varepsilon > 0$, we can choose n so that $1 \geq a_n > 1 - \varepsilon$, where $a_n \in A$. Hence $1 = \sup A$.

An analogous result for infima can be stated and proved in a similar way.

Functions on the ConstructiveReals. Considered constructively, a *function* from $\mathbb{R}$ to $\mathbb{R}$ is a rule F which enables us, when given a real number x, to compute another real number $F(x)$ in such a way that, if $x = y$, then $F(x) = F(y)$. It is easy to check that every polynomial is a function in this sense, and that various power series and integrals, for example, those defining tan x and e^x, also determine functions. Viewed constructively, some classically defined "functions" on $\mathbb{R}$ can no longer be considered to be defined on the whole of $\mathbb{R}$. Consider, for example, the "blip" function B defined by $B(x) = 0$ if $x \neq 0$ and $B(0) = 0$. Here the domain of the function is $\{x \in \mathbb{R}: x = 0 \vee x \neq 0\}$. But we have seen that we cannot assert dom$(B) = \mathbb{R}$. Accordingly,

the blip function is not well defined as a function from $\mathbb{R}$ to $\mathbb{R}$. Of course, classically, B is the simplest *discontinuous* function defined on $\mathbb{R}$. The fact that the simplest possible discontinuous function fails to be defined on the whole of $\mathbb{R}$ gives grounds for the suspicion that *no* function defined on $\mathbb{R}$ can be discontinuous; in other words, that, constructively speaking, *all functions defined on* $\mathbb{R}$ *are continuous* (as remarked in the previous section, this was a central tenet of intuitionism's founder, Brouwer). The claim is plausible. For if a function F is well defined on all reals x, it must be possible to compute the value for all rules x determining real numbers, that is, determining their sequences of rational approximations $x_1, x_2, \ldots$. Now $F(x)$ must be computed to accuracy ε in a finite number of steps – the number of steps depending on ε. This means that only finitely many approximations can be used, i.e., $F(x)$ can be computed to within ε only when x is known within δ for some δ. Thus F should indeed be continuous. In fact all known examples of constructive functions defined on $\mathbb{R}$ are continuous. Constructively, a real-valued function f is *continuous* if for each $\varepsilon > 0$ we can find a specific $\delta > 0$ such that $|f(x) - (y)| \leq \varepsilon$ whenever $|x - y| < \delta$. If all functions on $\mathbb{R}$ are continuous, then a subset A of $\mathbb{R}$ may fail to be genuinely *complemented*: that is, there may be no subset B of $\mathbb{R}$ disjoint from A such that $\mathbb{R} = A \cup B$. To see this, we first suppose that A, B are disjoint subsets of $\mathbb{R}$ and that there is a point $a \in A$ which can be approached arbitrarily closely by points of B (or vice versa). Then, assuming all functions on $\mathbb{R}$ are continuous, it cannot be the case that $\mathbb{R} = A \cup B$. For if so, we may define the function f on $\mathbb{R}$ by $f(x) = 0$ if $x \in A$, $f(x) = 1$ if $x \in B$. Then for all $\delta > 0$ there is $b \in B$ for which $|b - a| < \delta$, but $|f(b) - f(a)| = 1$. Thus f fails to be continuous at a, and we conclude that $\mathbb{R} \neq A \cup B$. Now if we take A to be any finite set of real numbers, any union of open or closed intervals, or the set $\mathbb{Q}$ of rational numbers, then in each case the set B of points "outside" A satisfies the above condition. Accordingly, for each such subset A, $\mathbb{R}$ is not "decomposable" into A and the set of points "outside" A, in the sense that these two sets of points together do not exhaust $\mathbb{R}$. This fact indicates that the constructive continuum is a great deal more "cohesive" than its classical counterpart. For classically, the continuum is merely *connected* in the sense that it is not (nontrivially) decomposable into two open (or closed) subsets. Constructively, however, $\mathbb{R}$ is indecomposable into subsets which are neither open nor closed. In this sense the constructive real line can be brought close to the ideal of a true continuum.

Certain well-known theorems of classical analysis concerning continuous functions fail in constructive analysis. One such is the *theorem of the maximum*: a uniformly continuous function on a closed interval assumes its maximum at some point. For consider, as Fig. 1 below, a function f: $[0, 1] \rightarrow \mathbb{R}$ with two relative

Fig. 1

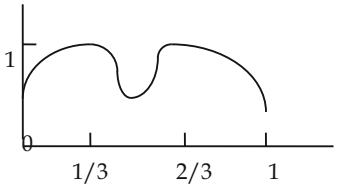


Fig. 2

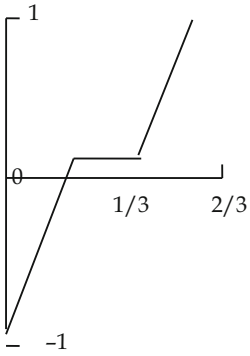


maxima, one at $x = 1/3$ and the other at $x = 2/3$ and of approximately the same value. Now arrange things so that $f\left(\frac{1}{3}\right) = 1$ and $f\left(\frac{2}{3}\right) = 1 + t$, where t is some small parameter. If we could tell where f assumes its absolute maximum, clearly we could also determine whether $t \leq 0$ or $t \geq 0$, which, as we have seen, is not, in general, possible. Nevertheless, it can be shown that from f we can in fact calculate the maximum value itself, so that at least one can assert the existence of that maximum, even if one cannot tell exactly where it is assumed.

Another classical result that fails to hold constructively in its usual form is the well-known *intermediate value theorem*. This is the assertion that, for any continuous function f from the unit interval [0, 1] to $\mathbb{R}$, such that $f(0) = -1$ and $f(1) = 1$, there exists a real number $a \in [0, 1]$ for which $f(a) = 0$. To see that this fails constructively, consider the function f depicted in Fig. 2 above: here f is piecewise linear, taking the value t (a small parameter) between $x = 1/3$ and $x = 2/3$. If the intermediate value theorem held, we could determine a for which $f(a) = 0$. Then either $a < 2/3$ or $a > 1/3$; in the former case $t \geq 0$; in the latter $t \leq 0$. Thus we would be able to decide whether $t \geq 0$ or $t \leq 0$; but we have seen that this is not constructively possible in general.

Nevertheless, it can be shown that, constructively, the intermediate value theorem is "almost" true in the sense that

$$\forall f \forall \varepsilon > 0 \exists a \, (|f(a)| < \varepsilon)$$

and also in the sense that, if we write $P(f)$ for

$$\forall b \forall a < b \exists c \, (a < c < b \wedge f(c) \neq\neq 0),$$

then

$$\forall f [P(f) \rightarrow \exists x \, (f(x) = 0)].$$

This example illustrates how a single classical theorem "refracts" into several constructive theorems.

Axiomatizing the Constructive Reals. The constructive reals can be furnished with an axiomatic description (Bridges 1999). We begin by assuming the existence of a set $\boldsymbol{R}$ with

- A binary relation $>$ (*greater than*)
- A corresponding *apartness relation* # defined by $x \# y \Leftrightarrow x > y$ or $y > x$
- A unary operation $x \mapsto -x$
- Binary operations $(x, y) \mapsto x + y$ (*addition*) and $(x, y) \mapsto xy$ (*multiplication*)
- Distinguished elements 0 (*zero*) and 1 (*one*) with $0 \neq 1$
- A unary operation $x \mapsto x^{-1}$ on the set of elements $\neq 0$

The elements of $\boldsymbol{R}$ are called *real numbers*. *A* real number x is *positive* if $x > 0$ and *negative* if $-x > 0$. The relation $\geq$ (*greater than or equal to*) is defined by

$$x \geq y \Leftrightarrow \forall z(y > z \Rightarrow x > z).$$

The relations $<$ and $\leq$ are defined in the usual way; x is *nonnegative* if $0 \leq x$.

The sets $\boldsymbol{N}$ of natural numbers, $\boldsymbol{N}^+$ of positive integers, $\mathbf{Z}$ of integers and $\boldsymbol{Q}$ of rational numbers are identified with the usual subsets of $\boldsymbol{R}$; for instance, $\boldsymbol{N}^+$ is identified with the set of elements of R of the form $1 + 1 + \cdots + 1$.

These relations and operations are subject to the following three groups of axioms, which, taken together, form the system **CA** of axioms for *constructive analysis*, or the *constructive real numbers.*

Field Axioms

$$x + y = y + x \quad (x + y) + z = x + (y + z) \quad 0 + x = x \quad x + (-x) = 0 \quad xy = yx$$
$$(xy)z = x(yz) \quad 1x = x \quad x \# 0 \rightarrow xx^{-1} = 1 \quad x(y + z) = xy + xz$$

Order Axioms

$$(x \geq y \wedge y \geq x) \leftrightarrow x = y.$$
$$\neg(x > y \wedge y > x) \quad x > y \rightarrow \forall z(x > z \vee z > y) \quad \neg(x \# y) \rightarrow x = y$$
$$x > y \rightarrow \forall z(x + z > y + z) \quad (x > 0 \wedge y > 0) \rightarrow xy > 0.$$

Notice that from the fourth of the order axioms it follows that $\neg(x \neq y) \rightarrow x = y$, that is, the equality relation is *balanced*. (Here and in the sequel $x \neq y$ is an abbreviation for $\neg(x = y)$).

The final two axioms introduce special properties of $>$ and $\geq$. In the second of these the notions *bounded above*, *bounded below*, *and bounded* are defined as in classical mathematics, and the *least upper bound*, if it exists, of a nonempty set S of real numbers is the unique real number b such that

- b is an upper bound for S.
- For each $c < b$ there exists $s \in S$ with $s > c$.

Here a "nonempty" has the stronger constructive meaning of being inhabited, to wit, that an element of the set in question can actually be constructed.

Special Properties of >.

Archimedean axiom. For each $x \in \boldsymbol{R}$ such that $x \geq 0$ there exists $n \in \boldsymbol{N}$ such that $x < n$.

The least upper bound principle. Let S be a nonempty subset of R that is bounded above, such that for all real numbers a, b with $a < b$, either b is an upper bound for S or else there exists $s \in S$ with $s > a$. Then S has a least upper bound.

The following basic properties of $>$ and $\geq$ can then be established.

$$\neg(x > x)\ x \geq x\ (x > y \wedge y > z) \rightarrow x > z\ \neg(x > y \wedge y \geq x)$$
$$(x > y \geq z) \rightarrow x > z \neg(x > y) \leftrightarrow y \geq x\ \neg(x \geq y) \leftrightarrow \neg$$
$$\neg(y > x)\ (x \geq y \geq z) \rightarrow x \geq z\ \neg(x > y \wedge x = y)$$
$$x \geq 0 \rightarrow (x = 0 \leftrightarrow \forall \varepsilon > 0(x < \varepsilon))x + y > 0 \rightarrow (x > 0 \vee y > 0)$$
$$x > 0 \rightarrow -x < 0\ (x > y \wedge z < 0) \rightarrow yz > xz\ x0 \leftrightarrow x^2 > 0\ 1 > 0$$
$$0 < x < 1 \rightarrow x > x^{-2}\ n \in N^+ \rightarrow n^{-1} > 0$$
$$\textit{if}\ x > 0 \text{ and } y \geq 0, \text{then there exists } n \in \mathbf{Z} \text{ such that } nx > y$$
$$x > 0 \rightarrow x^{-1} > 0\ xy > 0 \rightarrow (x \neq 0 \vee y \neq 0)$$
$$\text{if } a < b, \text{then there exists } r \in \mathbf{Q} \text{ such that } a < r < b$$

The constructive real line $\mathbb{R}$ as introduced above is a model of **CA**. Are there any other models, that is, models not isomorphic to $\mathbb{R}$? If classical logic is assumed, **CA** is a categorical theory and so the answer is no. But this is not the case within intuitionistic logic, for it can be shown that, in intuitionistic set theory, both the Dedekind and Cantor reals are models of **CA**, while these may fail to be isomorphic.

The Intuitionistic Continuum. In constructive analysis, a real number is an infinite (convergent) sequence of rational numbers generated by an effective rule, so that the constructive real line is essentially just a restriction of its classical counterpart. Brouwerian intuitionism takes a more liberal view of the matter, resulting in a considerable enrichment of the arithmetical continuum over the version offered by strict constructivism. As conceived by intutionism, the arithmetical continuum admits as real numbers "not only infinite sequences determined in advance by an effective rule for computing their terms, but also ones in whose generation free selection plays a part." (Dummett 1977, p. 62). The latter are called (*free*) *choice sequences*. Without loss of generality we may and shall assume that the entries in choice sequences are natural numbers.

Hermann Weyl describes Brouwer's conception of choice sequences in the following terms:

> *In Brouwer's analysis*, *the individual place in the* continuum, *the real number*, *is to be defined not by a set but by a* sequence *of natural numbers*, *namely*, *by a law which correlates with every natural number n a natural number* $\varphi(n)$. . . *How then do assertions arise which concern*. . . *all real numbers*, *i.e.*, *all values of a real variable? Brouwer shows that frequently statements of this form in traditional analysis*, *when correctly interpreted*, *simply concern the totality of natural numbers*. *In cases where they do not*, *the notion of sequence changes its meaning*: *it no longer signifies a sequence determined by some law or other*, *but rather one that is created* step by step by free acts of choice, *and thus necessarily remains* in

> statu nascendi. *This* "*becoming*" selective sequence (werdende Wahlfolge) *represents the continuum*, *or the variable*, *while the sequence determined* ad infinitum *by a law represents the individual real number in the continuum*. *The continuum no longer appears*, *to use Leibniz's language*, *as an aggregate of fixed elements but as a medium of free* "*becoming*". *Of a selective sequence* in statu nascendi, *naturally only those properties can be meaningfully asserted which already admit of a yes-or-no decision* (*as to whether or not the property applies to the sequence*) *when the sequence has been carried to a certain point*; *while the continuation of the sequence beyond this point*, *no matter how it turns out*, *is incapable of overthrowing that decision*. (Weyl 1949, p. 52).

While constructive analysis does not formally contradict classical analysis and may in fact be regarded as a subtheory of the latter, a number of intuitionistically plausible principles have been proposed for the theory of choice sequences, which render intuitionistic analysis divergent from its classical counterpart. (Intuitionistic analysis, nevertheless, an extension of CA.)

One such principle is *Brouwer's Continuity Principle*. This asserts that, given a relation $R(\alpha, n)$ between choice sequences α and numbers n, if for each α a number n may be determined for which $R(\alpha, n)$ holds, then n can already be determined on the basis of the knowledge of a finite number of terms of α. This may be seen to be plausible if one considers that according to Brouwer the construction of a choice sequence is incompletable; at any given moment we can know nothing about it outside the identities of a finite number of its entries. Brouwer's Continuity Principle amounts to the assertion that every function from $\mathbb{N}^{\mathbb{N}}$ to $\mathbb{N}$ is continuous.

From this one can prove a weak version of the Continuity Theorem, namely, that every function from $\mathbb{R}$ to $\mathbb{R}$ is continuous (Bridges and Richman 1987, p. 109). Another such principle is *Bar Induction*, a certain form of induction for well-founded sets of finite sequences (Dummett 1977; Bridges and Richman 1987). Brouwer used Bar Induction and the Continuity Principle in proving his Continuity Theorem that every real-valued function defined on a closed interval is uniformly continuous, from which it follows that the intuitionistic continuum, and all of its closed interval, are cohesive.

Brouwer gave the intuitionistic conception of mathematics an explicitly subjective twist by introducing the *creative subject*. The creative subject was conceived as a kind of idealized mathematician for whom time is divided into discrete sequential stages, during each of which he may test various propositions, attempt to construct proofs, and so on. In particular, it can always be determined whether or not at stage n the creative subject has a proof of a particular mathematical proposition p. While the theory of the creative subject remains controversial, its purely mathematical consequences can be obtained by a simple postulate, which is entirely free of subjective and temporal elements. The creative subject allows us to define, for a given proposition p, a binary sequence $<a_n>$ by $a_n = 1$ if the creative subject has a proof of p at stage n; $a_n = 0$ otherwise.

Now if the construction of these sequences is the only use made of the creative subject, then references to the latter may be avoided by postulating the principle known as *Kripke's Scheme:*

For each proposition p there exists an increasing binary sequence $<a_n>$ such that p holds if and only if $a_n = 1$ for some n.

Taken together, these principles have been shown to have remarkable consequences for the cohesiveness of subsets of the continuum. Not only is the intuitionistic continuum cohesive, but, assuming Brouwer's Continuity Principle and Kripke's Scheme, it remains cohesive even if one pricks it with a pin "The [intuitionistic] continuum has, as it were, a syrupy nature, one cannot simply take away one point." If in addition Bar Induction is assumed, then, even more surprisingly, cohesiveness is maintained even when all the rational points are removed from the continuum. Thus it is appropriate to describe the classical continuum as the "frozen intuitionistic continuum."

5 Nonstandard Analysis and the Hyperreal Line

Once the continuum had been provided with a set-theoretic foundation, the use of the infinitesimal in mathematical analysis was largely abandoned. And so the situation remained for a number of years. The first signs of a revival of the infinitesimal approach to analysis surfaced in the 1950s with a paper by A. H. Laugwitz and C. Schmieden (Laugwitz and Schmieden 1958). But the major breakthrough came in 1960 when it occurred to the mathematical logician **Abraham Robinson** (1918–1974) that "the concepts and methods of contemporary Mathematical Logic are capable of providing a suitable framework for the development of the Differential and Integral Calculus by means of infinitely small and infinitely large numbers." (Robinson 1996, p. xiii). This insight led to the creation of *Nonstandard Analysis* (**NSA**), which Robinson regarded as realizing Leibniz's conception of infinitesimals and infinities as ideal numbers possessing the same properties as ordinary real numbers. In the introduction to his book on the subject he writes:

It is shown in this book that Leibniz's ideas can be fully vindicated and that they lead to a novel and fruitful approach to classical Analysis and to many other branches of mathematics. The key to our method is provided by the detailed analysis of the relation between mathematical languages and mathematical structures which lies at the bottom of contemporary model theory.

After Robinson's initial insight, a number of ways of presenting Nonstandard Analysis were developed. Here is a sketch of one of them (Bell and Machover 1977; Keisler 1994).

Starting with the classical real line $\mathbb{R}$, a set-theoretic universe – the *standard universe* – is first constructed over it: here by such a universe is meant a set U containing $\mathbb{R}$ which is closed under the usual set-theoretic operations of union, power set, Cartesian products, and subsets. Now write $\mathbf{U}$ for the structure $(U, \in)$, where $\in$ is the usual membership relation on U: associated with this is the extension $\mathcal{L}(U)$ of the first-order language of set theory to include a name u for each element u

of U. Now, using the well-known compactness theorem for first-order logic, U is extended to a new structure $^*\mathbf{U} = (^*U, {}^*\in)$, called a *nonstandard universe*, satisfying the following key principle:

> ***Saturation Principle.*** *Let* $\mathbf{\Phi}$ *be a collection of* $\mathcal{L}(U)$*-formulas with exactly one free variable. If* $\mathbf{\Phi}$ *is* finitely satisfiable *in* $\mathbf{U}$, *that is, if for any finite subset* $\mathbf{\Phi}'$ *of* $\mathbf{\Phi}$ *there is an element of* U *which satisfies all the formulas of* $\mathbf{\Phi}'$ in $\mathbf{U}$, *then there is an element of* $^*U$ *which satisfies all the formulas of* $\mathbf{\Phi}$ *in* $^*\mathbf{U}$.

The saturation property expresses the intuitive idea that the nonstandard universe is very rich in comparison to the standard one. Indeed, while there may exist, for each finite subcollection F of a given collection P of properties, an element of U satisfying the members of F in U, there may not necessarily be an element of U satisfying *all* the members of P. The saturation of $^*\mathbf{U}$ guarantees the existence of an element of $^*U$ which satisfies, in $^*\mathbf{U}$, all the members of P. For example, suppose the set $\mathbb{N}$ of natural numbers is a member of U; for each $n \in \mathbb{N}$ let $P_n(x)$ be the property $x \in \mathbb{N}$ & $n < x$. Then clearly, while each finite subcollection of the collection $\mathrm{P} = \{P_n: n \in \mathbb{N}\}$ is satisfiable in U, the whole collection is not. An element of $^*U$ satisfying all the members of P in $^*\mathbf{U}$ will then be a "natural number" greater than every member of $\mathbb{N}$, that is, an *infinite* number.

From the saturation property it follows that $^*\mathbf{U}$ satisfies the important

Transfer Principle. *If* σ *is any sentence of* $\mathcal{L}$(U), *then* σ *holds in* $\mathbf{U}$ *if and only if it holds in* $^*\mathbf{U}$.

The transfer principle may be seen as a version of Leibniz's continuity principle: it asserts that all first-order properties are preserved in the passage to or "transfer" from the standard to the nonstandard universe.

The members of U are called *standard sets*, or *standard objects*; those in $^*U - U$ *nonstandard sets* or *nonstandard objects*: $^*U$ thus consists of both standard and nonstandard objects. The members of $^*U$ will also be referred to as **-sets* or **-objects.* Since $U \subseteq {}^*U$, under this convention every set (object) is also a *-set (object). The **-members* of a *-set A are the *-objects x for which $x \,{}^*\in A$

If A is a standard set, we may consider the collection $\mathrm{A}^\star$ – the *inflate* of A – consisting of all the *-members of A: this is not necessarily a standard set nor even a *-set. The inflate of a standard set may be regarded as the same set viewed from a nonstandard vantage point. While clearly $A \subseteq A^\star$, $A^\star$ may contain "nonstandard" elements not in A. It can in fact be shown that *infinite* standard sets always get "inflated" in this way. Using the transfer principle, any function f between standard sets automatically extends to a function – also written f – between their inflates.

Each mathematical structure $\mathbf{A} = (A, R, \ldots)$ has an inflate $\mathbf{A}^\star = (A^\star, R^\star)$. From the transfer principle it follows that $\mathbf{A}$ and $\mathbf{A}^\star$ have precisely the same first-order properties.

Now suppose that the set $\mathbb{N}$ of natural numbers is a member of U. Then so is the set $\mathbb{R}$ of real numbers, since each real number may be identified with a set of natural numbers. $\mathbb{R}$ may be regarded as an ordered field, and the same is therefore true of its inflate $\mathbb{R}^\star$. This, the *hyperreal line*, has precisely the same first-order properties as $\mathbb{R}$.

The members of $\mathbb{R}^\star$ are called *hyperreals*. A standard hyperreal is then just a real, to which we shall refer for emphasis as a *standard real*. Since $\mathbb{R}$ is infinite, nonstandard hyperreals must exist. The saturation principle implies that there must be an *infinite* (nonstandard) hyperreal, that is, a hyperreal a such that $a > n$ for every $n \in \mathbb{N}$. In that case its reciprocal $\frac{1}{a}$ is infinitesimal in the sense of exceeding 0 and yet being smaller than $\frac{1}{n+1}$ for every $n \in \mathbb{N}$. In general, we call a hyperreal *a infinitesimal* if its absolute value $| a |$ is $< \frac{1}{n+1}$ for every $n \in \mathbb{N}$. In that case the set I of infinitesimals contains not just 0 but a substantial number (in fact, infinitely many) of other elements. Clearly I is an additive subgroup of $\mathbb{R}$, that is, if $a, b \in I$, then $a - b \in I$.

Note that $\mathbb{R}^\star$ is thus a nonarchimedean ordered field. One might question whether this is compatible with the facts that $\mathbb{R}^\star$ and $\mathbb{R}$ share the same first-order properties, but the latter is archimedean. These data are consistent because the archimedean property is not first-order. However, while $\mathbb{R}^\star$ is nonarchimedean, it is **-archimedean* in the sense that, for any $a \in \mathbb{R}^\star$ there is $n \in \mathbb{R}^\star$ for which $a < n$.

The members of the inflate $\mathbb{N}^\star$ of $\mathbb{N}$ are called *hypernatural numbers*. As for the hyperreals, it can be shown that $\mathbb{N}^\star$ also contains nonstandard elements which must exceed every member of $\mathbb{N}$: these are called *infinite* hypernatural numbers.

For hyperreals a, b we define $a \approx b$ and say that a and b are *infinitesimally close* if $a - b \in I$. This is an equivalence relation on the hyperreal line: for each hyperrreal a we write $\mu(a)$ for the equivalence class of a under this relation and call it the *monad* of a. The monad of a hyperreal a thus consists of all the hyperreals that are infinitesimally close to a: it may be thought of as a small cloud centered at a. Note also that $\mu(0) = I$.

A hyperreal a is *finite* if it is not infinite; this means that $| a | < n$ for some $n \in \mathbb{N}$. It is not difficult to show that finiteness is equivalent to the condition of *near-standardness*: here a hyperreal a is *near-standard* if $a \approx r$ for some standard real r.

Much of the usefulness of Nonstandard Analysis stems from the fact that statements of classical analysis involving limits or the (ε, δ) criterion admit succinct, intuitive translations into statements involving infinitesimals or infinite numbers, in turn enabling comparatively straightforward proofs to be given of classical theorems. Here are some examples of such translations:

- *Let* $< s_n >$ be *a standard infinite sequence of real numbers and let s be a standard real number. Then s is the limit of* $< s_n >$ *within* $\mathbb{R}$, $\lim_{n\to\infty} s_n = s$ *in the classical sense, if and only if* $s_n \approx s$ *for all* infinite *subscripts n*.
- A *standard sequence* $< s_n >$ *converges if and only if* $s_n \approx s_m$ *for all infinite n and m*. (Cauchy's criterion for convergence.)

Now suppose that f is a real-valued function defined on some open interval (a, b). We have remarked above that f automatically extends to a function – also written f – on (a, b).

- *In order that the standard real number c be the limit of* $f(x)$ *as x approaches* x_0, $\lim_{x\to x_0} f(x) = c$, *with* x_0 *a standard real number in* (a, b), *it is necessary and sufficient that* $f(x) \approx f(x_0)$ *for all* $x \approx x_0$.

- *The function f is continuous at a standard real number x_0 in (a, b) if and only if $f(x) \approx f(x_0)$ for all $x \approx x_0$.* (This is *equivalent to saying that f maps the monad of x_0 into the monad of $f(x_0)$.*
- *In order that the standard number c be the derivative of f ay x_0 it is necessary and sufficient that*

$$\frac{f(x) - f(x_0)}{x - x_0} \approx c$$

for all $x \neq x_0$ in the monad of x_0.

Many other branches of mathematics admit elegant and fruitful nonstandard formulations.

Finally, it should be pointed out that while the usual models of Nonstandard Analysis are obtained using highly nonconstructive tools, other methods have been developed for producing such models which are constructively acceptable. (Moerdijk 1995; Palmgren 1998, 2001).

6 The Continuum in Smooth Infinitesimal Analysis

Smooth Infinitesimal Analysis. In differential geometry it is customary to confine attention to functions between spaces which are *smooth*, that is, arbitrarily many times differentiable. *Smooth Infinitesimal Analysis* (**SIA**) provides a framework for mathematical analysis which embodies the practice of differential geometry in a remarkably direct and powerful way, namely, by stipulating that *all* functions – however defined – between spaces be smooth. In particular all functions defined on the real line **R** to itself are required to be smooth. In **SIA** this requirement is satisfied through the following considerations. Starting with a differentiable function f: $\mathbf{R} \to \mathbf{R}$, draw the graph of f, so generating a curve in the Cartesian plane. Now pick any point on the curve and consider a short length L of the curve around the point. If L is taken to be sufficiently short, it will appear to be *approximately* a straight line. In **SIA** it is required that, if L is taken to be of *infinitesimal* length, then it will be a straight line *exactly*. This idea in its turn is realized by postulating the existence in **R** of a set Δ of infinitesimals with the property that all functions on Δ are linear.

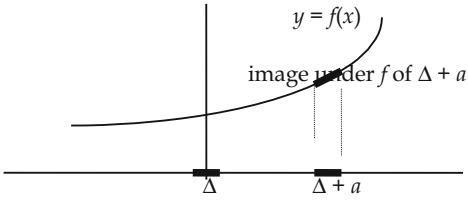
Thus in **SIA** we are given:

- An object **R** called the *real* line (or *smooth line*), on which the usual operations of addition and multiplication are defined and satisfy the usual algebraic laws governing real numbers (in particular 0 and 1 are present and are neutral elements under + and $\times$, respectively.
- A subset $\boldsymbol{\Delta}$ of the set **R** of real numbers called the *domain of infinitesimals*. $\boldsymbol{\Delta}$ is assumed to satisfy the following conditions:
  (1) $0 \in \boldsymbol{\Delta}$
  (2) *Any multiple of an infinitesimal is an infinitesimal*, that is, for any $a \in \mathbf{R}$, $x \in \boldsymbol{\Delta} \Rightarrow ax \in \boldsymbol{\Delta}$. It follows immediately from this that $\boldsymbol{\Delta}$ is *symmetric around* 0, that is, $\forall x\, (x \in \boldsymbol{\Delta} \Leftrightarrow -x \in \boldsymbol{\Delta})$.

(3) The ***Infinitesimal Linearity Principle*** or the ***Kock-Lawvere axiom.*** This asserts that all maps $\mathbf{\Delta}\to\mathbf{R}$ are *linear* (strictly speaking, *affine*, but no matter) in the following strong sense: for any f: $\mathbf{\Delta}\to\mathbf{R}$ there is a *unique* $a \in \mathbf{R}$ such that, for all $\varepsilon \in \mathbf{\Delta}$, $f(\varepsilon) = f(0) + \varepsilon a$. (Here and in the sequel we shall use symbols ε, η to denote arbitrary elements of $\mathbf{\Delta}$.) This real number a is called the *slope* of f, and is written $\mathbf{slp}(f)$. Thus, for any f: $\mathbf{\Delta}\to\mathbf{R}$ and all $\varepsilon \in \mathbf{\Delta}$, $f(\varepsilon) = f(0) + \varepsilon\, \mathbf{slp}(f)$.

Given f: $\mathbf{\Delta}\to\mathbf{R}$, let f^*: $\mathbf{\Delta}\to\mathbf{R}\times\mathbf{R}$ defined by $f^*(\varepsilon) = (\varepsilon, f(\varepsilon))$. The map f^* may be thought of as the graph of the map f n the plane. The Infinitesimal Linearity Principle can be seen as asserting that this graph is a straight line with slope $\mathbf{slp}(f)$ passing through $(0, f(0))$. Thus the effect of any map on $\mathbf{\Delta}$ is to translate and rotate it; in effect $\mathbf{\Delta}$ behaves like a short "rigid rod," just long enough to have a slope, but too short to bend. It is, as it were, a geometric object possessing location and direction but lacking extension.

The Infinitesimal Linearity Principle can also be presented in the following way. Think of a real function f: $\mathbf{R}\to\mathbf{R}$ as defining a curve C in the plane. Then the Infinitesimal Linearity Principle amounts to the assertion that, for any such f and for any point $a \in \mathbf{R}$, the image under f of the "infinitesimal interval" $\mathbf{\Delta} + a$ obtained by translating $\mathbf{\Delta}$ to a is a straight line and coincides with the tangent to C at $x = a$.



Thus each real function has the effect of "bringing" $\mathbf{\Delta}$ into coincidence" with the tangent vector to the curve associated with the function at any point on it. In this sense, then, $\mathbf{\Delta}$ plays the role of a *generic tangent vector.* Also, since the image of $\mathbf{\Delta}$ under a function is necessarily a straight line and a part of the associated curve, it follows that each point on a curve is contained in a nondegenerate infinitesimal straight segment of the curve. Accordingly in **SIA** *curves are infinitesimally straight*. This is called the **Infinitesimal Straightness Principle**.

The Infinitesimal Linearity Principle has two immediate formal consequences:

- **The nondegeneracy of Δ:** $\Delta \neq \{0\}$. For suppose $\Delta = \{0\}$, and let a, b be any unequal real numbers. Then the two maps $\varepsilon \mapsto \varepsilon a$ and $\varepsilon \mapsto \varepsilon b$ would both be identically 0, contradicting the Linearity Principle.
- **The Cancellation Principle:** for any a, $b \in \mathbf{R}$, if $\varepsilon a = \varepsilon b$ for all $\varepsilon \in \Delta$, then $a = b$. This follows immediately from the uniqueness condition in the Linearity Principle.

We can now show that Δ consists of *nilpotent*, in fact *nilsquare* quantities, that is,

$$\forall x\big(x \in \Delta \Rightarrow x^2 = 0\big).$$

To prove this, write s: $\mathbf{\Delta}\rightarrow\mathbf{R}$ for the map $\varepsilon \mapsto \varepsilon^2$. Then we have, for $\varepsilon \in \Delta$,

$$\varepsilon^2 = \mathrm{s}(\varepsilon) = s(0) + \varepsilon\ \mathbf{slp}(s) = \varepsilon\ \mathbf{slp}(s)$$

and, since $-\varepsilon \in \Delta$,

$$\varepsilon^2 = (-\varepsilon)^2 = s(-\varepsilon) = s(0) - \varepsilon\ \mathbf{slp}(s) = -\varepsilon\ \mathbf{slp}(s).$$

Hence $\varepsilon^2 = -\varepsilon^2$, so that $\varepsilon^2 = 0$.

Notice that we do not claim that Δ comprises *all* nilsquare quantities. This, although usually assumed in presentations of **SIA**, is not needed.

Here is a further fact of interest. Without assuming the symmetry of Δ around 0, the following conditions are equivalent:

(i) $\forall x\ (x \in \Delta \Rightarrow x^2 = 0)$.
(ii) $\mathbf{slp}(s) = 0$.

(i) $\Rightarrow$ **(ii)**. Assuming **(i)**, we have, for all $\varepsilon \in \Delta$, $0 = \varepsilon^2 = s(\varepsilon) = s(0) + \varepsilon\ \mathbf{slp}(s) = \varepsilon.\ \mathbf{slp}(s)$. The Cancellation Principle yields $\mathbf{slp}(s) = 0$.

(ii) $\Rightarrow$ **(i)** Assuming **(ii)**, we have, for all $\varepsilon \in \Delta$, $\varepsilon^2 = s(\varepsilon) = s(0) + \varepsilon\ \mathbf{slp}(s) = 0 + 0 = 0$. Hence **(i)**.

The Differential Calculus in SIA. Let us call a *real function* any real-valued function defined on a closed interval into **R**. The derivative of an arbitrary real function can be formulated as follows. Given a closed interval **I** in **R** and a function f: $\mathbf{I}\rightarrow\mathbf{R}$, for each $x \in \mathbf{I}$ define the function f_x: $\Delta\rightarrow\mathbf{R}$ by $f_x(\varepsilon) = f(x + \varepsilon)$. (Intervals are defined by providing **R** with a suitable order relation. We assume that closed intervals are stable under the addition of infinitesimals: see below.)

The *derivative* f': $\mathbf{I}\rightarrow\mathbf{R}$ of f is defined by $f'(x) = \mathbf{slp}\ (f_x)$. It follows easily that

$(*)$ $\qquad f(x + \varepsilon) = f(x) + \varepsilon\, f'(x)$.

This is the *Fundamental Equation of the Differential Calculus* in **SIA**. The quantity $f'(x)$ is the slope at x of the curve determined by f and the infinitesimal

$$\varepsilon\ f'(x) = f(x + \varepsilon) - f(x)$$

is the infinitesimal change or *increment* in the value of f on passing from x to $x + \varepsilon$.

The fundamental equation (*) can be thought of as a rigorous formulation of the engineers' "practical" version of the Taylor series of a function. For (*) is what we get if in the Taylor series

$$f(x + \varepsilon) = f(x) + \varepsilon\ f'(x) + 1/2!\varepsilon^2 f''(x) + \ldots$$

we follow the practice of engineers to treat as "vanishingly small" the square and higher powers of the "small" quantity ε.

Derivatives of elementary functions are easily calculated in **SIA** using the Cancellation Principle. For example, here is the calculation of the derivative of the function x^n:

$$\varepsilon(x^n)' = (x+\varepsilon)^n - x^n = \varepsilon n\, x^{n-1} + \text{terms in } \varepsilon^{2-} \text{ and higher powers} = \varepsilon n\, x^{n-1}.$$

Hence, by the Cancellation Principle,

$$(x^n)' = n\, x^{n-1}.$$

And here is the calculation of the derivative of the function $1/x$ (for $x > 0$):

$$\begin{aligned}\varepsilon(1/x)' &= 1/x + \varepsilon - 1/x = -\varepsilon/x(x+\varepsilon) = -\varepsilon(x-\varepsilon)/x(x+\varepsilon)(x-\varepsilon)\\ &= -\varepsilon x + \varepsilon^2/x\left(x^2-\varepsilon^2\right)\\ &= -\varepsilon x/x^3\\ &= -\varepsilon/x^2.\end{aligned}$$

Cancelling ε on both sides of the equation gives

$$(1/x)' = -1/x^2.$$

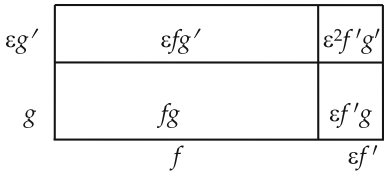
Let us derive in **SIA** a basic law of the differential calculus, the *product rule*:

$$(fg)' = f'g + fg'.$$

To do this we compute

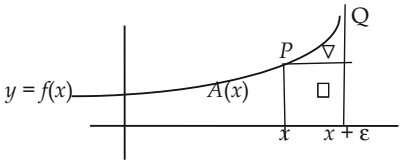
$$\begin{aligned}(fg)(x+\varepsilon) &= (fg)(x) + (fg)'(x) \quad = f(x)g(x) + (fg)'(x),\\ (fg)(x+\varepsilon) &= f(x+\varepsilon)g(x+\varepsilon) = [f(x) + f'(x)].[g(x) + g'(x)]\\ &= f(x)g(x) + \varepsilon(\, f'g + fg') + \varepsilon^2 f'g'\\ &= f(x)g(x) + \varepsilon(\, f'g + fg'),\end{aligned}$$

since $\varepsilon^2 = 0$. Therefore $\varepsilon(fg)' = \varepsilon(f'g + fg')$, and the result follows by the Cancellation Principle. This calculation is depicted in the diagram below.



Infinitesimals in **SIA** have two fundamental aspects, *algebraic* and *geometric*. Algebraically, they are real numbers whose squares vanish; geometrically, they are straight segments of curves. Both of these aspects are used in applications.

The interplay of these aspects is well illustrated by the derivation in **SIA** of the *Fundamental Theorem of the Calculus*. To this end, let **I** be a closed interval $\{x: a \leq x \leq b\}$ in **R** – or **R** itself – and let f: **I**→**R**; also let $A(x)$ be the area under the curve $y = f(x)$ as indicated in the figure:



Then

$$\varepsilon A'(x) = A(x+\varepsilon) - A(x) = \square + \nabla = \varepsilon f(x) + \nabla.$$

Now, by the Infinitesimal Straightness Principle, the arc PQ is a straight line; accordingly ∇ is a triangle of area ½ $\varepsilon.\varepsilon f'(x) = 0$. It follows that $\varepsilon A'(x) = \varepsilon f(x)$, and the Cancellation Principle gives

$$A'(x) = f(x).$$

Thus, if we regard $A(x)$ as the integral of $f(x)$, the above equation asserts that differentiation is the inverse of integration – the Fundamental Theorem of the Calculus.

*Smoothness of Functions in **SIA***. From the Fundamental Equation the *Principle of Continuity* can be deduced, namely, that in **SIA** *all real functions are continuous*, in the sense of *sending neighboring points to neighboring points*. (Here two points x, y on **R** are said to be *neighbors* if $x - y$ is in $\mathbf{\Delta}$, that is, if x and y differ by an infinitesimal.) To see this, given a real function f and neighboring points x, y, note that $y = x + \varepsilon$ with ε in $\mathbf{\Delta}$, so that

$$f(y) - f(x) = f(x+\varepsilon) - f(x) = \varepsilon f'(x).$$

Since $\varepsilon f'(x)$ is infinitesimal, the result follows.

From the fact that in **SIA** every real function has a derivative, which is itself differentiable, it follows that any real function is arbitrarily many times differentiable. This fact justifies the use of the term "smooth."

In **SIA** there is a sense in which *everything is generated by the domain of infinitesimals*. For consider the set $\mathbf{\Delta}^{\mathbf{\Delta}}$ of all maps $\mathbf{\Delta}$→$\mathbf{\Delta}$. It follows from the Linearity Principle that **R** can be identified as the subset of $\mathbf{\Delta}^{\mathbf{\Delta}}$ consisting of all maps vanishing at 0. In this sense **R** is "generated" by $\mathbf{\Delta}$.

Explicitly, $\mathbf{\Delta}^{\mathbf{\Delta}}$ is a monoid under composition which may be regarded as acting on $\mathbf{\Delta}$ by composition: for $f \in \Delta^{\Delta}$, $f \cdot \varepsilon = f(\varepsilon)$. The subset V consisting of all maps

vanishing at 0 is a submonoid naturally identified as the set of *ratios of infinitesimals*. The identification of **R** and V made possible by the principle of infinitesimal linearity thus leads to the characterization of **R** itself as the set of ratios of infinitesimals. This was essentially the view of Euler, who regarded infinitesimals as formal zeros and real numbers as representing the possible values of 0/0. For this reason Lawvere has suggested that **R** in **SIA** should be called the space of *Euler reals*.

Once one has **R**, Euclidean spaces of all dimensions may be obtained as powers of **R**, and arbitrary Riemannian manifolds may be obtained by patching together subspaces of these.

*The "Internal Logic" of **SIA** is Intuitionistic*. We observe that the postulates of **SIA** are *incompatible with the Law of Excluded Middle of classical logic* (LEM) – the assertion that, for any proposition p, either p holds or not p holds. This incompatibility can be demonstrated in two ways, one informal and the other rigorous. First the informal argument. Consider the function f defined for real numbers x by $f(x) = 1$ if $x = 0$ and $f(x) = 0$ whenever $x \neq 0$. If LEM held, each real number would then be either equal or unequal to 0, so that the function f would be defined on the whole of **R**. But, considered as a function with domain **R**, f is clearly discontinuous. Since, as we know, in **SIA** every function on **R** is continuous, f cannot have domain **R** there. (The domain of f is in fact $(\mathbf{R} - \{0\}) \cup \{0\}$, which, because of the failure of the law of excluded middle in **SIA**, is provably unequal to **R**.)

So LEM fails in **SIA**. To put it succinctly, *universal continuity implies the failure of the Law of Excluded Middle*.

Here now is the rigorous argument. We derive the failure of LEM from the Cancellation Principle. To begin with, if $x \neq 0$, then $x^2 \neq 0$, so that, if $x^2 = 0$, then necessarily not $x \neq 0$. This means that

$$\text{for all infinitesimal } \varepsilon, \text{ not } \varepsilon \neq 0. \qquad (*)$$

Now suppose that LEM were to hold. Then we would have, for any ε, either $\varepsilon = 0$ or $\varepsilon \neq 0$. But (*) allows us to eliminate the second alternative, and we infer that, for all ε, $\varepsilon = 0$. This may be written

$$\text{for all } \varepsilon, \varepsilon.1 = \varepsilon.0,$$

from which we derive by Cancellation Principle the falsehood $1 = 0$. So again LEM must fail.

The "internal" logic of **SIA** is accordingly not full classical logic. It is, instead, *intuitionistic* logic, that is, the logic derived from the constructive interpretation of mathematical assertions. In practice when working in **SIA** one does not notice this "change of logic" because, like much of elementary mathematics, the topics discussed there are naturally treated by constructive means such as direct computation.

It is worth noting that the refutability of the Law of Excluded Middle in **SIA** leads to the refutability of an important principle of set theory, the *Axiom of Choice*. This is the assertion

(AC) for any family **A** of inhabited sets, there is a *choice function on* **A**, that is, a function f: $\mathbf{A} \to \cup\mathbf{A}$ for which $f(X) \in X$ whenever $X \in \mathbf{A}$. (A set t is said to be *inhabited* if it can be constructively shown to have a member. In intuitionistic logic this is a stronger condition than the assertion that the set be nonempty.)

Now the Law of Excluded Middle can be derived merely from the very special case of the Axiom of Choice which asserts merely that any *doubleton* $\{U, V\}$ has a choice function. For let p be any proposition, define

$$U = \{x \in 2 : x = 0 \vee p\} V = \{x \in 2 : x = 1 \vee p\}$$

and let f be a choice function on $\{U, V\}$. Writing $a = f(U)$, $b = f(V)$, we have $a \in U$, $b \in V$, i.e.,

$$[a = 0 \vee p] \wedge [b = 1 \vee p].$$

It follows that

$$[a = 0 \vee b = 1] \vee p,$$

whence

$$(*) \qquad\qquad a \neq b \vee p.$$

Now clearly

$$p \to U = V = 2 \to a = b,$$

whence

$$a \neq b \to \neg p,$$

but this and (*) together imply $\neg p \vee p$.

Thus LEM is derivable from this special case of the Axiom of Choice. Since LEM is refutable in **SIA**, so equally, then, is **AC**.

The refutability of the Axiom of Choice in **SIA**, and hence its incompatibility with the Principle of Continuity which prevails there, is not surprising in view of the Axiom's well-known "paradoxical" consequences. One of these is the famous *Banach-Tarski paradox* which asserts that any solid sphere can be decomposed into finitely many pieces which can themselves be reassembled to form two solid spheres each of the same size as the original, or into one solid sphere of any preassigned size. Paradoxical decompositions such as these become possible only when continuous geometric objects are, recalling Dedekind's words, "dissolved to atoms ... [through a] frightful, dizzying discontinuity" into discrete sets of points which the Axiom of Choice then allows to be rearranged in an arbitrary (discontinuous) manner. Such procedures violate the Principle of Continuity.

*The Link Between the Infinitesimal and the Real in **SIA**; the Constancy Principle.* Suppose that we are investigating the behavior of some variable quantity represented by a function F. The approach taken in **SIA**, as (implicitly) in the differential calculus, is to begin the investigation by confining it initially to the infinitesimal world. Life in the infinitesimal world is beautifully simple: curves are just straight lines, and the squares of incremental changes vanish. This makes the determination of infinitesimal increments equally simple, enabling the increment $\varepsilon F'(x)$ in $F(x)$ to be presented in the form $\varepsilon k(x)$, where $k(x)$ is some explicit function whose form has been obtained by "infinitesimal" analysis. Thus we obtain an "infinitesimal" equation of the form $\varepsilon F'(x) = \varepsilon k(x)$. Applying the Cancellation Principle in turn yields the "differential" equation

$$(*) \qquad F'(x) = k(x)$$

which holds in the world "in the large."

The Cancellation Principle thus provides a formal, astonishingly simple link between the infinitesimal world and the real world, the world "in the large." The idea of a linkage between these two worlds was the animating principle behind applications of the calculus throughout the seventeenth and eighteenth centuries.

In practice, of course, the equation (*), while of fundamental importance, is only the first step in determining the explicit form of the function F. For this, it is necessary to "integrate" k, that is, to provide k with an *antiderivative,* an explicit function G such that $G' = k$. It will then follow that $F' = G'$, from which we will be able to conclude that $F = G$. (Strictly speaking, F and G may differ by a constant function but we shall ignore this here.)

To carry out this procedure in **SIA**, we need to introduce an additional postulate. Let **I** be a closed interval. We define a *stationary point* of a function f: **I**→**R** to be a point $a \in \mathbf{I}$ in whose vicinity "infinitesimal changes in the value of the argument fail to change the value of f'', that is, for which $f(a + \varepsilon) = f(a)$ for all ε. This means that $f(a) + \varepsilon f'(a) = f(a)$, so that $\varepsilon f'(a) = 0$ for all ε, from which it follows by the Cancellation Principle that $f'(a) = 0$. Thus a stationary point of a function is precisely a point at which the derivative of the function vanishes.

In classical analysis, if the derivative of a function is identically zero, the function is constant. This fact is the source of the following postulate concerning stationary points adopted in **SIA**:

Constancy Principle. If every point in a closed interval **I** is a stationary point of f: **I**→**R** (that is, if f' is identically 0), then f is constant.

It follows from the Constancy Principle that two functions with identical derivatives differ by at most a constant.

Put succinctly, the Constancy Principle asserts that "universal infinitesimal (or "local") constancy implies global constancy," or "infinitesimal behaviour determines global behaviour." The Constancy Principle brings into sharp focus the difference in **SIA** between points and infinitesimals. For if in the Constancy Principle one replaces

"infinitesimal constancy" by "constancy at a point" the resulting "Principle" is false because *any function whatsoever* is constant at every point. But since in **SIA** all functions on **R** are smooth, the Constancy Principle embodies the idea that for such functions local constancy is sufficient for global constancy, that a nonconstant smooth function must be somewhere nonconstant over arbitrarily small intervals.

The Constancy Principle provides another bridge between the infinitesimal world and the world "in the large." Hermann Weyl could not see such a direct linkage between the two worlds, and inferred that this absence doomed the idea of infinitesimal, leading to its inevitable replacement by the limit concept. In his *Philosophy of Mathematics and Natural Science* he says:

> [In its struggle with the infinitely small] *the limiting process was victorious. For the* limit *is an indispensable concept, whose importance is not affected by the acceptance or rejection of the infinitely small. But once the limit concept has been grasped, it is seen to render the infinitely small superfluous. Infinitesimal analysis proposes to draw conclusions by integration from the behavior in the infinitely small, which is governed by elementary laws, to the behavior in the large; for instance, from the universal law of attraction for two material "volume elements" to the magnitude of attraction between two arbitrarily shaped bodies with homogeneous or non-homogeneous mass distribution. If the infinitely small is not interpreted 'potentially' here, in the sense of the limiting process, then the one has nothing to do with the other, the process in infinitesimal and finite dimensions become independent of each other, the tie which binds them together is cut.*

In **SIA**, the Constancy Principle reconnects the infinitesimal and the extended. Behavior "in the large" is completely determined by behavior "in the infinitely small."

*Cohesiveness of the Continuum in **SIA**.* In classical analysis the continuum and its closed intervals are connected in the sense that they cannot be split into two nonempty subsets neither of which contains a limit point of the other. In **SIA**, the Constancy Principle ensures that these have the vastly stronger property of *cohesiveness* (or indecomposability) which, we recall, is the property of not being splittable into two disjoint nonempty parts *in any way whatsoever.* This is clearly equivalent to the condition that any map defined on **R** or one of its closed intervals to $\{0, 1\}$ takes a constant value.

To show that this condition holds, let A be **R** or any closed interval, and suppose $f: A \to \{0, 1\}$. We claim that f is constant. For we have, for any $x \in A$,

$$(\, f(x) = 0 \text{ or } f(x) = 1) \& (\, f(x + \varepsilon) = 0 \text{ or } f(x + \varepsilon) = 1).$$

This gives four possibilities:

(i) $f(x) = 0$ & $f(x + \varepsilon) = 0$
(ii) $f(x) = 0$ & $f(x + \varepsilon) = 1$
(iii) $f(x) = 1$ & $f(x + \varepsilon) = 0$
(iv) $f(x) = 1$ & $f(x + \varepsilon) = 1$

Possibilities (ii) and (iii) may be ruled out because f is continuous. This leaves (i) and (iv), in either of which $f(x) = f(x + \varepsilon)$. So f is locally, and hence globally, constant, that is, constantly 1 or 0.

From the cohesiveness of closed intervals it can be inferred (Bell 2001) that in **SIA** *all intervals in* **R** *are cohesive.*

Smooth Infinitesimal Analysis as an Axiomatic Theory: Consequences for the Continuum.

SIA can be *axiomatized* as a theory formulated within (higher-order) intuitionistic logic. Here are the basic axioms of the theory (Moerdijk and Reyes 1991).

Axioms for the continuum, or smooth real line R. These include the usual axioms for a commutative ring with unit expressed in terms of two operations + and · (we usually write xy for $x \cdot y$) and two distinguished elements $0 \neq 1$. In addition we stipulate that **R** is an *intuitionistic field*, i.e., satisfies the following axiom:

$$x \neq 0 \text{ implies} \exists y(xy = 1).$$

Axioms for the strict order relation < on R. These are:

O1. $a < b$ and $b < c$ implies $a < c$.
O2. $\neg(a < a)$
O3. $a < b$ implies $a + c < b + c$ for any c.
O4. $a < b$ and $0 < c$ implies $ac < bc$
O5. either $0 < a$ or $a < 1$.
O6. $a \neq b$ implies $a < b$ or $b < a$.
O7. $0 < x$ implies $\exists y\ (x = y^2)$.

Arithmetical Axioms. These govern the set **N** of *Archimedean* (or smooth) *natural numbers,* and read as follows:

1. **N** is a cofinal or Archimedean subset of **R**, i.e., $\mathbf{N} \subseteq \mathbf{R}$ and $\forall\ x \in \mathbf{R}\ \exists n \in \mathbf{N}$ $x < n$.
2. *Peano axioms*:

$$0 \in \mathbf{N}$$

$$\forall x \in \mathbf{R}(x \in \mathbf{N} \rightarrow x + 1 \in \mathbf{N})$$

$$\forall x \in \mathbf{R}(x \in \mathbf{N} \rightarrow x + 1 \neq 0)$$

3. *Restricted Induction scheme.* For every formula $\varphi(x)$ Involving Just $=$, $\wedge$, $\vee$, $\top$ ("True"), $\perp$ ("False"), $\exists$

$$\varphi(0) \wedge \forall x \in \mathbf{N}[\varphi(x) \rightarrow \varphi(x + 1)] \rightarrow \forall x \in \boldsymbol{N}\varphi(x).$$

Using restricted induction it follows that

- **N** has *decidable equality,* i.e., $\forall x \in \mathbf{N} \forall y \in \mathbf{N}(x = y \vee x \neq y)$.
- **N** is *linearly ordered,* i.e., $\forall x \in \mathbf{N} \forall y \in \mathbf{N}(x < y \vee x = y \vee y < x)$.
- **N** satisfies *decidable induction:* for any formula $\varphi(x)$,

$$\forall x \in \mathbf{N}(\varphi(x) \vee \neg\varphi(x)) \rightarrow [[\varphi(0) \wedge \forall x \in \mathbf{N}(\varphi(x) \rightarrow \varphi(x+1)] \rightarrow \forall x \varphi(x)].$$

The relation $\leq$ on **R** is defined by $a \leq b \Leftrightarrow \neg(b < a)$. The open interval (a, b) and closed interval $[a, b]$ are defined as usual, viz., $(a, b) = \{x: a < x < b\}$ and $[a, b] = \{x: a < x < b\}$; similarly for half-open, half-closed, and unbounded intervals. It can be shown from the axioms introduced so far that closed intervals are stable under the addition of infinitesimals.

We have written $\mathbf{\Delta}$ for the subset $\{x: x^2 = 0\}$ of **R** consisting of (nilsquare) *infinitesimals.* As before, we use the letter ε as a variable ranging over $\mathbf{\Delta}$.

The two final axioms are:

Infinitesimal Linearity Axiom. *For any map g:* $\mathbf{\Delta} \rightarrow \mathbf{R}$ *there exist unique* $a, b \in \mathbf{R}$ *such that, for all* ε, *we have*

$$g(\varepsilon) = a + b\varepsilon.$$

Constancy Axiom. *If* $A \subseteq \mathbf{R}$ *is any closed interval on* **R**, *or* **R** *itself, and* $f: A \rightarrow \mathbf{R}$ *satisfies* $f(a + \varepsilon) = f(a)$ *for all* $a \in A$ *and* $\varepsilon \in A$, *then f is constant.*

It follows easily from the Infinitesimal Linearity Axiom that $\mathbf{\Delta}$ is *nondegenerate,* i.e., $\mathbf{\Delta} \neq \{0\}$ (It should be noted that, while Δ does not reduce to $\{0\}$, nevertheless 0 is the only explicitly nameable element of Δ. For it is easily seen to be inconsistent to assert that Δ actually contains an element $\neq 0$.). For if $\mathbf{\Delta} = \{0\}$, then the identity map $i: \mathbf{\Delta} \rightarrow \mathbf{\Delta}$ can be represented as $i(\varepsilon) = b\varepsilon$ for any b, in violation of the uniqueness condition on b. It should be noted that, while $\mathbf{\Delta}$ does not reduce to $\{0\}$, nevertheless 0 is the only *explicitly nameable* element of $\mathbf{\Delta}$. For it is easily seen to be inconsistent to assert that $\mathbf{\Delta}$ actually contains an element $\neq 0$.

From the nondegeneracy of $\mathbf{\Delta}$ we can also (again) refute the Law of Excluded Middle in **SIA**, more particularly, we can prove

$$(*) \qquad \neg\forall\varepsilon(\varepsilon = 0 \vee \varepsilon \neq 0).$$

For we have, for $\varepsilon \in \mathbf{\Delta}$, $\varepsilon^2 = 0$, whence $\neg(\varepsilon \neq 0)$, and (*) would give $\varepsilon = 0$. So $\mathbf{\Delta}$ would be degenerate, contrary to what we have already shown. It follows from (*) that, using x and y as variables ranging over **R**,

$$\neg\forall x \forall y(x = y \vee x \neq y).$$

In a word, the identity relation is *undecidable* on **R**.

Call a binary relation S on **R** *balanced* if it satisfies

$$\forall x \forall y(\neg\neg xRy \rightarrow xRy).$$

Then the nondegeneracy of **Δ** implies that, in **SIA** the equality relation is *unbalanced.* For suppose that $=$ were balanced. Then, for any ε, it would be the case that $\neg\varepsilon \neq 0 \rightarrow \varepsilon = 0$. But we have already shown above that $\neg(\varepsilon \neq 0)$, so it would follow that $\varepsilon = 0$. This being the case for any ε, **Δ** would be degenerate.

On the other hand, in **SIA** the order relation $<$ is balanced. For suppose $\neg\neg a < b$. Then certainly $a \neq b$, since $a = b \rightarrow \neg a < b$ by irreflexivity. Therefore, by axiom O6, $a < b$ or $b < a$. The second disjunct together with $\neg\neg a < b$ and transitivity gives $\neg\neg a < a$, which contradicts $\neg a < a$. Accordingly, we are left with $a < b$. Hence $<$ is balanced.

Even allowing for the presence of intuitionistic logic, we note that the *algebraic structure* on **R** in **SIA** differs little from that of the usual classical system of real numbers. In **SIA**, **R** is equipped with the usual addition and multiplication operations under which it is a field. In particular, **R** satisfies the condition that each $x \neq 0$ has a multiplicative inverse. Notice, however, that since in **SIA** no infinitesimal (apart from 0 itself) is provably $\neq 0$, they are not required to have multiplicative inverses (a requirement which would lead to inconsistency). From a strictly algebraic standpoint, **R** in **SIA** differs from its classical counterpart only in being required to satisfy the Cancellation Principle.

The situation is otherwise, however, as regards the order structure of **R** in **SIA**. Since infinitesimals do not have multiplicative inverses, and **R** is an intuitionistic field, it must be the case that $\forall\varepsilon\neg(\varepsilon \neq 0)$, whence

$$\forall\varepsilon(\neg\varepsilon < 0 \wedge \neg\, \varepsilon > 0),$$

or equivalently

$$\forall\varepsilon(\varepsilon \leq 0 \wedge \varepsilon \geq 0).$$

It follows easily from this and the nondegeneracy of **Δ** that

$$\neg\forall x\forall y(x < y \vee y < x \vee x = y).$$

In other words the order relation $<$ on **R** in **SIA** *fails to satisfy the trichotomy law;* it is a *partial,* rather than a *total* ordering.

The axioms of **SIA** entail that **R** differs in certain key respects from its counterpart in *constructive analysis* **CA** (Sect. 4). For example, in **CA** the equality relation is balanced, while we have shown above that in **SIA** it is unbalanced. Also in **CA** the ordering relation $<$ satisfies

$$(*) \qquad \neg(x < y \vee y < x) \rightarrow x = y;$$

and this is incompatible with the axioms of **SIA**. For (*) implies

$$(**) \qquad \forall x\neg(x < 0 \vee 0 < x) \rightarrow x = 0.$$

But in **SIA** it is easy to derive

$$\forall x \in \mathbf{\Delta} \neg (x < 0 \vee 0 < x),$$

and this, together with (**), would give $\mathbf{\Delta} = \{0\}$, contradicting the nondegeneracy of $\mathbf{\Delta}$.

In **CA** the object $\mathbf{\Delta}$ is degenerate while the nondegeneracy of $\mathbf{\Delta}$ in **SIA** is one of its characteristic features.

In **SIA** cohesive subsets of $\mathbf{R}$ correspond, *grosso modo,* to connected subsets of $\mathbb{R}$ in classical analysis, that is, to intervals. This is borne out by the fact that any puncturing of $\mathbf{R}$ is *decomposable,* for it follows immediately from Axiom O6 that

$$\mathbf{R} - \{a\} = \{x : x > a\} \cup \{x : x < a\}.$$

The set $\mathbf{Q}$ of (smooth) *rational numbers* is defined as usual to be the set of all fractions of the form m/n with $m, n \in \mathbf{N}$, $n \neq 0$. The fact that $\mathbf{N}$ is cofinal in $\mathbf{R}$ ensures that $\mathbf{Q}$ is dense in $\mathbf{R}$.

The set $\mathbf{R} - \mathbf{Q}$ of *irrational* numbers is decomposable as

$$\mathbf{R} - \mathbf{Q} = [\{x : x > 0\} - \mathbf{Q}] \cup [\{x : x < 0\} - \mathbf{Q}\}.$$

This is in sharp contrast with the situation in *intuitionistic analysis* that is, **CA** augmented by Kripke's scheme, Brouwer's Continuity Principle, and bar induction. For we have observed (Sect. 4) that in intuitionistic analysis not only is any puncturing of $\mathbf{R}$ cohesive, but that this is even the case for the irrational numbers. This would seem to indicate that in some sense the continuum in **SIA** is considerably less "syrupy" than its counterpart in **SIA**.

*Comparing the Smooth and Dedekind Real Lines in **SIA**.* The usual set $\mathbb{R}$ of real numbers can be constructed in **SIA** as Dedekind cuts. A *Dedekind real* is a pair $(U, V) \in \mathcal{P}\,\mathbf{Q} \times \mathcal{P}\mathbf{Q}$ (here $\mathcal{P}\mathbf{Q}$ is the power set of $\mathbf{Q}$, the set of rational numbers) satisfying the conditions:

$$\exists x \exists y (x \in U \wedge y \in V)$$

$$U \cap V = \varnothing$$

$$\forall x (x \in U \leftrightarrow \exists y \in U . x < y)$$

$$\forall x (x \in V \leftrightarrow \exists y \in V . y < x)$$

$$\forall x \forall y (x < y \leftrightarrow x \in U \vee y \in x).$$

The set $\mathbb{R}$ of Dedekind reals as thus defined can be turned into an ordered ring (Johnstone 1977). This ring is always *constructively complete,* that is, satisfies the condition: Let A be an inhabited subset of $\mathbb{R}$ that is bounded above. Then sup A exists if and only if for all $x, y \in \mathbb{R}$ with $x < y$, either y is an upper bound for A or there exists $a \in A$ with $x < a$. (A real number b is called a *supremum*, or *least upper bound*, of A if it is an upper bound for A and if for each $\varepsilon > 0$ there exists $x \in A$ with $x > b - \varepsilon$.)

Although $\mathbb{R}$ is constructively complete, it is not conditionally complete in the classical sense. (This is because of the failure in **SIA** of the logical law $\neg p \vee \neg\neg p$. The failure of the latter in **SIA** follows immediately from the cohesiveness of **R** by considering the predicate $x \neq 0$.)

But $\mathbb{R}$ shares some features of the constructive reals not possessed by **R**, e.g.,

$$\neg\neg x = y \rightarrow x = y$$

$$x \leq y \wedge y \leq x \rightarrow x = y$$

$$x^n = 0 \rightarrow x = 0.$$

There is a natural order preserving homomorphism φ: $\mathbf{R} \rightarrow \mathbb{R}$ given by

$$\varphi(r) = (\{q \in \mathbf{Q} : q < r\}, \{q \in \mathbf{Q} : q > r\})$$

This is injective on **Q**, and embeds **Q** as the rational numbers in $\mathbb{R}$. Moreover, the kernel of φ coincides with the ideal **I** of strict infinitesimals in **R**, so φ induces an embedding of the quotient ring **R/I** into $\mathbb{R}$. **R/I** is **R** *shorn of its nilpotent infinitesimals:* it is both an intuitionistic field and an integral domain, that is, satisfies

$$\forall x(x \neq 0 \rightarrow x \text{ is invertible}) \qquad \forall x \forall y[xy = 0 \rightarrow x = 0 \vee y = 0].$$

It can be shown that φ is *surjective* – so that $\mathbf{R/I} \cong \mathbb{R}$ – precisely when **R** is constructively complete in the sense above. In that event $\mathbb{R}$ is both an intuitionistic field and an integral domain.

In **SIA** the usual *open interval topology* can be defined on $\mathbb{R}$. It can be shown (Stout 1976) that with this topology $\mathbb{R}$ is always *connected* in the sense that it cannot be partitioned into two disjoint inhabited *open* subsets. In **SIA** $\mathbb{R}$ actually inherits a stronger cohesiveness property from **R**. To see this, call a subset X of a set A *detachable* if there is a subset Y of A such that $X \cap Y = \emptyset$, $X \cup Y = A$. Now we can show that, if X is a detachable subset of the set of Dedekind reals, then $\varphi[\mathbf{R}] \subseteq X$ or $X \cap \varphi[\mathbf{R}] = \emptyset$. For suppose $X \subseteq \mathbb{R}$ detachable and define f: $\mathbb{R} \rightarrow \{0, 1\}$ by $f(x) = 1$ if $x \in X$, $f(x) = 0$ if $x \notin X$. Then $f \circ \varphi : \mathbf{R} \rightarrow \{0, 1\}$ must be constant since **R** is cohesive. If $f \circ \varphi$ is constantly 1, then $\varphi[\mathbf{R}] \subseteq X$; if constantly 0, then $A \cap \varphi[\mathbf{R}] = \emptyset$. It follows easily that if φ is surjective then $\mathbb{R}$ is itself cohesive.

*Nonstandard Analysis in **SIA**.* In certain formulations of **SIA** the system of *natural numbers* possesses some intriguing features which make it possible to introduce another type of infinitesimal – the so-called *invertible* infinitesimals – resembling those of Nonstandard Analysis.

We recall that the set **N** of smooth natural numbers is required to satisfy not the full principle of mathematical induction for arbitrary properties but only the weaker restricted induction scheme. This raises the possibility that **N** may not coincide with the set $\mathbb{N}$ of *standard natural numbers,* which is defined to be the *smallest* subset of **R** containing 0 and closed under the operation of adding 1. Now, models of **SIA** have

been constructed (Moerdijk and Reyes 1991) in which $\mathbb{N}$ is a *proper subset* of $\mathbf{N}$; accordingly the members of $\mathbf{N} - \mathbb{N}$ may be considered *nonstandard integers.* Multiplicative inverses of nonstandard integers are infinitesimals, but, being themselves invertible, they are of a different type from the (necessarily noninvertible) nilpotent infinitesimals which are basic to **SIA**.

Proceeding formally, we define the set $\mathbb{N}$ of *standard* natural numbers to be the intersection of all *inductive* subsets of $\mathbf{N}$, i.e., $\mathbb{N} = \{n \in \mathbf{N} : \forall X \subseteq \mathbf{N}[0 \in X \wedge \forall m(m \in X \rightarrow m + 1 \in X) \rightarrow n \in X]$.

$\mathbb{N}$ evidently satisfies *full induction*:

$$\forall X \subseteq \mathbf{N}[0 \in X \wedge \forall m(m \in X \rightarrow m + 1 \in X) \rightarrow X = \mathbf{N}].$$

The space of *arithmetical infinitesimals* is the set

$$\mathbf{AIN} = \{x \in \mathbf{R} : \forall n \in \mathbb{N}(-1/(n+1) < x < 1/(n+1)\}.$$

This may be considered the largest infinitesimal neighborhood of zero in **SIA**: it contains the space $\mathbf{\Delta}$ of nilsquare infinitesimals as well as the space of *invertible* or *Robinsonian infinitesimals*

$$\mathbf{IN} = \{x \in \mathbf{AIN} : x \textit{ is invertible}\}.$$

As inverses of "infinitely large" reals (i.e., reals r satisfying $\forall n \in \mathbb{N}.\ n < r \vee \forall n \in \mathbb{N}.\ r < -n$) invertible infinitesimals are the counterparts in **SIA** of the infinitesimals of Nonstandard Analysis.

To assert the existence of invertible infinitesimals is to assert that **I**N be inhabited: this is equivalent to asserting that the set $\mathbf{N} - \mathbb{N}$ of *nonstandard integers* be inhabited, or equivalently, that the following holds:

$$\exists n \in \mathbf{N} \forall m \in \mathbb{N}\ m < n.$$

When this condition is satisfied, as it is in certain models of **SIA**, we shall say that nonstandard integers, or invertible infinitesimals, are *actually present.* It is consistent to assert the actual presence of invertible infinitesimals, i.e., that **I**N be inhabited,.

One may also postulate the condition

$$\forall n \in \mathbf{N}[\forall x \in \mathbf{N} - \mathbb{N}(x < n) \rightarrow n \in \mathbb{N}],$$

i.e., "a natural number which is smaller than all nonstandard natural numbers must be standard." This is in fact equivalent to the condition that $\mathbb{N}$ be a stable subset of $\mathbf{N}$, i.e., $\mathbf{N} - (\mathbf{N} - \mathbb{N}) = \mathbb{N}$. Assuming that nonstandard integers are actually present, this latter may be understood as asserting that as many as possible of these are actually present.

In the presence of invertible infinitesimals, $\mathbb{R}$ is a nonstandard model of the reals lacking nilsquare infinitesimals. The passage via the function φ from $\mathbf{R}$ to $\mathbb{R}$

eliminates the nilsquare infinitesimals but preserves the invertible infinitesimals. When φ is onto, $\mathbb{R}$ is a cohesive *nonstandard model of the reals.*

*Consistency and Models of **SIA***. Smooth Infinitesimal Analysis is a fascinating theory with many attractive, even exotic features, but one may well ask whether is it *consistent.* Now the consistency of an axiomatic theory is usually established by producing a *model* for it, that is, providing an interpretation of the basic constituents of the theory under which all the axioms of the theory can be shown to be true. The consistency of **SIA** can be established by these means. *Models* of **SIA** are *categories* of a certain kind known as *toposes* (or *topoi*). These originated through the work of Alexander Grothendieck in algebraic geometry in the 1950s and 1960s as a generalization of the idea of a category of sheaves on a topological space (hence the term *topos*). In the late 1960s F William Lawvere and Myles Tierney formulated a simple but powerful set of first-order axioms characterizing the idea underlying Grothendieck's concept of topos. A category satisfying the Lawvere-Tierney axioms was initially known as an *elementary topos*, and later just a *topos.* Although the origin of the topos concept lay in topology and algebraic geometry, elementary toposes have deep connections with logic and set theory. In particular, a topos can be thought of as a "generalized model of set theory." The remarkable thing is that the body of laws satisfied by the logical operations in a topos – its "internal logic" – does not, in general, correspond to classical logic, but rather to the *intuitionistic* or *constructive* logic of Brouwer and Heyting in which the law of excluded middle is not affirmed.

Within a topos, mathematical concepts can be formulated, arguments carried out and constructions performed much as one does in "ordinary" set theory, only observing the rules of intuitionistic logic.

In fact, any topos may be regarded as a model of *intuitionistic set theory* **IST**. (By intuitionistic set theory **IST** is meant the theory in intuitionistic first-order logic whose axioms are the "usual" axioms of Zermelo set theory (without the Axiom of Choice), namely: Extensionality, Pairing, Union, Power set, Infinity, and Separation. For an exposition of **IST**). This means that, within a topos, mathematical constructions can be carried out as if within **IST**. In particular, the rational numbers can be defined as usual and the real numbers constructed by employing either Dedekind's procedure of making cuts in the rationals or Cantor's procedure employing equivalence classes of Cauchy sequences of rationals. While classically these two constructions lead to isomorphic results, this is *not true* in **IST**: indeed, a number of toposes have been constructed in which the ordered rings of Dedekind and Cantor reals fail to be isomorphic (Johnstone 2002).

Accordingly, in a topos-theoretic or constructive universe there is more than one candidate for the role of the mathematical continuum. The classical view that the linear continuum is a uniquely determined entity gives way to a pluralistic conception under which the continuum has a number of embodiments with essentially different properties. Even when one decides to choose the Dedekind reals as one's continuum, its properties may fall far short of those possessed by its classical counterpart. For example, in intuitionistic logic it cannot be proved that the

Dedekind reals satisfy the least upper bound property. It can be shown (Johnstone 2002) that, in a topos, the Dedekind reals possess this property exactly when the logical law $\neg(\alpha \wedge \beta) \rightarrow (\neg\alpha \vee \neg\beta)$ holds there. This is an arresting instance of the connection between logic and the properties of the mathematical continuum made visible by the shift from classical to constructive logic.

The practice of topos theory quickly spawned an associated philosophy – jocularly known as "toposophy" – whose chief tenet is the idea that, like a model of set theory, any topos may be taken as an autonomous universe of discourse or "world" in which mathematical concepts can be interpreted and constructions performed (Bell 1986, 1988). These "worlds" opened up by topos theory can have startlingly different properties from the world of classical mathematics. For example, recall that in 1924 Brouwer proved from his intuitionistic principles that every real-valued function on a closed interval of the intuitionistic continuum of real numbers is uniformly continuous; in short, that the intuitionistic continuum has the *Brouwer Property.* This is of course inconsistent with the classical account of the continuum. But a number of toposes have been constructed in which the continuum of Dedekind reals has the Brouwer property (Mac Lane and Moerdijk 1992). In these all closed intervals in the Dedekind continuum are cohesive.

Toposes which are models of **SIA** have also been constructed. The basic ideas here go back to Lawvere. In the 1960s he conceived the ideas of developing the concept of smoothness in category-theoretic terms and of employing nilpotent infinitesimals in the calculus and differential geometry. The framework he formulated is known as *synthetic differential geometry* (**SDG**). The key principle of **SIA**, what we have termed the Infinitesimal Linearity Principle, was given its explicit form by Lawvere and Anders Kock, and, as remarked above, is often called the *Kock-Lawvere axiom*. The explicit construction of topos models of **SIA** in which differential geometry can be fully developed – so-called *smooth toposes* (Moerdijk and Reyes 1991), was first achieved by Dubuc in 1979. This, no easy task, established fully the consistency of **SIA**.

*Contrasting Nonstandard Analysis with **SIA.*** **SIA** shares with Nonstandard Analysis (**NSA**) the feature that continuity is represented by the idea of "preservation of infinitesimal closeness." Nevertheless, there are a number of differences between the two approaches:

- In models of **SIA**, only smooth maps between objects are present. In models of **NSA**, all set-theoretically definable maps (including, in particular, discontinuous ones) appear.
- The logic of **SIA** is intuitionistic, while the logic of SIA is classical. (It should be pointed out, however, that constructive versions of **NSA** have been developed. See Palmgren 1998).
- In **SIA**, all curves are infinitesimally straight. Nothing resembling this is present in **NSA**.
- The nilpotency of the infinitesimals of **SIA** reduces the differential calculus to simple algebra. In **NSA** the use of infinitesimals is a disguised form of the classical limit method.

- The hyperreal line in **NSA** is obtained by augmenting the classical real line with infinitesimals (and infinite numbers), while the smooth real line **R** comes already equipped with infinitesimals.
- In any model of **NSA**, the hyperreal line $\mathbb{R}^\star$ has exactly the same set-theoretically expressible properties as does the classical real line: in particular $\mathbb{R}^\star$ is an archimedean field in the sense of that model. This means that the infinitesimals (and infinite numbers) of **NSA** are not intrinsically so in the sense of the model in which they "live," but only relative to the "standard" model with which the construction began. That is, speaking figuratively, an inhabitant of a model of **NSA** would be unable to detect the presence of infinitesimals or infinite numbers in $\mathbb{R}^\star$. This contrasts with **SIA** in two respects. First, in models of **SIA** containing invertible infinitesimals, the real line is nonarchimedean with respect to the set of standard natural numbers, which is itself an object of the model. In other words, the presence of (invertible) infinitesimals and infinite numbers would be perfectly detectable by an inhabitant of the model. And secondly, the characteristic property of nilpotency possessed by the microquantities of a model of **SIA** is an intrinsic property, perfectly identifiable within the model. In **NSA** the hyperreals have precisely the same algebraic properties as do the classical real numbers, but the smooth reals in **SIA** do not.

The differences between **NSA** and **SIA** arise because the former is essentially a theory of infinitesimal numbers designed to provide a succinct formulation of the limit concept, while the latter is, by contrast, a theory of infinitesimal geometric objects, designed to provide an intrinsic formulation of the concept of differentiability.

***SIA** and Physics*. In the past, physicists showed no hesitation in employing infinitesimal methods, In this connection we recall the words of Hermann Weyl:

> *The principle of gaining knowledge of the external world from the behaviour of its infinitesimal parts is the mainspring of the theory of knowledge in infinitesimal physics as in Riemann's geometry and, indeed, the mainspring of all the eminent work of Riemann* (Weyl 1922, p. 92).

The use of infinitesimals relied on the implicit assumption that the (physical) world is smooth, or at least that the maps encountered there are differentiable as many times as needed. For this reason **SIA** provides an ideal framework for the rigorous derivation, using infinitesimals, of results in classical physics (Bell 1998). We present two of these here.

First, we derive the *equation of continuity for fluids,* first derived in 1757 by Euler. The derivation in **SIA** will follow Euler's very closely, but the use of nilsquare infinitesimals and the Cancellation Principle will render the argument entirely rigorous.

Before we begin we require a few observations on *partial derivatives* in **SIA**. Given a function f: $\mathbf{R}^n \to \mathbf{R}$ of n variables $x_1, \ldots, x_n$, the partial derivative $\frac{\partial f}{\partial x_i}$ is defined as usual to be the derivative of the function $f(a_1, \ldots, x_i, \ldots, a_n)$ obtained by

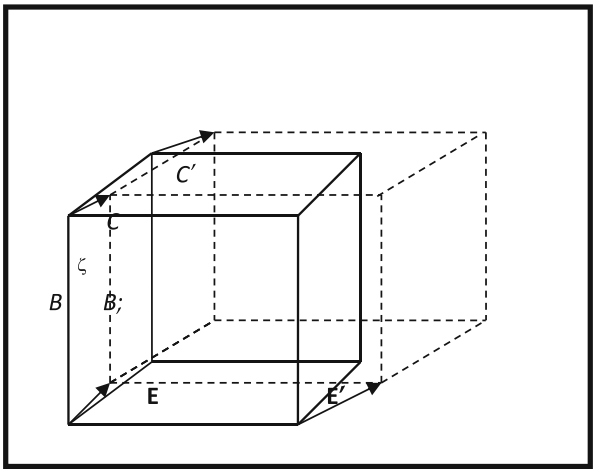
fixing the values of all the variables apart from x_i. In that case, for an arbitrary infinitesimal ε, we have

$$f(x_1, \ldots, x_i + \varepsilon, \ldots, x_n) = f(x_1, \ldots, x_n) + \varepsilon \frac{\partial f}{\partial x_i}(x_1, \ldots, x_n). \tag{2}$$

Using the fact that $\varepsilon^2 = 0$, it is then easily shown that

$$f(x_1 + a_1\varepsilon, \ldots, x_n + a_n\varepsilon) = f(x_1, \ldots, x_n) + \varepsilon \sum_{i=1}^{n} a_i \frac{\partial f}{\partial x_i}(x_1, \ldots, x_n). \tag{3}$$

These equations are pivotal in deriving the equation of continuity. Here we are given a inviscid fluid of varying density flowing smoothly in space. At any point $O = (x, y, z)$ in the fluid and at any time t, the fluid's density ρ and the components u, v, w of the fluid's velocity are given as functions of x, y, z, t. Following Euler, we consider the elementary volume element **E** – an infinitesimal parallelepiped – with origin O and edges OA, OB, BC of infinitesimal lengths ε, η, ζ and so of mass εηζρ:



Fluid flow during the infinitesimal time τ transforms the volume element **E** into the infinitesimal parallelepiped **E**′ (see figure above) with vertices O', A', B', C'. We first calculate the length of the side $O'A'$. Now, using (1), the rate at which A is moving away from O in the x-direction is

$$u(x + \varepsilon, y, z, t) - u(x, y, z, t) = \varepsilon \frac{\partial u}{\partial x}.$$

The change in length of OA during the infinitesimal time τ is thus $\varepsilon\tau \frac{\partial u}{\partial x}$, so that the length of $O'A'$ is

$$\varepsilon + \varepsilon\tau\frac{\partial u}{\partial x} = \varepsilon\left(1 + \tau\frac{\partial u}{\partial x}\right).$$

Similarly, the lengths of $O'B'$ and $O'C'$ are, respectively,

$$\eta\left(1 + \tau\frac{\partial v}{\partial y}\right), \zeta\left(1 + \tau\frac{\partial w}{\partial z}\right).$$

The volume of $\mathbf{E}'$ is the product of these three quantities, which, using the fact that $\tau^2 = 0$, comes out as

$$\varepsilon\eta\zeta\left[1 + \tau\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right)\right]. \tag{4}$$

Since the coordinates of O' are $(x + u\tau, y + v\tau, z + w\tau)$, the fluid density ρ' at time $t + x$ is, using (3),

$$\rho + \tau\left(\frac{\partial \rho}{\partial t} + u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + w\frac{\partial \rho}{\partial z}\right). \tag{5}$$

The mass of $\mathbf{E}'$ is then the product of (4) and (5), which, again using the fact that $\tau^2 = 0$, comes out as

$$\varepsilon\eta\zeta\rho + \varepsilon\eta\zeta\tau\left(\frac{\partial \rho}{\partial t} + \rho\frac{\partial u}{\partial x} + \rho\frac{\partial v}{\partial y} + \rho\frac{\partial w}{\partial z} + u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + w\frac{\partial \rho}{\partial z}\right). \tag{6}$$

Now by the principle of conservation of mass, the masses of the fluid in $\mathbf{E}$ and $\mathbf{E}'$ are the same, so equating the mass $\varepsilon\eta\zeta\rho$ of $\mathbf{E}$ to the mass of $\mathbf{E}'$ given by (6) yields

$$\varepsilon\eta\zeta\tau\left(\frac{\partial \rho}{\partial t} + \rho\frac{\partial u}{\partial x} + \rho\frac{\partial v}{\partial y} + \rho\frac{\partial w}{\partial z} + u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + w\frac{\partial \rho}{\partial z}\right) = 0.$$

The Cancellation Principle gives

$$\frac{\partial \rho}{\partial t} + \rho\frac{\partial u}{\partial x} + \rho\frac{\partial v}{\partial y} + \rho\frac{\partial w}{\partial z} + u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y} + w\frac{\partial \rho}{\partial z} = 0,$$

i.e.,

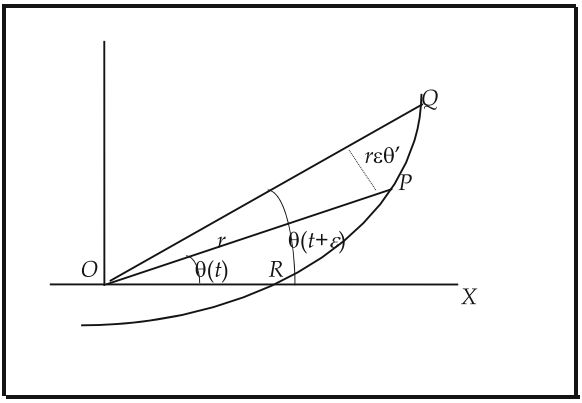
$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho u) + \frac{\partial}{\partial y}(\rho v)\frac{\partial}{\partial z}(\rho w) = 0.$$

This is Euler's equation of continuity.

Next, we derive the *Kepler-Newton areal law of motion under a central force.* We suppose that a particle executes plane motion under the influence of a force directed

toward some fixed point O. If P is a point on the particle's trajectory with coordinates $x, y,$ we write r for the length of the line PO and θ for the angle that it makes with the x-axis OX. Let A be the area of the sector ORP, where $\boldsymbol{R}$ is the point of intersection of the trajectory with OX. We regard x, y, r, θ as functions of a time variable t: thus

$$x = x(t), y = y(t), r = r(t), \theta = \theta(t), A = A(t).$$



Now let Q be a point on the trajectory at which the time variable has value $t + \varepsilon$, with ε in $\boldsymbol{\Delta}$ (figure above). Then by Infinitesimal Straightness the sector OPQ is a triangle of base $r(t + \varepsilon) = r + \varepsilon r'$ and height

$$r \sin [\theta(t + \varepsilon) - \theta] = r \sin \varepsilon\theta' = r\varepsilon\theta'.$$

Here we have used the fact in **SIA** $\sin \varepsilon = \varepsilon$ for infinitesimal ε (Bell 1998).

The area of OPQ is accordingly

$$2 \text{ base} \times \text{height} = 2(r + \varepsilon r')r\varepsilon\theta' = 2\left(r^2\varepsilon\theta' + \varepsilon^2 r r'\theta'\right) = 2r^2\varepsilon\theta'.$$

Therefore

$$\varepsilon A'(t) = A(t + \varepsilon) - A(t) = \textit{area } OPQ = 2\varepsilon r^2\theta',$$

so that, cancelling ε,

$$A'(t) = 2r^2\theta'. \qquad (*)$$

Now let $H = H(t)$ be the acceleration toward O induced by the force. Resolving the acceleration along and normal to OX, we have

$$x'' = H \cos\theta \qquad y'' = H \sin\theta.$$

Also $x = r \cos\theta$, $y = r \sin\theta$. Hence

$$yx'' = Hy\cos\theta = Hr\sin\theta\cos\theta \qquad xy'' = Hx\sin\theta = Hr\sin\theta\cos\theta,$$

from which we infer that

$$(xy' - yx')' = xy'' - yx'' = 0.$$

Hence

$$xy' - yx' = k, \qquad (**)$$

where k is a constant.

Finally, from $x = r\cos\theta$, $y = r\sin\theta$, it follows in the usual way that

$$xy' - yx' = r^2\theta',$$

and hence, by (**) and (*), that

$$A'(t) = 2k.$$

Assuming $A(0) = 0$, we conclude that

$$A(t) = 2kt.$$

Thus the radius vector joining the body to the point of origin sweeps out equal areas in equal times (Kepler's law).

There is an intriguing use of infinitesimals in Einstein's celebrated 1905 paper *On the Electrodynamics of Moving Bodies* (Einstein et al. 1952) in which the special theory of relativity is first formulated. In deriving the Lorentz transformations from the principle of the constancy of the velocity of light, Einstein obtains the following equation for the time coordinate $\tau(x', y, z, t)$ of a moving frame:

(i)
$$\frac{1}{2}\left[\tau(0,0,0,t) + \tau\left(0,0,0,t + \frac{x'}{c-v} + \frac{x'}{c+v}\right)\right] = \tau\left(x',0,0,t + \frac{x'}{c-v}\right).$$

He continues:

Hence, if x' be chosen infinitesimally small,

(ii)
$$\frac{1}{2}\left(\frac{1}{c-v} + \frac{1}{c+v}\right)\frac{\partial\tau}{\partial t} = \frac{\partial\tau}{\partial x'} + \frac{1}{c+v}\frac{\partial\tau}{\partial t},$$

or

$$\frac{\partial\tau}{\partial x'} + \frac{v}{c^2 - v^2}\frac{\partial\tau}{\partial t} = 0.$$

Now the derivation of equation (ii) from equation (i) can be simply and rigorously carried out in **SIA** by *choosing x' to be a nilsquare infinitesimal* ε. For then (i) becomes

$$\frac{1}{2}\left[\tau(0,0,0,t)+\tau\left(0,0,0,t+\varepsilon\left(\frac{1}{c-v}+\frac{1}{c+v}\right)\right)\right]=\tau\left(\varepsilon,0,0,t+\frac{\varepsilon}{c-v}\right).$$

From this we get, using Eq. (1) above,

$$\tau(0,0,0,t)+\frac{1}{2}\varepsilon\left(\frac{1}{c-v}+\frac{1}{c+v}\right)\frac{\partial\tau}{\partial t}=\tau(0,0,0,t)+\varepsilon\left(\frac{\partial\tau}{\partial x'}+\frac{1}{c-v}\frac{\partial\tau}{\partial t}\right).$$

So

$$\frac{1}{2}\varepsilon\left(\frac{1}{c-v}+\frac{1}{c+v}\right)\frac{\partial\tau}{\partial t}=\varepsilon\left(\frac{\partial\tau}{\partial x'}+\frac{1}{c-v}\frac{\partial\tau}{\partial t}\right),$$

and (ii) follows by the Cancellation Principle.

Spacetime metrics have some intriguing properties in **SIA**. In a spacetime the metric can be written in the form

$$(*)\qquad ds^2=\sum g_{\mu\nu}dx_\mu dx_\nu \qquad \mu,\nu=1,2,3,4.$$

In the classical setting (*) is in fact an abbreviation for an equation involving derivatives and the "differentials" ds and dx_μ are not really quantities at all. What form does this equation take in **SIA**? Notice that the "differentials" cannot be taken as infinitesimals in the sense of **SIA** since all the squared terms would vanish. But the equation does have a very natural form in **SIA**. Here is an informal way of obtaining it.

Think of the dx_μ as being multiples $k_\mu e$ of some small quantity e. Then (*) becomes

$$ds^2=e^2\sum g_{\mu\nu}k_\mu k_\nu,$$

so that

$$ds=e\sqrt{\sum g_{\mu\nu}k_\mu k_\nu}.$$

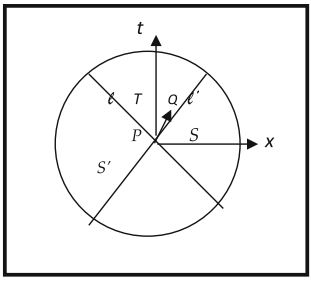
Now replace e by a nilsquare infinitesimal ε. Then we obtain the *metric relation:* in **SIA**

$$ds=\varepsilon\sqrt{\sum g_{\mu\nu}k_\mu k_\nu}.$$

This tells us that the "infinitesimal distance" ds between a point P with coordinates (x_1, x_2, x_3, x_4) and an infinitesimally near point Q with coordinate (x_1 + $k_1\varepsilon$,

$x_2 + k_2\varepsilon, x_3 + k_3\varepsilon, x_4 + k_4\varepsilon)$ is $\varepsilon\sqrt{\Sigma g_{\mu\nu}k_\mu k_\nu}$. Here a curious situation arises. For when the "infinitesimal interval" ds between P and Q is timelike (or lightlike), the quantity $\Sigma g_{\mu\nu}k_\mu k_\nu$ is nonnegative, so that its square root is a real number. In this case ds may be written as εd, where d is a real number. On the other hand, if ds is spacelike, then $\Sigma g_{\mu\nu}k_\mu k_\nu$ is negative, so that its square root is imaginary. In this case, then, ds assumes the form $i\varepsilon d$, where d is a real number (and, of course $i = \sqrt{-1}$). On comparing these we see that, if we take ε as the "infinitesimal unit" for measuring infinitesimal *timelike* distances, then iε serves as the "imaginary infinitesimal unit" for measuring infinitesimal *spacelike* distances.

For purposes of illustration (see figure below), let us restrict the spacetime to two dimensions (x, t), and assume that the metric takes the simple form $ds^2 = dt^2 - dx^2$. The infinitesimal light cone at a point P divides the infinitesimal neighborhood at P into a timelike region T and a spacelike region S bounded by the null lines l and l, respectively (see figure below). If we take P as origin of coordinates, a typical point Q in this neighborhood will have coordinates ($a\varepsilon$, $b\varepsilon$) with a and b real numbers: if $|b| > |a|$, Q lies in T; if $a = b$, P lies on l or l′; if $|a| < |b|$, P lies in S. If we write $d = \sqrt{|\, a^2 - b^2 \,|}$, then in the first case, the infinitesimal distance between P and Q is εd, in the second, it is 0, and in the third it is $i\varepsilon d$.



At the beginning of the twentieth century Poincaré and Minkowski introduced "ict" to replace the "t" coordinate so as to make the metric of relativistic spacetime positive definite. This was purely a matter of formal convenience and was later rejected by (general) relativists. In conventional physics one never works with nilpotent quantities so it is always possible to replace formal imaginaries by their (negative) squares. But spacetime theory in **SIA** *forces* one to use imaginary units, since, infinitesimally, one cannot "square oneself out of trouble." This being the case, it would seem that, infinitesimally the dictum *Farewell to ict* (Misner et al. 1973) needs to be replaced by

$$Vale\text{“}ict\text{”}, ave\text{“}i\varepsilon\text{”}!$$

We conclude this section with a speculation. The infinitesimal domain Δ can be seen to be "tiny" in the order-theoretic sense. For, using ε, η, as variables ranging over Δ, it is not hard to show that

$$\forall\varepsilon\forall\eta\neg(\varepsilon < \eta \vee \eta < \varepsilon)^*.$$

whence

$$\forall\varepsilon\forall\eta(\varepsilon \leq \eta \wedge \eta \leq \varepsilon).$$

In particular, the members of $\mathbf{\Delta}$ are all simultaneously ≤ 0 and ≥ 0 but cannot (because of the nondegeneracy of $\mathbf{\Delta}$) be shown to coincide with zero.

In his book *Just Six Numbers* (Rees 2001) the astrophysicist Martin Rees comments on the microstructure of space and time, and the possibility of developing a theory of quantum gravity. In particular he says:

> *Some theorists are more willing to speculate than others. But even the boldest acknowledge the "Planck scales" as an ultimate barrier. We cannot measure distances smaller than the Planck length [about 10^{19} times smaller than a proton]. We cannot distinguish two events (or even decide which came first) when the time interval between them is less than the Planck time (about 10^{-43} seconds).*

On this account, Planck scales seem very similar in certain respects to $\mathbf{\Delta}$. In particular, the sentence (*) above seems to be an exact embodiment of the idea that we cannot decide of two "events" in $\mathbf{\Delta}$ which came first; in fact it makes the stronger assertion that actually neither comes "first."

Could $\mathbf{\Delta}$ serve as a suitable model for "Planck scales"? While $\mathbf{\Delta}$ is unquestionably small enough to play the role, it inhabits a domain in which everything is smooth and continuous, while Planck scales live in the quantum world which, if not outright discrete, is far from being universally continuous. So if Planck scales could indeed be modeled by microneighborhoods in **SIA**, then one might begin to suspect that the quantum microworld, the Planck regime – smaller, in Rees's words, "than atoms by just as much as atoms are smaller than stars" – is not, like the world of atoms, discrete, but instead continuous like the world of stars. This would be a major victory for the Continuous in its long struggle with the Discrete.

Abstract

In ancient Greek, continuity referred to lines, figures, and solids, or time, place, and motion. All these objects were considered continuous in the same sense: they were divisible into infinitely divisible parts. Bolzano 1817 *Rein analytischer Beweis* (Bolzano, Rein analytischer Beweis des Lehrsatzes, dass zwischen je zwey Werthen, die ein ent-gegengesetzes Resultat gewäihren, wenigstens eine reelle Wurzel der Gleichung liege. Gottlieb Hasse, Prague. In: [53], 253–277, 1817a) gave rise to two brand new ideas: $\varepsilon\delta$ concept of continuous function and continuity of total order in terms of the least upper bound principle. The first was related to motion, the second to a straight line. The chapter aims to reveal the mathematical motives that lead Bolzano to these ideas. In the first part, we discuss Aristotle's definition and examples of continuity, Euclid's concept of magnitude and number, and Pappus' account of mechanical curves. Then we show how the idea of the punctiform curve emerged in Descartes' (Descartes, La Géométrie. Jan Maire, Leiden, 1637). The second part includes a detailed analysis of (Bolzano, Rein analytischer Beweis des Lehrsatzes, dass zwischen je zwey Werthen, die ein ent-gegengesetzes Resultat gewäihren, wenigstens eine reelle Wurzel der Gleichung liege. Gottlieb Hasse, Prague. In: [53], 253–277, 1817a).

Keywords

Continuity · Continuous function · Least upper bound · Magnitudes · Real numbers · Topological continuum

1 Introduction

In modern mathematics, continuity refers to a function or a total order. Continuity of function, whether voiced in terms of $\varepsilon\delta$ or limits of sequences, is the core concept of calculus. Advanced courses prefer a more general, topological definition: a function is continuous when the inverse image of an open set is open.

The characteristic of continuous order depends on whether one considers a totally ordered set or a totally ordered algebraic structure. For the first case, $(X, <)$ has to be a separable space (in the order topology) and satisfy Dedekind cut principle (C1, as formalized below).[1] For the second, we focus on an ordered field, then the continuity means the so-called completeness of real numbers. Regarding real numbers, two

[1] This result is due to Cantor (Cantor 1895), though, originally stated in alternative terms; see (Błaszczyk and Fila 2020a), Sect. 7.

approaches developed at the turn of the nineteenth and twentieth century still play a role in mathematical practice, namely, the axiomatic account initiated by (Hilbert 1900) and the construction of real numbers, as exemplified in (Cantor 1872; Dedekind 1872; Heine 1872; Méray 1869; Weber 1895). Due to analysis of Bolzano (Bolzano 1817a), we prefer the first option. Thus,

Definition 1
The field of real numbers is an ordered field $(\mathbb{F}, +, \cdot, 0, 1, <)$, *in which every Dedekind cut* (L, U) *in* $(\mathbb{F}, <)$ *satisfies the following condition*.[2]

(C1) $(\exists x \in \mathbb{F})(\forall y \in L)(\forall z \in U)(y \leqslant x \leqslant z)$.

This definition refers to the fact that there is only one (up to isomorphism) complete ordered field (see (Birkhoff and Mac Lane 1977), 105–106).

Here are other equivalent versions of C1 we will refer to in sections dedicated to Bolzano (Bolzano 1817a).

(C2) If $A \subset \mathbb{F}$ is a nonempty set which is bounded above, then there exists $a \in \mathbb{F}$ such that $a = \sup A$.
(C3) The field is Archimedean and every Cauchy (fundamental) sequence $(a_n) \subset \mathbb{F}$ has a limit in $\mathbb{F}$.

The Archimedean axiom can also take alternative forms. We will need the following two:

(A1) $(\forall x \in \mathbb{F})(\exists n \in \mathbb{N})(n > x)$.
(A2) $(\forall x, y \in \mathbb{F})(\exists q \in \mathbb{Q})(x < y \Rightarrow x < q < y)$.

Another equivalent form of C1 which plays a role when (Bolzano 1817a) is under scrutiny is the Intermediate Value Theorem (see Sect. 6 below).

By combining the continuity of function and the concept of an ordered field, one gets a topological field, that is, an algebraic field $(\mathbb{F}, +, \cdot, 0, 1, \tau)$, where τ is a topology on $\mathbb{F}$, in which addition, multiplication, and the operation of the inverse element x^{-1} are all continuous in the topology τ. Pontriagin (Pontriagin 1932) provides an insightful characterization of real and complex numbers in terms of topological fields: any locally compact and connected topological field is isomorphic to the field of real or complex numbers.[3] Pontriagin's theorem, thus, provides grounds for the uniqueness of real numbers in the class of topological fields.[4]

[2] It is the standard definition, let us just recall that a pair of nonempty sets A,B is a Dedekind cut in $(\mathbb{F}, <)$ iff (1) $A \bigcup B = \mathbb{F}$, (2) $(\forall x \in A)(\forall y \in B)(x < y)$. See Cohen and Ehrlich (1963).

[3] See Pontriagin (1932), p. 164. Pontriagin theorem also provides a topological characterization of the field of quaternions, which is a non-commutative.

[4] The concept of topological dimension enables determining the difference between fields of real and complex numbers.

Since axioms characterize both ordered and topological fields, there are two unique characteristics of real numbers: in terms of an ordered and topological field.

The idea of continuity is also related to a topological continuum, that is, a compact and connected set. Yet another thread in this history of continuity concerns curves. The concepts of continuous function and topological continuum cover different aspects of that issue (see (Błaszczyk and Fila 2020b), §3).

This variety of ideas mirrors the variety of techniques applied in modern studies of the ancient old phenomenon of continuity. In Greek philosophy, however, it was simple. Examination of continuous objects meant the geometrical studies of lines, figures, and solids, or physical of time, place, and motion. Moreover, all these objects were continuous in the same sense: they were divisible into infinitely divisible parts, while divisibility, interpreted in modern terms, meant addition.

From ancient to modern times, mathematics has undergone a tremendous transformation. Our analysis of (Bolzano 1817a) discusses only two issues. First, the replacement of the ancient technique of proportion by processing formulas according to the rules of an ordered field. Second, the replacement of the mechanical curves of ancient mathematics by punctiform functions. In chapter *Descartes' transformation of the Greek notion of proportionality* (in this *Handbook*) we explore in part the first topic. Throughout (Bolzano 1817a), Bolzano applies laws of an ordered field regularly, some of them explicitly, others implicitly. Considering his explicit use of the LUB principle, variables x, y, z in (Bolzano 1817a) range over the domain of real numbers. In this way, real numbers frame Bolzano's study of continuous function and continuous line.

The plan of the chapter is as follows. In Sects. 2 and 3, we discuss the idea of continuity in Aristotle's philosophy and ancient mathematics. Section 4 is a methodological interlude. In Sect. 5, we show how the Greek concept of a curve was turned into a punctiform line of modern mathematics. Sections 6, 7, 8, 9, and 10 include a detailed analysis of (Bolzano 1817a). Section 11 presents Bolzano and Cantor's concept of the topological continuum in a metric space.

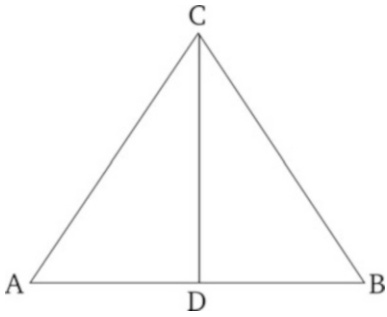
2 Continuity in the Greek Philosophy

Boyer (1949) overviews competing trends in the ancient philosophy of continuity. In this section, we present a sample of Aristotle's statements concerning continuity and discreteness. His definitions and examples parallel the mathematical treatment of magnitudes and numbers. We show they are a philosophical characterization of entities studied by Euclid, Archimedes, and Pappus, to mention only those who we refer to in sections that follow.

Let us start with the famous definition: "I call continuous (συνεχές) that which is divisible into infinitely (ἀεί) divisible divisibles" (*Physics* VI.2, 232b24–25).[5]

[5] English translations of Aristotle by Benjamin Wilck.

Fig. 1 The *Elements*, I.10



A model example of a continuous object is a segment line. In proposition I.10 of the *Elements*, Euclid shows how to cut a given line in half. Figure 1 represents the accompanying diagram.

Line segment *AB* is divided into other line segments *AD*, *DB*. Given the same construction applies to *AD*, and, say D_1, cuts *AD* in half, *AD* will be divided into AD_1, and D_1D. This procedure can be iterated ad infinitum, and on each stage, it will output new line segments. That is how Euclid's proof supports Aristotle's definition: a line segment is divisible into infinitely divisible line segments.

In the following quotation, Aristotle exemplifies continuous and discrete entities: "Of quantities (ποσόν) some are discrete (διωρισμένον), others continuous. [. . .] Discrete are, for instance, number and language, continuous are lines, surfaces, bodies, and, besides these, time and place" (*Categories* 6, 4b20–25). Here, Aristotle characterizes geometrical objects and numbers as objects of substantially different nature. Elsewhere he alludes, they need a different way of studying.[6] Indeed, in Euclid's *Elements*, geometrical objects and numbers are studied by different techniques in separate books. In the next section, we point out substantial mathematical differences between these domains.

In *Physics*, books V to VII, Aristotle also takes motion to be continuous. At *Physics* V.4, 228a20 he says plainly "every motion is continuous." The same is dedicated to Zeno paradox *Physics*, VI.2. It starts as follows: "Since every magnitude (μέγεθος) is divisible into magnitudes (for we have shown that it is impossible for anything continuous (συνεχές) to be composed of indivisibles, and every magnitude is continuous), it is necessary for that which is faster to traverse a greater magnitude in an equal time, and equal magnitude in less time, and a greater magnitude in less time, just as some people have defined 'faster'" (*Physics* VI.2, 232a23–27).

Continuity of motion will turn to be relevant in our discussion of mechanical curves and continuity of function.

[6] At *Posterior Analytics* I.7, 75a38–39, Aristotle states that one cannot cross from one kind (e.g., numbers) to another (e.g., magnitudes). From *Posterior Analytics* I.7, 75b9 follows that this applies to mathematical proofs: one cannot derive theorems on magnitudes from principles in the domain of numbers. Interestingly, Bolzano, raised in the scholastic tradition, refers to that methodological rule in (Bolzano 1817a).

3 Continuous vs Discrete in the Greek Mathematics

3.1 Magnitudes

In ancient Greek mathematics, the general term μέγεθος; (magnitude, quantity) covers line segments, triangles, convex polygons, circles, angles, arcs, and solids.[7] Euclid's book V develops rigorous treatment of magnitudes, ratios, and proportions.

We formalize magnitudes of the same kind (line segments being of one kind, triangles being of another, etc.) as an additive semi-group with a total order, $(M, +, <)$, characterized by the following five axioms:

E1 $(\forall x, y)(\exists n \in \mathbb{N})(nx > y)$,
E2 $(\forall x, y)(\exists z)(x < y \Rightarrow x + z = y)$,
E3 $(\forall x, y, z)(x < y \Rightarrow x + z < y + z)$,
E4 $(\forall x)(\forall n \in \mathbb{N})(\exists y)(x = ny)$,
E5 $(\forall x, y, z)(\exists v)(x : y :: z : v)$.
The term nx is defined by $nx = \underbrace{x + \ldots + x}_{n-times}$.

The transitivity and the trichotomy laws characterize the relation *greater than*, $<$. Equality of line segments, angles, and arcs means congruence. Equality of figures should be interpreted in Euclid's theory of area, as explained in (Błaszczyk 2018); equality of solids involves a similar theory developed in book XII of the *Elements.*

E1 interprets definition V.4, the so-called Archimedean axiom: "Magnitudes [x, y] are said to have a ratio with respect to one another which, being multiplied [nx] (*πολλαπλασιαζόμενα*), are capable of exceeding one another [$nx > y$]."[8] The term *nx,* as it stands here, interprets the phrase *multiple of the magnitude.*

Axioms E2 and E3 apply all through book V, for example, in V.8 and V.25. E2 also occurs in Aristotle's writings. They are, then, easily identified.

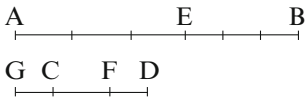
From the logical point of view, E4 is inessential since it follows from the remaining four axioms, that is, E1–E3, and E5. Yet, it bears a deep philosophical sense; we consider it a formalization of Aristotle's definition of continuity.

E4 implicitly applies in proposition V.5. Therein Euclid proves the following relation (see Fig. 2): "[L]et the magnitude AB be the same multiple of the magnitude CD that the (part) taken away AE (is) of the (part) taken away CF (respectively). I say that the remainder EB will also be the same multiple of the remainder FD as that which the whole AB (is) of the whole CD (respectively)." In symbols: $AB = kCD$, $AE = kCF \Rightarrow EB = kFD$.

[7] Euclid's definition I.8 provoked a philosophical debate whether angles are magnitudes; see (Wilck 2020), p. 381. From the perspective of book V, angles are terms in proportions on a par with line segments or circles. However, one can raise strictly mathematical objections whether angles satisfy axiom E3.

[8] English translations of the Elements after (Euclid 2007).

Fig. 2 The *Elements*, V.5



In the proof, he assumes such a point G that the relation obtains $EB = kGC$. In other words, for any EB and any k, there exists GC such that $EB = kGC$.

Proposition VI.9, where Euclid shows how to divide a line segment into any number of parts, demonstrates the infinite divisibility of line segments. In Book V, line segments in diagrams represent magnitudes of any kind, yet, E4 stands for divisibility of magnitudes rather than line segments alone.

E5 represents the so-called fourth proportional axiom. In book V, it applies in proposition V.18. Next, it is explored in the method of exhaustion (see, e.g., XII.1).

For a symbolic representation of proportion, we adopt the term x: y:: z: v. It was introduced already in the seventeenth century. The definition of proportion, V.5, is verbal. We interpret it by the following formula:

$$x : \ y :: \ \mathrm{z} : \ v \Leftrightarrow_{df} (\forall m, n \in \mathbb{N})[(nx >_1 my \Rightarrow nz >_2 mv) \wedge$$

$$\wedge (nx = my \rightarrow nz = mv) \wedge (\mathrm{nx} <_1 \mathrm{my} \Rightarrow \mathrm{nz} <_2 \mathrm{mv})].$$

The assumption regarding magnitudes x, y, on the one hand, and z, v, on the other, being of the same kind is formalized by $x, y \in \mathfrak{M}_1 = (M_1, +, <_1)$, and z, $v \in \mathfrak{M}_2 = (M_2, +, <_2)$.

Definition V.7 introduces a relation *greater than* between pairs of magnitudes. We interpret it as follows:

$$x : \ y \succ z : \ v \Leftrightarrow_{df} (\exists m, n \in \mathbb{N})[(nx >_1 my) \wedge (nz \leqslant_2 mv)].$$

Thus, the structure of magnitudes is an ordered semigroup equipped with the 4-ary relation of proportion $(M, +, ::, <)$.[9]

3.2 Numbers

Euclid's *Elements* books VII to IX provide foundations for the ancient Greek number theory.[10] Number (ἀριθμός) means the modern integer greater than 1. Zero does not occur in the *Elements,* while 1 is the so-called monad (μονάς). The first three definitions of book VII clarify the relation between monads and numbers. They read:

[9] For detailed analysis leading to axioms for book V, see (Beckmann 1967; Błaszczyk and Mrówka 2013), or (Mueller 2006). See also Descartes' transformation of Greek notion of proportionality in this Handbook.

[10] More advanced arithmetic was developed by Diophantus, see (Christianidis and Oaks 2021).

"A unit (μονάς) is (that) according to which each existing (thing) is said (to be) one. And a number (is) a multitude (πλῆθος) composed of units. A number is part of a number, the lesser of the greater [$n < m$], when it measures the greater."

We formalize definition VII.2 as follows:

$$n = \underbrace{1 + \ldots + 1}_{n-times}. \tag{1}$$

The term *n measures m* means that for some $k \in \mathbb{N}$ the equality holds

$$m = kn = \underbrace{n + \ldots + n}_{k-times}.$$

Multiplication of numbers as introduced by definition VII.15, we formalize by

$$n \cdot m = \underbrace{m + \ldots + m.}_{n-times}$$

Hence, *n measures m* means *n* divides *m* in the ring of integers.

Euclid's numbers, then, form a structure (A, +, ·, <), where addition and relation *greater than* are primitive notions characterized by the above axioms E2, E3. *Greater than* is a transitive relation that satisfies the trichotomy law. Both addition and multiplication are associative and commutative operations.

The infinite divisibility of magnitudes, demonstrated as the axiom E4, does not hold in the domain of numbers. On an ontological level, a number is a discrete object for it consists of units, and units have no parts.

Next to these arithmetic operations, in definition VII.20, Euclid introduces a proportion of numbers. It reads:

> Numbers are proportional when the first is the same multiple, or the same part, or the same parts, of the second that the third (is) of the fourth.

We formalize it by

$$m : \ n :: \ k : \ l \Leftrightarrow \exists \mathrm{p}(pn = m, pl = k) \vee \exists p(pm = n, pk = 1) \vee$$

$$\vee (\exists u_1, u_2)(\exists \mathrm{p}, q)(m = pu_1, n = qu_1, k = pu_2, l = qu_2).$$

The proportion of numbers, contrary to magnitudes, does not refer to the relation *greater than.* There is also no counterpart of definition V.7 in Euclid's arithmetic. Moreover, axiom E5 does not hold in the domain of numbers. Indeed, the fourth proportional usually is linked with continuous rather than discrete structures. Weber (Weber 1895), for example, develops a theory of real numbers based on a tricky account of proportions. In his approach, the fourth proportional follows from the

Dedekind cut principle. Then, through the fourth proportional, Weber defines addition and multiplication of ratios, and as a result, real numbers.[11]

Finally, Euclidean numbers are well-ordered, that is, in every non-empty subset of A, there is the least element. This principle, explicitly or implicitly, applies in books VII–IX.[12] Let us start with the train of propositions VII.30–32. They anticipate the fundamental theorem of arithmetic. VII.31 reads:

> Every composite number is measured by some prime number.

The *reductio ad absurdum* proof runs as follows. Let A be a composite number. By definition VII.13, it is measured by some number, say B. If B is prime, the work is done. If it is composite, another number, say C, measures it. Since C measures B, it also measures A. Reiterations of this procedure produce an endless chain of composite numbers $A > B > C > \ldots$ such that a less divides each one greater. At this stage, Euclid concludes: "the number A will be measured by an infinity of numbers (ἄπειροι ἀριθμοί), each of which is less than the preceding. The very thing is impossible for numbers."

Thus, Euclid explicitly assumes that there are no infinite decreasing sequences of numbers. This condition is equivalent to the well-ordering of numbers.[13] The well-ordering of numbers plus E2 and E3 entail the axiom E1.

In proposition VII.2, Euclid determines the greatest common measure of numbers AB and CD (not prime to one another). The crucial step in his procedure includes the division algorithm (in modern terms), or an algorithm of continuous subtraction (ἀνθυφαίρεσις), as Euclid refers to it. It runs as follows: "if CD does not measure AB then some number will remain from AB and CD, the lesser being continually subtracted, in turn, from the greater, which will measure the (number) preceding it. For a unit will not be left."[14] In symbols

$$AB = kCD + EA, CD > EA > 1.$$

Given the continuous subtraction applies to CD and EA, another equality obtains

$$CD = mEA + FC, EA > F\,C.$$

Finally, Euclid assumes "let CF measure AE," which is

[11] For Weber's concept of magnitude see (Błaszczyk and Fila 2020a).

[12] In proposition V.8, Euclid assumes there is the least element in the set {k: kx > y}, given x, y are magnitudes. Euclid's argument is as follows. He considers multiples of D, L = 2D,M = 3D,N = 4D, and declares "the quadruple multiple N of D — the first greater than K." It means $M \leqslant K \leqslant N$. In this context, 'any multiples' are 2D, 3D, 4D because Euclid does not use the big quantifier. In a modern interpretation, that argument would be like this N = (k + 1)D, M = kD.

[13] This equivalence is easily demonstrable, yet it requires the use of the axiom of choice (see (Kuratowski and Mostowski 1976), 225).

[14] E1 and the well-ordering of numbers justify the division algorithm.

$$EA = nF\ C.$$

Then he shows that CF measures both AB and CD, and it is also their greatest common measure.

The proof, thus, includes what we currently know as the so-called Euclidean algorithm (actually three while loop iterations of that algorithm). Euclid assumes that the algorithm stops regardless of input numbers. Indeed, it is guaranteed by the continuous decreasing of remainders, plus the assumption that every decreasing series of numbers is finite.[15]

Interestingly, in book X of the *Elements*, the algorithm of continuous subtraction is applied to line segments. When it stops, two lines are considered commensurable, otherwise incommensurable (see proposition X.2). According to Knorr (Knorr 1975), that algorithm was known long before Euclid. It looks like Euclid applied it also to numbers. With the rule that every decreasing series of numbers is finite, it turned into an effective procedure. One could speculate further that definition VII.2 could play a heuristic role in that process. Although it hardly bears any mathematical sense, it could have contributed to establishing the well-ordering of numbers.

To sum up this section, Euclidean numbers form a structure $(A, +, \cdot, <)$ which satisfies axioms E1–E3. Moreover, the total order of numbers is well-ordering.[16]

3.3 Mechanical Curves

Book IV of Pappus' *Collection* introduces quadratrix, spiral, and conchoid. A characteristic of each curve repeats the same pattern of genesis followed by symptomata. The genesis part determines a movement of a point, say C, being a composition of a turning straight line and a rectilinear motion of another straight line or point. As a result, it is the moving point C that describes a curve. The symptomata part defines the decisive feature of the curve employed in any further analysis. While genesis refers to the non-mathematized concept of movement, symptomata provides purely mathematical characteristics. Pappus applies symptomata straightforwardly. However, he seeks to relate phenomena of different kinds: non-mathematized movement and mathematized genesis of a curve.

Here is how Pappus sets forth conchoida:

[15] For the modern mathematical account of the Euclidean algorithm see (Birkhoff and Mac Lane 1977), 18–22.

[16] (Malmendier 1975) provides a concise axiomatic interpretation of Euclid's book VII. (Mueller 2006) interprets Euclid's books VII to IX, though it is rather an exercise in lengthy discussions. Both (Malmendier 1975) and (Mueller 2006) are focused on a formalization of proportions of numbers. Neither (Malmendier 1975) nor (Mueller 2006) discusses the role of well-ordering in Euclid's arithmetic.

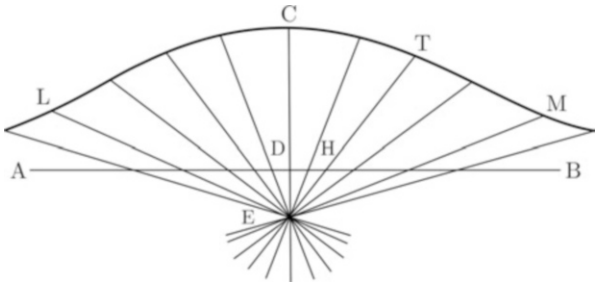


Fig. 3 Pappus, *Collection*, Book IV, p. 126

Genesis: "the straight line CDEZ travels along the straight line ADB, dragged via the point E in such a way that [. . .] it is obvious that the point C will describe a line such as LCM is" (Pappus of Alexandria 2010, 126).

Symptomata: "[. . .] whenever some straight line from the point E toward the line meets it, the [straight line] cut off between the straight line AB and the line LCM is equal to the straight line CD" (Pappus of Alexandria 2010), 126) (Fig. 3).

Compared with current courses, a definition of curve plays the role of symptomata, while genesis is usually only a heuristic supplement. Moreover, the modern curve is a set of points that meet some conditions. For instance, the modern definition of conchoid reads: "Let S be any curve and let A be a fixed point. If a straight line is drawn through A to meet S at Q, and if P and P' are points on this line such that $P'Q = PQ = k$ (constant), the locus of P and P' is called *a conchoid of S with respect to A*" (Lockwood 1961), 127).

When S is a straight line, and A does not lie on S, the resulting curve is the so-called conchoid of Nichomedes. On the Cartesian plane $\mathbb{R}^2$, when the straight line rotates around the point $O = (0, 0)$, and S is the vertical line $x = a$, the conchoid is the following set of points $\{(x, y) \in \mathbb{R}^2 : (x^2 + y^2)(x - a)^2 = k^2x^2\}$. In that context, the early modern term *locus* takes the meaning of set. In the set-theoretical framework, the cardinality of the set $\mathbb{R}^2$ represents a multitude of points on a curve.[17]

4 Toward Modern Mathematics

Ancient philosophy characterization of magnitudes and numbers concern individual objects: a line segment and a number. Their mathematical counterparts seem very simple. It is the axiom E4 and formula (1), respectively. However, the above characteristic of magnitudes and numbers consists of axioms E1–E5 and a list of properties including E1–E3 plus the well-ordering. It is because we adopt the modern perspective and shift a focus from individual objects to the algebra (structure) of magnitudes

[17] Here is a video presenting the ancient conchoida http://www.eudoxos.pl/kartezjusz/konstrukcje-nieklasyczne/.

(M, +, ::, <) or numbers (A, +, ·, <). There is no doubt that in Greek mathematics, a comparison *A greater than B* did not pair with the concept of a totality of As, and Bs ordered by a relation *greater than*. On the other hand, it is also obvious that thinking in terms of operations and their properties precedes the set-theoretic paradigm.

The modern concept of continuity refers to structures, whether an ordered field, a topological field, a totally ordered set, or a topological space. As regards continuity of a function, it assumes that a function consists of points. This idea predates Bolzano's definition of a continuous function by 180 years.

5 Curves Consisting of Points

Brouwer's choice sequences aiming to represent real numbers sparked the early twentieth-century philosophical debate over the nature of continuum. Intuitionists proudly declared that contrary to classical mathematics, their continuum did not fall apart into individual points. Bell (Bell 2005) essentially reiterates the same criticism regarding the entire twentieth-century mathematics.

The term continuum in that debate stands for the domain of functions studied by the calculus techniques and implicitly is related to the set-theoretical account of mainstream mathematics. Indeed, 1872s papers of Heine, Cantor, and Dedekind introducing real numbers implied mathematical objects were point sets. The twentieth-century achievements have completed the project of founding mathematics on the set theory. Nevertheless, the second wave of the foundational studies, that is, the axiomatic account of real numbers developed by[18] (Hilbert 1900; Artin and Schreier 1926; Tarski 1931) does not rely on the idea of a punctiform number-line. Moreover, in the context of elementary geometry, straight lines consisting of points occur in axiomatic systems developed by (Birkhooff 1932; Borsuk and Szmielew 1960). Yet (Hilbert 1903) does not go beyond the ancient Greek idea of points lying on a line, while (Tarski 1959) develops geometry without the concept of a straight line.

Bolzano's ideas of continuous total order and continuous function apply to point set objects. In the context of elementary geometry, the idea of straight lines consisting of points was explicitly introduced by Bolzano already in (Bolzano 1804). His later works applied it in his studies of the topological continuum, time, and space (see (Bolzano 1851), §38). Yet, it is not Bolzano who introduced this new perspective. It all started with Descartes and his formula representing a curve.

5.1 Descartes' Curves Described by Rotating Lines

In ancient Greek mathematics, a line is not a composition of points, yet we find specific relations between lines and points. (1) A straight line is usually a line segment with its

[18] Hilbert 1900; Artin and Schreier 1926; Tarski 1931.

ends. In a proposition and on an accompanying diagram, it is represented by its endpoints such as AB. Conics and other curves, when bounded, are also taken with their endpoints. Points lying on a half-line with one end or an infinite line with no ends represent these objects. Circles, as a rule, are identified by three random points. (2) On lines, there are random points employed in proofs. Capital letters such as *A* and *B* represent them. (3) Each intersection of lines determines a point represented by a capital letter. When, for example, in proposition I.10, a finite straight line *AB* is cut in half, a new point occurs, *D*. It is the intersection of *AB* and the bisector of the angle $\angle ACB$. New straight lines, *AD* and *DB* share point *D* in common (see Fig. 1 above).

These three relations significantly affected Descartes' concept of the curve. In book II of (Descartes 1637), he studies curves described by intersecting lines: a turning straight line and a curve that moves along some other straight line. That procedure carries out three times in (Descartes 1637).[19] The resulting curves are represented in Figs. 4 and 5.

In the first case, the turning line *GCL* intersects with the straight line *CKN*. In the second, it intersects with the circle. Here is how Descartes portrays these moving lines and their intersections.[20]

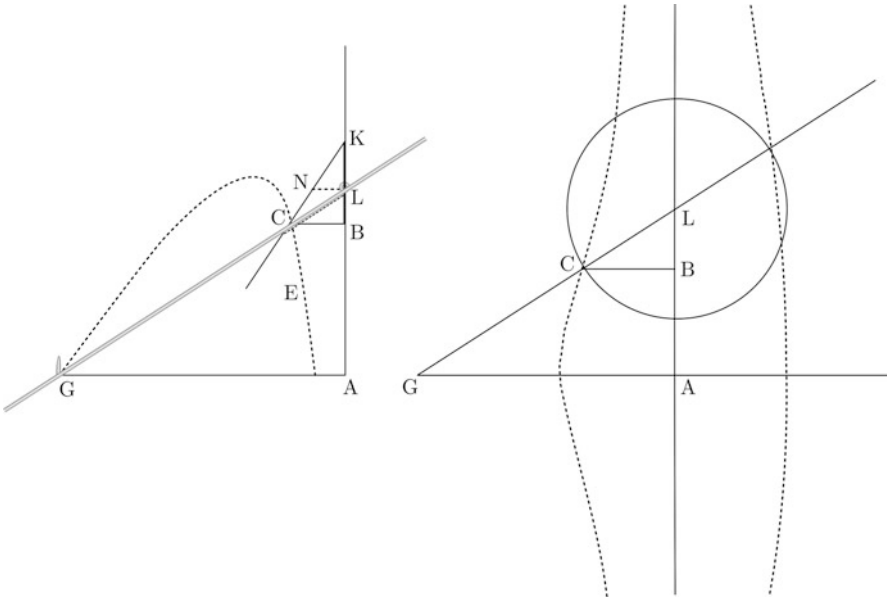

Fig. 4 *La Géométrie*, p. 321 (left). Descartes' conchoid (right)

[19] One can also add to that group curves drawn by mezolabium of Descartes.

[20] Here is a video presenting Descartes' hyperbola http://www.eudoxos.pl/hiperbola-kartezjusza/. Here is another one presenting his conchoida http://www.eudoxos.pl/konchoida/.

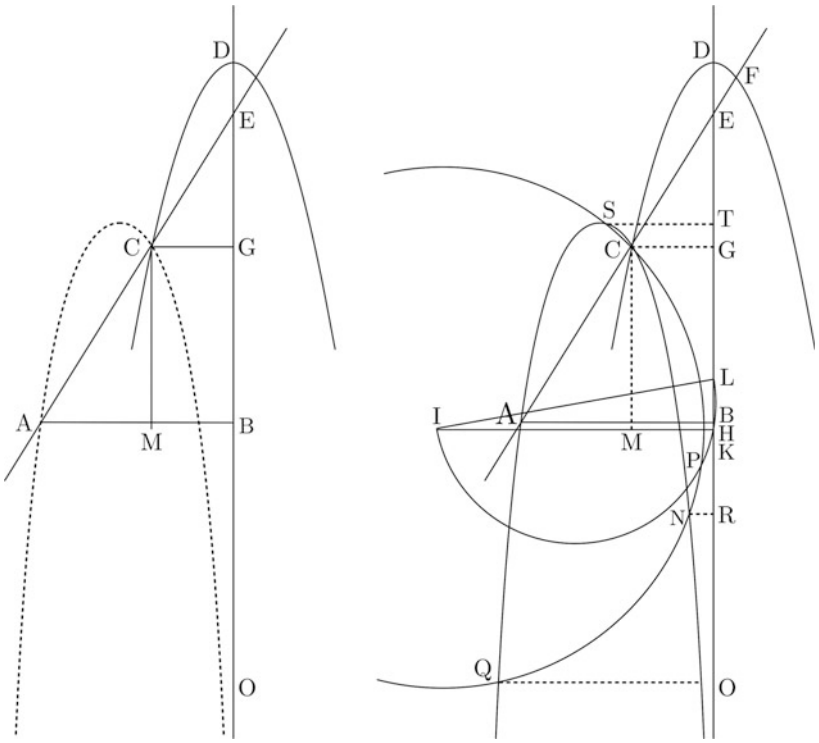

Fig. 5 Descrates' cubic parabola (left). *La Géométrie*, p. 404 (right)

> Suppose the curve EC to be described by the intersection (*decrite par l'intersection*) of the ruler GL and the rectilinear plane figure CNKL [. . .] the curve EC belongs to the first class, it being, in fact, a hyperbola (Smith and Lathan 2007, pp. 51, 55).
>
> [I]f CNK be a circle having its center at L, we shall describe the first conchoid of the ancients (Smith and Lathan 2007, p. 55).

In Fig. 5, the diagram on the left, the turning line ACE intersects with the parabola CD. The resulting cubic parabola (marked with a dashed line) applies in the construction of roots of a sixth-degree polynomial. The genesis of the curve plays a role in that problem (see Fig. 5, the diagram on the right).

In (Descartes 1637), the formula of a curve replaced Pappus' symptomata. Moreover, the genesis of the curve is not relevant in deriving the formula. In the case of hyperbola, it relies on a relationship between coordinates x, y of a specific intersection point, $C = C(x, y)$. That relation is encoded in a polynomial equation $f(x, y)$ – it is the formula of the curve. Yet, $f(x, y)$ is derived from relations between similar triangles, as represented in Fig. 6 below. Here is how Descartes describes the derivation process:

"Then I say that as NL is to LK, or as c is to b, so CB, or y, is to BK, which is therefore equal to $\frac{b}{c}y$. Then BL is equal to $\frac{b}{c}y - b$, and AL is equal to $x + \frac{b}{c}y - b$.

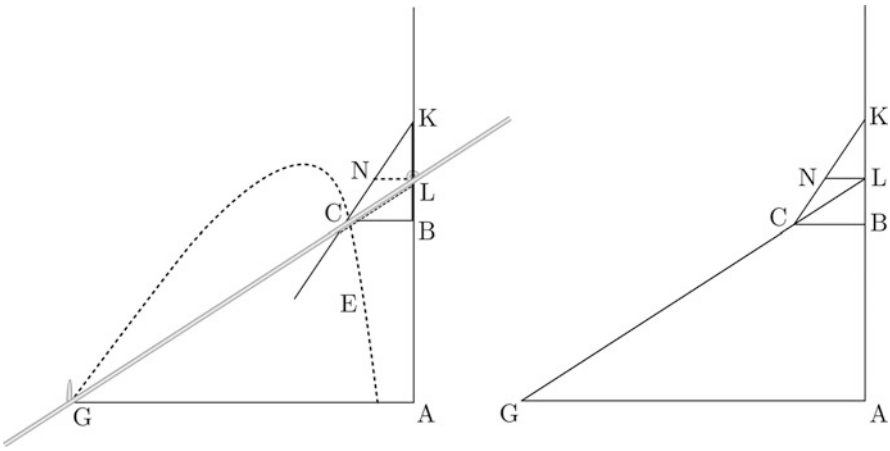

Fig. 6 *La Géométrie*, p. 320 (left). Similar triangles used in deriving the formula of the hyperbola (right)

Moreover, as CB to LB, that is, as y is to $^{-}\frac{b}{c}y - b$, so AG or a is to LA or $x + \frac{b}{c}y - b$ Multiplying the second by the third, we get $\frac{ab}{c}y - ab$ equal to $xy + \frac{b}{c}yy - by$, which is obtained by multiplying the first by the last. Therefore, the required equation is $yy = cy - \frac{cx}{b}y + ay - ac$" (Smith and Lathan 2007, 51).

In sum, the hyperbola consists of intersection points $C = C(x, y)$, and no other points. A required *locus* is characterized by the formula $f(x, y)$. However, the continuity of that curve comes from the continuous motion of the point C tracing the curve. Although the formula $f(x, y)$ represents the curve, there is no idea of a domain of f. Curve is still continuous in the ancient style. The modern concept of continuous function requires both formula and domain.

6 Continuity and Intermediate Value Theorem

(Bolzano 1817a) plays a crucial role in the bifurcation of the ancient concept of continuity. In this paper, Bolzano provides modern characteristics of a continuous function and continuity of a totally ordered set. These two concepts are involved in his proof of the Intermediate Value Theorem, IVT, in short. Interestingly, Bolzano seeks to prove what we would call a specific case of this theorem, namely, the IVT for a polynomial, IVT for a continuous function is a lemma in his study. Nowadays, his lemma is the main theorem. Arguably, it is so, for Bolzano's characterization of a continuous function was a brand new idea at that time, while it is the basic concept of current calculus courses. To be clear, it took more than five decades to rephrase Bolzano's interpretation of continuous function into the modern $\varepsilon\delta$ continuity. Even throughout his paper, the account of continuous function evolves significantly: it starts with the *Preface's* definition adopting the two quantifiers form $\forall\exists$, then, through the proof of the so-called sign preserving principle where it finds a three

quantifiers version ∀∃∀, finally it reaches yet another recast in proving the continuity of a polynomial. Moreover, in (Bolzano 2000), Bolzano's sense of discontinuity is by no means a negation of any of these three versions of continuity. Therefore, instead of focusing on the explicit definition, we prefer to study its actual applications.

While the paper discusses the concept of a continuous function carefully, the import of continuity of total order disappears in a maze of inferences between the least upper bound principle, the so-called Cauchy completeness, and implicit use of the Archimedean axiom. In fact, from the perspective of the general plan of (Bolzano 1817a), the continuous order plays but a side role. Yet, it is hard to overestimate its mathematical importance. We address this topic in Sect. 9.

To build a perspective, we start this part with a remainder of the modern proof of IVT.[21]

6.1 Intermediate Value Theorem

Here is the standard wording of IVT: If a continuous function f changes its sign in an interval of real numbers [a, b], then there exists an argument c in (a, b) such that $f(c) = 0$. In symbols,

$$f : [a, b] \mapsto \mathbb{R}, f(a) \cdot f(b) < 0 \Rightarrow \exists c \in (a, b)[f(c) = 0]. \tag{2}$$

The classic proof emulates the proof developed by Bolzano. It goes like that. Assume that $f(a) < 0 < f(b)$. Put $S = \{x \in [a, b] : f(x) < 0\}$. The set S is not empty, since $a \in S$; it is also bounded above by b. Therefore we can apply the least upper bound principle, LUB. Let

$$c = \sup S. \tag{3}$$

There are three possibilities: $f(c) < 0, f(c) = 0, f(c) > 0$. If $f(c) < 0$, then due to the assumed continuity of f, the sign of $f(c)$ is preserved in some neighborhood of c, that is:

$$(\exists \delta)(\forall x)[x \in (c - \delta, c + \delta) \Rightarrow f(x) < 0]. \tag{4}$$

From (4) it follows that there is x such that $c < x$ and $f(x) < 0$. This contradicts (3). The case $f(c) > 0$ is treated similarly. Hence, $f(c) = 0$ (see Fig. 7).

This proof, thus, relies on two different concepts of continuity: the definition (3) appeals to the continuity (completeness) of an order of real numbers, formula (4)

[21] Błaszczyk (2016) shows that IVTf is equivalent to (C1). This result enables a new interpretation of (Bolzano 1817a) in terms of real-closed fields. For the concept of real-closed field and its relation to IVTp see (Jacobson 1969), ch. VI. In what follows, we present, say, a conservative reading of (Bolzano 1817a).

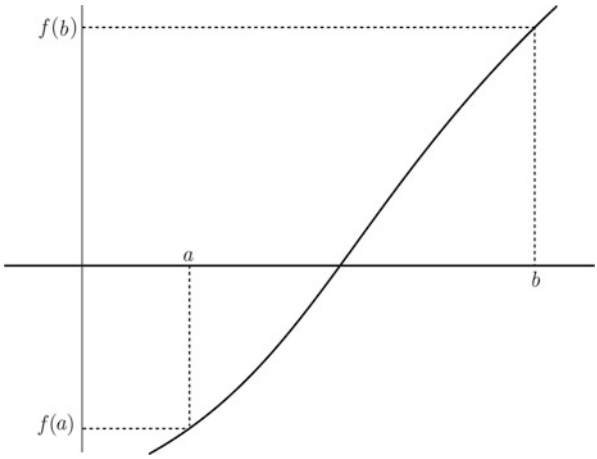

Fig. 7 Diagram for IVT

follows from the assumed continuity of *f*. In fact, (Bolzano 1817a) provides the first-ever formulation of the LUB principle and the first-ever εδ-kind characteristic of continuous function.

7 The Structure of *Rein Analytischer Beweis*

Figure 8 represents the logical structure of (Bolzano 1817a). In this paper, Bolzano aims to show the Intermediate Value Theorem for polynomials, IVT_P in short. The proof applies, on the one hand, the theorem that a polynomial is a continuous function, *cont of poly*, on the other, the Intermediate Value Theorem for a continuous function, IVT_f. Both of these results apply the definition of a continuous function, *df of cont*; the first directly, the other via the so-called sign preserving property, SPP, as explained by formula (4) above. The proof of IVT_f also employs LUB. Bolzano proves it by referring to Cauchy Completeness, CC. He also seeks to prove CC, which seems incorrect from the modern axiomatic perspective. Throughout the paper, he implicitly refers to two different forms of the Archimedean axiom, namely: (1) $(\forall r \in \mathbb{R})(\exists n \in \mathbb{N})(n > r)$, (2)$(\forall D, d \in \mathbb{R}_+)(\exists n \in \mathbb{N})\left(\frac{D}{2^n} < d\right)$.[22]

Hypothetically, it was possible to prove IVT_P by applying the concept of continuity straight to a polynomial with no reference to the general concept of function.[23]

[22] In (Bolzano 1817b), Bolzano calls axioms of Archimedes the following conditions: "I. Every curved line is longer than the straight line lying between the same end-points. II. Of two curved lines which are both concave on one side the enclosing one is longer than the enclosed one. III. If a curved and a plane surface have the same boundaries the former is greater than the latter. IV. Of two curved surfaces which are both concave on one side the enclosing one is greater than the enclosed one" (Russ 2004), 281. These axioms mimic assumptions of Archimedes' treaty On the Sphere and Cylinder, see (Heath 2002), pp. 3–4.

[23] That is how Birkhoff and Mac Lane prove the Fundamental Theorem of Algebra 150 years after Bolzano; see (Birkhoff and Mac Lane 1977), ch. 4, or (Błaszczyk 2016), p. 19.

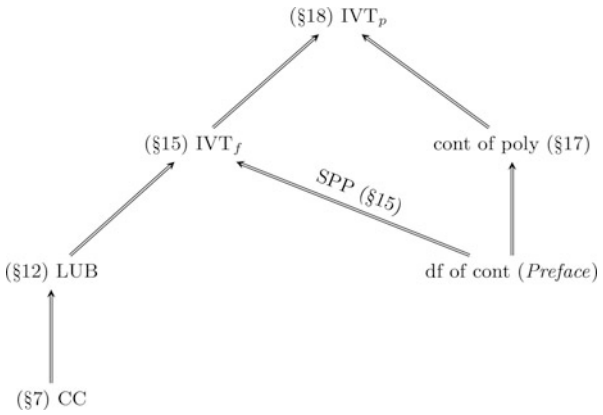

Fig. 8 Plan of Bolzano's *Rein analytischer Beweis*

Whether applied to a function or a polynomial, the analytic form of continuity introduced by Bolzano was then a brand new idea.[24]

7.1 Two-Functions Pattern

Contrary to the modern version, Bolzano's IVT$_f$ involves two functions as it reads: "If two functions of x, fx and φx, vary according to the law of continuity either for all values of x or for all those lying between α and β, and furthermore if $f\alpha < \varphi\alpha$ and $f\beta > \varphi\beta$, then there is always a certain value of x between α and β for which $fx = \varphi x$" (Russ 2004), 274).

Thus, for continuous functions f, φ on the interval $[\alpha, \beta]$ the following implication holds

$$f(\alpha) < \varphi(\alpha), f(\beta) > \varphi(\beta) \Rightarrow \exists x \in (\alpha, \beta)[f(x) = \varphi(x)]. \tag{5}$$

Putting $f := f - \varphi$, we get IVT in version (2). In Sect. 9.3 below, we will address the issue of whether f, φ are real maps.

As for the main theorem of (Bolzano 1817a), it reads: "If a function of the form $x^n + ax^{n-1} + bx^{n-2} + \ldots + px + q$, in which n denotes a positive integer, takes a *positive* value for $x = \alpha$, but a *negative* value for $x = \beta$, then the equation $x^n + ax^{n-1} + bx^{n-2} + \ldots + px + q = 0$ has at least one *real root* lying between α and β" (Russ 2004), 276).

Its proof is as follows. Let $W(x) = x^n + ax^{n-1} + bx^{n-2} + \ldots + px + q$, let $0 < \alpha < \beta$, and $W(\alpha) > 0 > W(\beta)$. Then, some terms of $W(\alpha)$ are positive, some are negative.

[24] There is an ongoing debate over a relation between Bolzano and Cauchy definitions of a continuous function; see (Bair et al. 2020) for the latest position in this dispute. In Sect. 8.3, we show how Otto Stolz obtained the modern $\varepsilon\delta$ definition of a continuous function by interpreting Bolzano's proof of the continuity of polynomial.

Moreover, "it is clear that exactly the same terms of the function which are positive or negative for $x = \alpha$ also keep this sign for $x = \beta$ and for all values of x lying between α and β" (Russ 2004, 277).

Indeed, since x^k are positive for every integer k, due to the condition $W(\alpha) > 0 > W(\beta)$, some coefficients among $a,b,\ldots,p,q$ are positive, some are negative. For instance, suppose $a,b > 0$, $p,q < 0$, then $W(x) = x^n + ax^{n-1} + bx^{n-2}$ — (| p| x+| q|). The sum of *positive* terms forms a polynomial $\varphi(x)$, the sum of *negative* terms forms another polynomial $f(x)$. To give a more specific example, when $W(x) = x^2 - x^3$, $\alpha = ½$, $\beta = 2$, then $\varphi(x) = x^2$, $f(x) = x^3$.

Since polynomials are continuous functions, and $f(\alpha) < \varphi(\alpha)$, $f(\beta) > \varphi(\beta)$, by applying (5) Bolzano gets the result $f(x) = \varphi(x)$, for some x. The other two cases, that is, $\alpha < 0 < \beta$, and $\alpha < \beta < 0$ are reduced to the first one.

This seemingly odd strategy, both in the proof of IVT_f and IVT_p, results from the fact that Bolzano adopts Lagrange's scheme of proof introduced in his 1808s (Lagrange 1808).

7.2 Lagrange on IVT_p

In *Preface* to (Bolzano 1817a), Bolzano provides detailed analysis of previous proofs of IVT_P developed by Euler, Gauss, and others. Some of them apply mathematical assumptions questioned by Bolzano others rely on diagrams or non-mathematical concepts such as movement.

Regarding proofs referring to movement, Bolzano alludes to Lagrange's (Lagrange 1808). In this treaty, Lagrange interprets IVT_p in terms of a root of a polynomial $P - Q$. Yet, in the crucial step of his proof, he refers to the following intuition of race: when a quicker runner outruns a slower one, they must meet at some point. It is a point x, Lagrange concluded, in which $(P - Q)(x) = 0$. Here is the essential part of that argument.

> Let us present the generally proposed equation as $P - Q = 0$, where P is the sum of all terms that has a plus sign, and Q is the sum of all those that have a minus sign. Let's first assume that two numbers p and q are positive and that q is greater than p. Assuming further $x = p$, we have $P - Q < 0$, assuming $x = q$, we have $P - Q > 0$. In the first case, P will clearly be $< Q$, and in the second, P will be $> Q$. Thus, from the forms of P and Q, which contain only positive quantities and integral and positive powers, it is obvious that these quantities necessarily increase as x increases, and increasing x through all invisible degrees, from p to q, also increase by invisible degrees, but in this way that P will increase more than Q, because of the smaller it was, the larger it becomes. Thus, there must necessarily be a term between the two values p and q, where P will be equal to Q, **just like two moving bodies supposed to move on the same line in the same direction, starting from two different points at the same time, reach two other points at the same time, but in such a way that the one who, at first, was behind the other then is ahead, must necessarily meet on their way**. The value x, which makes P equal to Q, will, therefore, be one of the roots of the equation, and will be between the values of p and q. Similarly, if we take $x = p$, we get $P - Q > 0$, and when we take $x = q$, we get $P - Q < 0$; in the first case we will get $Q < P$, and in the second $Q > P$; and by increasing x from p up to q, the amount of Q will increase more than the amount of P, and equals it at a point between p and q. (Lagrange 1808, 98–99; emphasis added, English translation by P.B.)

7.3 From Movement to Continuous Function

Bolzano summarizes Lagrange's two-polynomial trick involved in the proof and then concludes: "This is further illustrated by the example of the *motion* of two bodies, of which one is initially *behind* the other and later *ahead* of the other. It necessarily follows that at one time it must have *passed* the other" (Russ 2004, 255). Then, he adds: "No one will want to deny that the concept of *time*, as well as that of *motion*, is just as alien to general mathematics as the concept of *space*" (Russ 2004, 255). In this context, Bolzano brings in his definition of continuous function. It is designed to supersede Lagrange's argument based on the parallelism between polynomials and moving bodies.

8 Continuous Function

8.1 *Preface's* Version of a Continuous Function

The definition of continuity (*Stetigkeit*) of function at point x given in *Preface* reads: *"function fx varies according to the law of continuity for all values of x inside or outside certain limits means only that, if x is any such value* ***the difference*** $f(x+\omega) - fx$ ***can be made smaller than any given quantity****, provided ω can be taken as small as we please* [...] or $f(x+\omega) = fx + \Omega$" (Russ 2004, 256; emphasizes added). Regarding the emphasized phrase and its supposed clarification, this definition is ambiguous. We formalize it in two ways as follows:

$$(\forall\Omega)(\exists\omega)(\ f(x+\omega) - fx < \Omega), \tag{6}$$

$$(\forall\Omega)(\exists\omega)(\ f(x+\omega) - fx = \Omega). \tag{7}$$

In this way, regardless of which formula is adopted, continuity of function replaces continuity of motion. Due to this substitution, Bolzano managed to introduce a kind of algebra of movements: assuming functions f, g represent movements, terms $f+g$, or $f-g$ have clear mathematical meaning, even though the concept of function is not yet defined.

8.2 Continuity and Sign Preserving Property

In (Bolzano 1817a) section § 15, the definition of a continuous function is employed, firstly, to infer SPP, secondly, to show the continuity of a polynomial. In the first case, Bolzano seeks to derive the following statement: "Now because $f\alpha < \varphi\,\alpha$, if u denotes a positive quantity which can become as small as we please, then also $f(\alpha+\omega) < \varphi(\alpha+\omega)$" (Russ 2004, 274).

Here the definition (6/7) is applied at the point α to two functions f and φ to get the same ω for each function. That is why Bolzano modifies the original formula.[25] To this end, he specifies the phrase "ω can be taken as small as we please." The amendment reads: "whenever we take $\omega < i$, then it must be possible to make $f(\alpha + \omega) - f\alpha$ and $\varphi(\alpha + \omega) - \varphi\alpha$ as small as we please if ω is taken small enough" (Russ 2004), 274). In symbols

$$(\forall\Omega)(\exists i)(\forall\omega)(0 < \omega < i \Rightarrow f(\alpha + \omega) - f(\alpha) = \Omega). \tag{8}$$

In what follows, Bolzano develops version (7) of his definition. Nonetheless, from (8), through some intricate arguments, he finally gets

$$(\exists i)(\forall\omega)(0 < \omega < i \Rightarrow f(\alpha + \omega) < \varphi(\alpha + \omega)) \tag{9}$$

Formula (9) represents Bolzano's version of SPP.

8.3 From the Continuity of Polynomial to *εδ* Continuity

In (Bolzano 1817a), the continuity of a polynomial function is stated as follows: "Every function of the form $a + bx^m + cx^n + \ldots + px^r$, in which $m,n,\ldots,r$ denote positive integer exponents, is a quantity which varies *according to the law of continuity* for all values of x" (Russ 2004, 275).

Put $W(x) = a + bx^m + cx^n + \ldots + px^r$. By binomial theorem, the difference $W(x + \omega) - W(x)$ takes the following form:[26]

$$W(x + \omega) - W(x) = \omega S = \omega\left(mbx^{m-1} + \ldots + p\omega^{r-1}\right).$$

where S represents a polynomial of two variables $S = S(x,\omega)$. As for S, Bolzano observes: "the whole expression is always *finite* for every value of x and ω" (Russ 2004, 276). Since the difference $W(x + \omega) - W(x)$ is determined at some point x, the sum S depends only on ω, that is $S = S(\omega)$. Now, the inequality obtains

$$S(\omega_1) \leq \mid mbx^{m-1} \mid + \ldots + \mid p\omega_1^{r-1} \mid . \tag{10}$$

The formula (10) represents the following sentence: "So if we denote by S the quantity arrived at by putting a definite value, say ω_1, for ω in all the individual terms of the expression, and summing as if they all had the same sign, then the actual value of this expression for this particular ω_1 is certainly not $> S$" (Russ 2004, 276).

[25] In this paragraph, Bolzano also copes with the claim that f − φ is continuous at α, given f and φ are continuous at α.

[26] There is a misprint in the formula representing W(x + ω) −W(x) in (Bolzano 1817a), p. 57. Instead of $p\omega^{r-1}$, there is ω^{r-1}, similarly, instead of ω^{m-1}, there should be $b\omega^{m-1}$. And instead of ω^{n-1} there should be $c\omega^{n-1}$.

Finally, Bolzano concludes with this claim: "Hence if it is required that the change in the function $a + bx^m + cx^n + \ldots + px^r$ should be $< D$, then we take an ω that is at the same time $< \omega_1$ and also $< \frac{D}{S}$. Then $\omega.S$ and, all the more, the product of ω with a quantity which is $< S$, must be $< D$" (Russ 2004, 276).

We formalize this argument by the following formula:

$$(\forall D)(\exists \omega_1)(\forall \omega)[0 < \omega < \omega_1 \Rightarrow |W(x+\omega) - W(x)| < D]. \tag{11}$$

It includes the now standard trick of the theory of limits to take ω fulfilling two conditions: it is smaller than ω_1 and $\frac{D}{S}$ at the same time.

From Bolzano's perspective, formula (11) follows, in some way, from (6/7). Logically, within the framework of an ordered field, it does not. However, it provides both a specific interpretation of continuity of a function and arithmetic of continuous functions. The latter consists of proofs of this kind: $f \pm g$, fg, and f/g are continuous at some point a, given f and g are continuous at a.

Interestingly, it is just in the context of the arithmetic of continuous functions that Stolz (Stolz 1885) refers to (Bolzano 1817a) and presents the following definition: "function $f(x)$ defined for all x in the interval $(a - d, a + d)$ is called continuous for the finite value $x = a$ when continuous limit processes is obtained: [if] $\lim x = a \pm 0$, [then] $\lim f(x) = f(a)$ [...] that is, for any $\varepsilon > 0$ there must be assigned a number $\delta > 0$ such that whenever $|x - a| < \delta$ then $|f(x) - f(a) < \varepsilon$" (Stolz 1885, 179, English translation by P.B.). Obviously, the second clause is formalized by

$$(\forall \varepsilon > 0)(\exists \delta > 0)(\forall x)(|x - a| < \delta \Rightarrow |f(x) - f(a)| < \varepsilon).$$

Stolz declares that he adopts Bolzano's definition (6/7); see (Stolz 1885), pp. 179, 340. In fact, he takes a formalized version of Bolzano's proof of continuity of a polynomial, that is, formula (11).

9 Continuity of Totally Ordered Set

In the set theory, the theory of ordered fields, or real analysis, continuity usually gets the name of completeness. Specified, it turns into Dedekind cut principle (Dedekind completeness), the least upper bound principle, or Cauchy completeness. Since these three versions are not equivalent (see Sect. 1 above) we prefer to use specific terms rather than the general term continuity.

9.1 Proof of IVT$_f$

In Bolzano (1817a) §15, Bolzano proves the theorem summarized by our formula (5). Figure 9 represents its general scheme.

Bolzano considers cases depending on how α, β are located relative to zero. We will trace the case $0 < \alpha < \beta$. Let $f(\alpha) < \varphi(\alpha)$. From SPP it follows that there is i such that

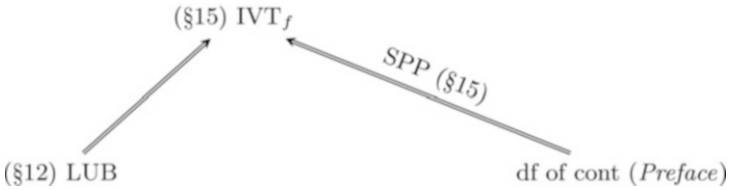

Fig. 9 Sections of *Rein analytischer Beweis* involved in the proof of IVT$_f$

$$(\forall\omega)[0 < \omega < i \Rightarrow f(\alpha + \omega) < \phi(\alpha + \omega)].$$

Then, Bolzano concludes: "Therefore it can be asserted that for *all* values of *u smaller* than a certain value the two functions $f(\alpha + \omega)$ and $\varphi(\alpha + \omega)$ stand in the relationship of smaller quantity to greater quantity. Let us denote this property of the variable quantity ω by M, then we can say that all ω that are smaller than a certain one possess the property M" (Russ 2004, 274); in symbols:

$$M(\omega) = \{0 < \omega < i : f(\alpha + \omega) < \varphi(\alpha + \omega)\}.$$

By applying LUB to the set $M(\omega)$, he gets the number U, which is

$$U = \sup M(\omega).$$

As a consequence of the theorem of Sect. 12 there must therefore be a certain quantity U which is the greatest of those of which it can be asserted that all ω which are $< U$ have the property M (Russ 2004, 274).

Now, Bolzano compares values $f(\alpha + U)$ and $\varphi(\alpha + U)$. Cases $f(\alpha + U) < \varphi(\alpha + U)$ and $f(\alpha + U) > \varphi(\alpha + U)$ are reduced to contradiction. For instance, Bolzano writes: "it cannot be that $f(\alpha + U) < \varphi(\alpha + U)$, for this would also give $f(\alpha + U + \omega) < \varphi(\alpha + U + \omega)$, if ω were taken small enough, and consequently $\alpha + U$ would not be the *greatest* value of which it can be asserted that all x below it have the property M" (Russ 2004, 274–275).

In conclusion, he finds: "Nothing else therefore remains but that $f(\alpha + U) = \varphi(\alpha + U)$, and so it is proved that there is a value of x lying between α and β, namely $\alpha + U$, for which $fx = \varphi(x)$" (Russ 2004, 275).

Thus, Bolzano proof falls under the same pattern as the proof presented in Sect. 6.1 above. The only difference is the status of LUB. While in modern mathematics it is the axiom characterizing real numbers, Bolzano seeks to prove it. At this stage, his reasoning does not meet modern standards for rigorous proof.

9.2 Least Upper Bound Principle

Bolzano proves LUB in (Bolzano 1817a) section § 12. The theorem reads: "If a property M does not apply to *all* values of a variable quantity x but does apply to *all*

values *smaller* than a certain u, then there is always a quantity U which is the greatest of those of which it can be asserted that all smaller x possess the property M" (Russ 2004, 269).

This thesis has the form of the following implication:

If

$$(\exists x)(\neg M(x)) \wedge (\exists u)(\forall x)(x < u \Rightarrow M(x)),$$

then

$$(\exists U)[(\forall x)(x < U \Rightarrow M(x)] \wedge (\forall u)(\forall x)[x < u \Rightarrow M(x) \Rightarrow u \leq U).$$

The set M is defined by criteria the least upper bound U does not meet. Thus, this version is not as general as the modern one worded in terms of any subset M of a totally ordered set – Bolzano considers sets defined by property. Still, it is much more precise than Dedekind's 1872 version. In section § 7 of his (Dedekind 1872), Dedekind seeks to show that the "essence of continuity" formulated in terms of cuts implies the following statement: "If a magnitude x grows continually but not beyond all limits it approaches a limiting value" (Dedekind 1901, 12). Dedekind's proof gives room to interpret this claim as the least upper bound principle, yet, it is not self-evident.

Bolzano's modern characterization of LUB contrasts with his scholastic methodology. He seeks to prove LUB by applying the so-called Cauchy completeness (CC). Then, however, he also attempts to prove CC. Current knowledge is that assuming axioms of an ordered field the equivalence holds $LUB \Leftrightarrow CC + Archimedean\ axiom$. Thus, viewed from the modern axiomatic perspective, Bolzano's argument is circular.

Yet, it took more than 50 years to point out unprovable mathematical truths. (Dedekind 1872) provides the first spectacular example. Regarding the "essence of continuity," Dedekind, first, states his cuts principle: "If all points of the straight line fall into two classes such that every point of the first class lies to the left of every point of the second class, then there exists one and only one point which produces this division of all points into two classes, this severing of the straight line into two portions" (Dedekind 1901, 5). Then, he adds: "I am utterly unable to adduce any proof of its correctness, nor has anyone the power. The assumption of this property of the line is nothing else than an axiom by which we attribute to the line its continuity, by which we find continuity in the line" (Dedekind 1901, p. 5).

9.3 Magnitudes as Real Numbers

Throughout (Bolzano 1817a), the adjective *reell* (real in (Russ 2004)) refers to a root of a polynomial, which means it is not an imaginary root. As for the domains of functions, the variable x is called *Größe (magnitude* or *quantity* in (Russ 2004)). In the second half of the nineteenth century, a series of mathematical papers occurred

dedicated to the concept of *magnitude*. They aimed to interpret the ancient Greek concept of μέγεθος. The common feature of these studies was to present magnitudes as a totally ordered, Archimedean group. During the first decades of the twentieth century, real numbers replaced the concept of magnitude.[27] Bolzano's magnitudes form a more complex structure than an ordered group: they are added and compared in terms of greater-lesser, they also form products. We will argue that they can be interpreted as real numbers.

In mathematics, real numbers are considered: (1) via a construction, (2) via an axiomatic approach. Historically, constructions have been studied first. Méray, Heine, Cantor, Dedekind, then Peano, and Weber complete the list of authors of the nineteenth-century constructions.[28] They rested on techniques of Cauchy sequences (or *Fundamentalreihen*, as Germans called them), Dedekind cuts, or ancient proportions smartly adjusted to a new role by Weber. Then, in 1900, Hilbert introduced an axiomatic approach. Yet, still, new constructions applying novel techniques have been discovered throughout the twentieth century and beyond.

Here is how Bolzano formulates what we currently call Cauchy completeness: "If a series of quantities

$$F^1x, F^2x, F^3x, \ldots, F^nx, \ldots, F^{n+r}x, \ldots$$

has the property that the difference between its nth term F^nx and every later one $F^{n+r}x$, however far this latter term may be from the former, remains smaller than any given quantity if n has been taken large enough, then there is always a certain *constant quantity*, and indeed only *one*, which the terms of this series approach and to which they can come as near as we please if the series is continued far enough" (Russ 2004, 266–267).

Now, while the continuity axiom is explicitly in the form of LUB as formulated in (Bolzano 1817a) section § 12, axioms for an ordered field are applied implicitly in Bolzano's proofs. Here is how one can reveal them.

In (Bolzano 1817a), the transitivity and the trichotomy laws characterize the total order of magnitudes. Let us start with the trichotomy.

The logical scheme of the final step in the proof of IVT_f as presented in Sect. 9.1 above is as follows:

$$\neg(f(\alpha+U)<\varphi(\alpha+U))\Lambda\neg(f(\alpha+U)>\varphi(\alpha+U))\Rightarrow f(\alpha+U)=\varphi(\alpha+U)$$

This implication is equivalent to the following alternative:

$$f(\alpha+U)<\varphi(\alpha+U)\vee f(\alpha+U)>\varphi(\alpha+U)\wedge f(\alpha+U)=\varphi(\alpha+U).$$

Implicitly it is also assumed that only one of these cases is satisfied.

[27] See (Błaszczyk and Fila 2020a), § 5–6.

[28] See (Cantor 1872; Dedekind 1872; Heine 1872; Méray 1869; Peano 1891; Weber 1895), respectively. See also Sect. 1 above.

Now, let us consider a sub-argument in the proof of SPP as discussed in Sect. 8.2 above: "assume that α and β are both *positive* and that (because it does not matter) β is the *greater* of the two, so $\beta = \alpha + \mathrm{i}$, where i denotes a positive quantity. [...] and $\alpha + \omega$ lies between α and β whenever we take $\omega < i$" (Russ 2004, 274).

Here, first, Bolzano applies the standard ordered field theory argument to the effect

$$\beta > \alpha \Rightarrow (\exists i > 0)(\beta = \alpha + i).$$

Note, the axiom E2 in Sect. 3.1 above also formalizes this rule. Thus, it was well-known to the ancient Greeks.

Then, the following axiom of an ordered field, the so-called compatibility of the order with addition,

$$(\forall x, y, z)(x < y \Rightarrow x + z < y + z)$$

is adopted as a self-evident truth. It occurs in the following form:

$$\omega < i \Rightarrow \alpha + \omega < \alpha + i.$$

Let us go back to the argument which proceeds formula (11). It reads: "Hence if it is required that the change in the function $\alpha + bx^m + cx^n + \ldots + px^r$ should be $<$ D, then we simply take an ω that is at the same time $< \omega_1$ and also $< \frac{D}{S}$. Then $\omega.S$ and, all the more, the product of ω with a quantity which is $< S$, must be $< D$" (Russ 2004, 276). Here Bolzano's argument is this

$$\omega < \frac{D}{S} \Rightarrow \omega S < S\frac{D}{S}$$

Meaning, he implicitly applies another axiom of an ordered field, the so-called compatibility of the order with multiplication

$$(\forall x, y, z)(x < y, 0 < z \Rightarrow xz < yz)$$

Moreover, considering the condition "simply take an ω that is at the same time $< \omega_1$ and also $< \frac{D}{S}$," the phrase "at the same time" should be interpreted as follows. Suppose that $\omega_1 < \frac{D}{S}$. Then

$$\omega < \omega_1 \Rightarrow \omega < \frac{D}{S}.$$

Here, the transitivity of the greater-lesser relation between magnitudes is assumed.

Similarly, we can analyze other parts of (Bolzano 1817a) and show that sums and products of magnitudes satisfy axioms of a commutative field.

10 Function vs Line

Bolzano considers two versions of IVT: for a geometric line and for a function. The first is stated like that: "every continuous [continuirlich] line of simple curvature of which the ordinates are first positive and then negative (or conversely), must necessarily intersect the abscissae-line somewhere at a point lying between those ordinates" (Russ 2004, 254). The version for two functions is as follows: "If two functions of x, fx and φx, vary *according to the law of continuity [nach dem Gesetze der Stetigkeit*] either for *all* values of x or for all those lying between α and β, and furthermore if $f\alpha < \varphi\alpha$ and $f\beta > \varphi\beta$, then there is always a certain value of x between α and β for which $fx = \varphi$x" (Russ 2004, 273). Bolzano also provides a version for one function, namely: "between any two Values, which give Results of Opposite Sign, there lies at least one real Root" (Russ 2004, 251).

The paper includes neither a definition of a geometric line nor a definition of a function. Moreover, it does not explain what continuity of line means.

Now, Bolzano declares that the truth [Wahrheit] of the geometric version of IVT "lies in nothing other than that general truth, as a result of which every continuous function" (Russ 2004, 255) has the IVT property. This claim presupposes that for every continuous line there is a representation by a continuous function. Yet, he never addressed this question. Anyway, that was the basis for the reduction of IVT for a geometric line to IVT_f.

In modern mathematics, the concept of function prevails, and the geometrical aspect of IVT is reduced to the graph of a function.

11 Topological Continuum

In this final section, we discuss Bolzano's attempts to characterize a topological continuum. Both Bolzano and Cantor refer to the ancient Greek model of a continuum, yet, they operate in a different mathematical framework, as their continuum consists of points. Nevertheless, they both compare their definitions of a continuum with Aristotle's idea of infinite divisibility.

11.1 Bolzanian Continuum

In section §38 of (Bolzano 1851), Bolzano discusses the paradoxes of "applied mathematics" concerning time and space. The paradox of extension is that when parts of a whole have no extension so the whole itself can not be extended: "a contradiction in the assumption that extension arises from parts which have no extension but are absolutely simple (points in time, or space, atoms, i.e., simple substances in the universe in the realm of reality" (Russ 2004, 642). Yet, Bolzano's solution is simple: "Every whole has and must have, some properties which the parts lack. [. . .] every two instants in time are separated by an infinite multitude of instants

in between, that likewise between every two points in space there is an infinite multitude of points lying in between them" (Russ 2004, 642).

Thus, first of all, a continuum is an "infinite multitude of points." Nevertheless, these points need some special arrangement, namely: "a finite multitude can never provide an extension and an infinite multitude only does so if the condition [...] that every point has certain neighbours at every sufficiently small distance" (Russ 2004, 644).

In this monograph (Kraus 2014) dedicated to Bolzano's concept of continuum, Kraus interprets the phrase "every sufficiently small distance" by two quantifiers. His reading, based on a thorough analysis of other fragments concerning continuum scattered across Bolzano's writings, offers the following definition: "Subset A of a metric space is *(Bolzanian) continuum* iff for every point p in A there is a real number $\varepsilon > 0$ such that for every $\eta \in (0, \varepsilon]$ there is at least one point q in A such that its distance from p equals η:

$$(\forall p \in A)(\exists \in > 0)(\forall \eta \in (0, \varepsilon])(\exists q \in A)[(d(p, q) = \eta]'' \ ([44], 31)."$$

Although Bolzano's idea of continuum consisting of "simple parts" (i.e., points) is foreign to the ancient Greek mathematics, he still refers to the Aristotelian characteristics: "it should be admitted that not every division of a given spatial thing into parts, namely no division into such parts whose number is only finite, not even every one such as goes on indefinitely (e.g. by continued bisection) [...] reaches the simple parts. [...] ultimately every continuum can arise from nothing else but from points and only points" (Russ 2004, 644).

11.2 Cantor on a Continuum in the Metric Space $\mathbb{R}^n$

Section § 9 of Cantor (Cantor 1883) summarizes some nineteenth-century theories of real numbers, namely: Weierstrass' as explained in (Kossak 1872), Dedekind's as developed in (Dedekind 1872), and Cantor's theory presented in (Cantor 1872). Section § 10 is dedicated to the concept of the continuum. Tracing back its history, Cantor discusses ancient Greek and Medieval philosophers. He believes that "the underlying idea has taken on different meanings." Therefore, his definition is comparable, for instance, with Aristotle's *ex partibus sine fine divisibilibus*. This section initiated a new branch of point-set topology – the theory of continua, a study of compact and connected spaces. Yet, Cantor's original definition is a bit different.

Thus, according to Cantor, a subset T of the space $\mathbb{R}^n$ with Euclidean metric is *connected* iff for any of its points t_0 and t^0 and any positive real number e there are finitely many points $t_1, t_2, \ldots, t_n$ of T such that the distances $d(t_0, t_1)$, $d(t_1, t_2)$, ..., $d(t_n, t^0)$ are all less than ε. T is perfect iff $T = T'$, where T' is defined as follows:

$$x \in T' \Leftrightarrow \lim_{n \to \infty} x_n = x$$

for some $(x_n) \subset \mathbb{R}^n \setminus \{x\}$; convergence of a sequence is defined in the metric space $\mathbb{R}^n$. The latter condition is equivalent to the following assertion: Every convergent series $(t_n) \subset$ T has a limit in T, and for every $t \in T$, there exists a sequence $(t_n) \subset T$ such that $\lim_{n\to\infty} t_n = t$.

Then comes the well-known definition: "I, therefore, define a point-continuum inside G_n [$\mathbb{R}^n$ in our notation] as *a perfect-connected*" (Ewald 1996, 906).

Indeed, one can show that in a metric space, Cantor's continuum agrees with the modern one, that is, it is a compact and connected set.

Based on this definition, Cantor rebukes the definition of the continuum as given in Bolzano (Bolzano 1851), §38. He claims that non-connected sets exemplify Bolzano's definition. In fact, for instance, set $A = [0,1) \cup (1, 2]$ is a *Bolzanian continuum* in the sense of Kraus while it is not a *Cantorian continuum.*[29]

12 Summary

In Greek mathematics, straight lines, curves, figures, solids, and movements involved in the genesis of mechanical curves were continuous, meaning divisible into infinitely divisible parts. The evolution of the concept of a curve is the most intriguing in the history of mathematical continuity. At first, Descartes turned the ancient scheme genesis-symptomata, involved in studies of mechanical curves, into genesis-formula, where genesis played a role in the derivation of a formula. In *La Geometire*, formula, inextricably linked to the curve, was an analytic description of the curve previously given by some other means. Then, with time, the formula evolved into the concept of a function and its domain. It enabled a separation of function and curve. This function-curve duality finds a spectacular manifestation in the very arrangement of the foremost analysis textbook in history – Euler's 1748 *Introductio in analysin infinitorum.* Its first volume explores functions, the second curves.

In Bolzano's *Rein analytischer Beweis*, a curve is an aspect – the graph, to use a modern term – of a function. His discussion on the geometric and analytic version of IVT echoes this function-curve duality. Due to methodological reasons, Bolzano assumes that the geometric version "lies in nothing other than that general truth [Wahrheit], as a result of which every continuous function" (Russ 2004, 255) has the IVT property. This solution paved his way to a purely analytic proof of IVT.

Like predecessors, Bolzano seeks to prove IVT for polynomials. To this end, he adopts a two-functions scheme originated from Lagrange (Lagrange 1808). Since the crucial step in Lagrange's proof involves the non-analytic concept of motion, Bolzano replaces it with a new concept of continuous function. This idea refers to a general function and evolves throughout the paper. The version applied in the proof of continuity of polynomial inspired Stolz to formulate the modern $\varepsilon\delta$ definition.

[29] Błaszczyk and Fila (2020b) discusses Cantor's definition of topological continuum in a broader context of his struggle with the concept of continuity.

When Bolzano managed to show the continuity of a polynomial, he could apply the lemma of IVT for continuous function. Proving this lemma, he devised another fundamental law of mathematics. His proof, in a simplified, one- rather than two-functions form, is like the modern one, given $f(a)f(b) < 0$, he determines a point c such that $c \in (a, b)$ and $f(c) = 0$. This point is defined as the least upper bound of the set $\{x \in [a, b] : f(x) < 0\}$. Bolzano does not realize the fundamental role of the LUB principle and seeks to prove it. Furthermore, since it applies to definable sets, it is not as general as the modern version. Despite imperfections, it gave rise to a new idea of a continuous (complete) total order.

In this way, in *Rein analytischer Beweis* (Bolzano 1817a) the Greek idea of a continuity of a curve bifurcates into the continuity of a function and continuity of its domain.

Abstract

During the first half of the 1830s, and as part of his project for a *Größenlehre*, Bernard Bolzano worked on a manuscript entitled *Reine Zahlenlehre* in which he introduced the notion of what he called "*meßbare Zahlen*." The various additions and corrections to its three extant versions are evidence of an unfinished work, the definitive edition of which was not published until 1976. The present chapter casts light upon the links between, on the one hand, his theory of "measurable numbers" and its conceptual framework, and, on the other hand, his insights and uncertainties with regard to the notions of number and quantity prior to the writing of that work. While Bolzano's proposal has usually been considered as an attempt at a theory of what nowadays is called the real-number continuum, this chapter shows that a more faithful reading must consider it as a pioneering and transitional theory of the number continuum which provided relevant insights into this latter but which remained, nonetheless, still bound to a not-yet-modern conception of mathematics and numbers.

Bernard Bolzano · Measurable numbers · Number continuum · Real numbers · Nineteenth-century mathematics

1 Introduction

Throughout the eighteenth century mathematics was usually defined as the "science of measuring everything that can be measured" or the "science of the quantities, that is, all those things that can be augmented or reduced."[1] However, by the end of the nineteenth century such an understanding of mathematics, which entailed the division of quantities into discrete (i.e., numbers) and continuous, was no longer advocated by most mathematicians. So, while certain appellations used by some of the authors who developed the first theories of real numbers, such as *Zahlengrössen* (numerical quantities; cf. Cantor 1872; Weierstraß 1868/1986), still evoked that earlier understanding, they nevertheless involved a different, relatively abstract conception of quantities and, ultimately, mathematics (cf. Ferreirós 2007, p. 125).

The disagreement between Richard Dedekind and Rudolf Lipschitz regarding a note included by the former in the introduction to his *Sur la théorie des nombres entiers algébriques* (1876–77) reveals the prevalence of the idea that Euclid's theory of proportions, and in particular definition 5 from Book V of his *Elements*, was enough "to guarantee the continuity of the domain of 'incommensurable magnitudes'" (Benis-Sinaceur 2015, p. 25; cf. Lipschitz 1876/1986, p. 72). Whereas Lipschitz advocated that idea, Dedekind explicitly rejected it and pointed out that, from his point of view, "arithmetic is to be kept free of any [mixture] of foreign elements,"[2] something on which he insisted in his own 1888 work (cf. Dedekind 1888, p. X).

This chapter draws attention to some of the complexities involved in the transition from a traditional notion of numbers to the definitions of real numbers published from c. 1870 onward, including the ones by Dedekind and Cantor. This is done by focusing specifically on the work of Bernard Bolzano, whose theory of "measurable numbers" (*meßbare Zahlen*) is considered to be an early "attempt at a theory of real numbers" (Russ 2004, p. 348; cf. Šebestík 1992, p. 354; Laugwitz 1982, p. 667; Rusnock 2000, p. 177). The work by Bolzano which is considered by some scholars to contain such an attempt is entitled *Pure Theory of Numbers* (*Reine Zahlenlehre*; henceforth *RZ*). Although this work was written in the first half of the 1830s and its manuscript was rediscovered at the beginning of the twentieth century, its definitive

[1](Wolff 1716, p. 863): "Ist eine Wissenschafft alles auszumessen, was sich ausmessen läst. Insgemein beschreibet man sie *per scientiam quantitatum*, durch eine Wissenschafft der Größen, das heisset, aller derjenigen Dinge, die sich vergrössern oder verkleinern lassen."

[2](Dedekind 1876, p. 284): "l'Arithmétique doit être maintenue exempte de tout mélange d'éléments étrangers."

edition was published only in 1976 as part of the *Bernard Bolzano Gesamtausgabe* (*Bernard Bolzano: The Complete Edition*; henceforth *BBGA*),[3] publication of which, by the publisher Frommann-Holzboog, has been ongoing from 1969 up to the present day.[4]

As it will be argued, Bolzano's *RZ*, which was developed within the framework of his project for a theory of quantities (*Größenlehre*), and in particular his theory of measurable numbers, was still tied to a not-yet-modern conception of numbers, quantities and, ultimately, mathematics. Thus, Sect. 2 discusses his insights and uncertainties with regard to the notions of quantity and number mainly as expressed in the mathematical works that preceded *RZ*, while also paying attention to certain documents (both posthumously published and as yet unpublished) preceding, contemporary with, and succeeding *RZ*, such as Bolzano's mathematical notebooks (*Miscellanea Mathematica*), which were published for the first time in the *BBGA*. Then, Sect. 3 goes on to focus on the introductory volume to Bolzano's theory of quantities, which precedes *RZ*, as well as on the first six sections of the latter work in order to better understand his project of a pure theory of numbers, while also paying attention to his mathematical notebooks written during the 1820s. Finally, Sect. 4 addresses his insights and uncertainties with regard to the number continuum by bringing to the fore the particularities of his "measurable numbers" and the other core notions of the seventh and last section of *RZ*.

The need to study Bolzano's manuscripts has recently been highlighted by both Steve Russ and Kateřina Trlifajová, with specific reference to *RZ* (cf. Russ and Trlifajová 2016, p. 44), and Jan Šebestík, with reference to Bolzano's project of a *Größenlehre*. As noted by Šebestík in the "Afterword" to *Bernard Bolzano: His Life and Work*, which he co-wrote with Paul Rusnock, in some cases such a study could "modify our understanding of Bolzano's thought" (Rusnock and Šebestík 2019, p. 597). This chapter will show that this is the case with Bolzano's notion of numbers and that the present research not only contributes to its elucidation but also accounts for the complexities of the emergence of our number continuum insofar as, to

[3]For a detailed account of the publication of *RZ* and its reception throughout the second half of the twentieth century, cf. (Spalt 1991, pp. 16–24; Russ 2004, pp. XX & 348). According to two letters written by Bolzano in the early 1840s and quoted by Eduard Winter, Bolzano resumed work on his project on mathematics between mid-1840 and mid-1841 (cf. Winter 1933, pp. 215–216).

[4]Founded by Jan Berg, Friedrich Kambartel, Jaromír Louzil, Bob van Rootselaar and Eduard Winter, and currently edited by Edgar Morscher, the *BBGA* comprises some introductory volumes (*Einleitungsbände*) and, up to the present day, about 100 published volumes divided into four series: (I) *Schriften*, the "works published during Bolzano's lifetime"; (II) *Nachlaß*, his "posthumous works" (subpart A) and his "scientific diaries" (subpart B); (III) *Briefwechsel*, his correspondence with various correspondents; and (IV) *Dokumente*, which includes various documents ranging from portraits and biographies to documents on Bolzano's trial (https://www.frommann-holzboog.de/editionen/20?lang=de). All references to volumes of the *BBGA*, therefore, contain: (a) the initials *BBGA*; (b) the letter "E" (for the introductory volumes) or the number of the series (1–4) and, in the case of the *Reihe* II, the subpart letter (i.e., 2A or 2B); and (c) the volume number and, in some cases, the supplement number.

paraphrase Russ, Bolzano's theory epitomizes those complexities vividly (cf. Russ 2004, p. 348). In this sense, this chapter follows Epple's recommendation to thoroughly investigate the "eventful atmosphere" that led to "the end of the paradigm of the science of quantity"[5] by addressing the subtleties of the work of an author writing somewhat earlier than those whom Epple discusses in *Das Ende der Grössenlehre. Eine Einführung in die Geschichte der Grundlagen der Analysis, 1860–1930*.

2 Bolzano's Uncertainties Regarding the Notions of Quantity and Number

Bolzano entered the Faculty of Philosophy at the Carl-Ferdinandischen Universität (Prague) as a student in 1796 and, as it is known from his lecture notes for the first academic year, was taught there the notions that were customary throughout the eighteenth century: mathematics was the "science of quantities," that is, "that which is capable of increase or decrease," while numbers were defined as "a multitude of things of one kind."[6] Such traditional notions can be found in almost all German-language mathematics textbooks of the time, including Abraham Gotthelf Kästner's *Anfangsgründe*, which had been the official textbook in Prague since 1784 (cf. *Handbuch* 1786, p. 407).[7]

As Bolzano explained in his 1804 *Considerations on Some Objects of Elementary Geometry* (henceforth *BG*), such a conception of "quantity" entailed that a thing could only be quantified if "regarded as consisting of a *number* (plurality) of things that are equal to the *unit* (or the measure)."[8] Thus, just as natural numbers would be a plurality of things equal to 1, a straight line would be a plurality of things equal to a certain straight line segment taken as unit of measurement. However, as he noted in his written examination for the chair of Elementary Mathematics at Prague University, which took place shortly after the publication of that work, certain things that at the time were regarded as "quantities" in fact posed a problem both conceptually and operationally, as in the case of the so-called infinitely small quantities. For Bolzano,

[5](Epple 1996, pp. 3 & 1): "Ende des Paradigmas der Größenlehre"; "bewegten Atmosphäre."

[6](LA PNP, C II 14/2, [2r] & [4v]): "Die Größe ist das, was einer Vermehrung, oder einer Verminderung fähig ist"; "Zahl ist eine Menge von Dingen einerley Art." LA PNP is the abbreviation for the Literární archiv Památníku národního písemnictví (Literary Archive of the Museum of National [Czech] Literature), in Prague, where Bolzano's notes are preserved.

[7]The above-cited definitions can be found almost verbatim in (Kästner 1786, pp. 1 & 21). I refer to the fourth edition of Kästner's work since it is the one which is known, with certainty, to have been available at the time at Prague's Public and University Library, which eventually became the National Library of the Czech Republic (cf. *Catalogus Mathematicorum* IX A 19 1781ff., p. 130 [r]).

[8](Bolzano 1804, pp. 3–4; cf. Russ 2004, p. 37): "Größe heißt ein Ding, insofern es angesehen wird als bestehend aus einer *Anzahl* (Vielheit) von Dingen, die der *Einheit* (oder dem Maße) gleich sind." The title of Bolzano's work is *Betrachtungen über einige Gegenstände der Elementargeometrie*.

the notion of these quantities was "incomprehensible" (*unverständlich*) inasmuch as they were either to be considered as "nothing" (*Nichts*), in which case they would not be a quantity but rather the absence of a quantity, or to be considered as something, in which case the usual procedure, according to which a piece of a curved line equals a piece of a straight line if their difference is an infinitesimal, would be strictly speaking unacceptable (*ČG Publicum* 1796–1805 98/755, p. [13v]). As he went on to explain further, such a procedure as this latter "does not fundamentally remove the difficulty; rather it only removes it for the eye, though not for the understanding."[9]

Such reluctance to accept infinitesimals can also be found in Bolzano's second published mathematical work, namely his 1810 *Contributions to a Better-Grounded Presentation of Mathematics* (henceforth *BD*).[10] There, addressing the so-called infinitely small and great quantities, he wrote that it was yet to be decided whether the "*infinite*" (whose notion comprised both), "or the *differential*," was "nothing else but a *symbolic expression*," as in the case of "$\sqrt{-1}$ and suchlike [expressions]."[11] At the time, "symbolic expression" was an appellation commonly used to refer to so-called imaginary quantities, as is attested to by the corresponding entry in the supplement to the famous mathematical dictionary initially developed by Georg Simon Klügel (cf. Grunert 1836, p. 387), as well as by the term's usage in Augustin-Louis Cauchy's *Cours d'Analyse* (cf. Cauchy 1821, p. 173ff.). Nevertheless, in the case of these two references, as in the case of so many others, there seems to have been no deep reflection, as there was in Bolzano, on why mathematical infinites and imaginaries could not legitimately be regarded as quantities, let alone as numbers, but at most as "symbolic expressions."[12]

Interestingly, among the extant notes for a section entitled "On the Properties of Numbers," which was to be part of the second installment of *BD* and would have been written around 1810 (cf. Berg 1977, pp. 7–8), Bolzano stated that "*if a number*

[9](*ČG Publicum* 1796–1805 98/755, p. [13v]): "hebt die Schwierigkeit nicht im Grunde; sondern entrückt sie nur dem Auge, nicht aber dem Verstande." For a detailed account of Bolzano's examination, as well as its transcription and English translation, cf. (Fuentes Guillén and Crippa 2021).

[10]The title of Bolzano's work is *Beyträge zu einer begründeteren Darstellung der Mathematik*. This was the first installment (*Lieferung*) of that work, the second—and unfinished—installment of which was reconstructed by Jan Berg, based on two versions, and not published until 1977 in *BBGA* 2A5.

[11](Bolzano 1810, p. 30): "das *Unendliche*, oder das *Differenzial*, nichts anders als ein *symbolischer Ausdruck* sey, gerade wie $\sqrt{-1}$, dgl."

[12]A noteworthy precedent here may possibly be found in Lambert, who in a letter to Kant, dated October 13, 1770, wrote: "The sign $\sqrt{-1}$ represents an unthinkable non-thing. And yet it can be used very well in finding theorems" (Zweig 1999, p. 118). It is worth mentioning that it had been only a short time before, in 1767/1768, that Lambert had composed and published his famous *Mémoire sur quelques propriétés remarquables des quantités transcendantes, circulaires et logarithmiques*, in which he seems to avoid the use of imaginaries (cf. Lambert 1761/1768, p. 319; Barnett 2004, pp. 24–25). I am grateful to Eduardo Dorrego López for bringing this to my attention.

is conceived as augmented by 1, *a new number arises*," so that, as he added in a marginal note, a new number would arise whenever two numbers were "*conceived together*."[13] As noted by Johan Blok, "such a statement would seem akin to the modern notion of a successor function" (Blok 2016, p. 256), inasmuch as the addition of the unit to each number would originate the subsequent one. Nonetheless, considering the aforementioned traditional notions of both number and quantity, the extension of the former beyond the sequence of the naturals still required, from Bolzano's point of view, some justification—something that, in the case of the irrationals, posed problems.

In a couple of notes included in his mathematical notebooks and dating from late 1814, Bolzano addressed the question of how to determine irrational quantities, irrationality being for him, as in the corresponding cases of the infinite and of fractions, a "predicat[e] [that] refer[s] to quantities" and not to numbers.[14] Thus, on October 26, he pointed out the possibility of considering an irrational as "a quantity for which the rule to determine it by numbers is indeed given but requires an operation which can never be brought to an end," which will allow one to approximate to said quantity "as closely as one desires."[15] Moreover, he said, an irrational would be a quantity that lies between two given quantities which involve two such rules, so that, for example, in the case of $\sqrt{2}$, one could establish the two following "rules (manners)" for determining it:

(a) to "[l]ook at any power of 10 as a denominator, and seek out the greatest possible number which, considered as numerator, gives a fraction the square of which would be smaller than 2";
(b) to "look at any power of 10 as a denominator, and seek out the smallest possible number which, considered as numerator, gives a fraction the square of which would be greater than 2."[16]

This would mean that $\sqrt{2}$ could be determined as the "limit" (*Grenze*) to which, following these rules, the quantities 1.4 (or $\frac{14}{10}$, i.e., the greatest fraction the square of which—according to the first rule—would be smaller than 2) and 1.5 (or $\frac{15}{10}$, i.e., the smallest fraction the square of which—according to the second rule—would be

[13](*BBGA* 2A5, p. 61 & fn. r): "*Wenn zu einer Zahl noch 1 hinzugedacht wird, entsteht eine neue Zahl*"; "*Wenn* 2 *Zahlen zusammengedacht werden, entsteht eine neue Zahl*." The title of the note is *Von den Eigenschaften der Zahlen*.

[14](*BBGA* 2B6/2, p. 195): "alle diese Prädicate beziehen sich meiner Ansicht nach auf *Größen*."

[15](*BBGA* 2B6/2, p. 195): "ist eine Größe, für welche die Regel sie durch Zahlen zu bestimmen, zwar gegeben ist, aber eine nie zu beendigende Operation erfordert"; "als man nur immer will."

[16](*BBGA* 2B6/2, p. 196): "*Regeln* (*Arten*)"; "Man sehe irgend eine Potenz der 10 als Nenner an, und suche dazu die möglichst größte Zahl, welche als Zähler betrachtet einen Bruch gibt, dessen Quadrat *kleiner* als 2 wäre"; "man sehe irgend eine Potenz der 10 als Nenner an, und suche dazu die möglichst kleinste Zahl, welche als Zähler betrachtet einen Bruch gibt, dessen Quadrat *größer* als 2 wäre."

greater than 2), 1.41 and 1.42, and so on, could approximate as closely as one desired (cf. *BBGA* 2B6/2, pp. 195–197).[17]

But then, in a note dated three days later (i.e., October 29, 1814) and entitled "*Irrational*, *transcendental quantities*," Bolzano added that, according to his previous note, "the *irrational* quantities are to *numbers* (arithmetic) what the *transcendent* ones are to functions, that is to say, to *finite* functions, i.e. to *algebraic* functions (algebra)," inasmuch as the former "cannot be expressed by a finite multitude of *numbers*," while the latter "cannot be expressed by a finite multitude of powers and products."[18] This was a quite interesting remark and meant that, strictly speaking, irrationals were not to be regarded as numbers but rather as quantities that could only be determined numerically according to the aforementioned rules. Indeed, he even suggested that his previous explanation could be shortened "by using only one instead of two *bounding* [or *limit*] *quantities*," so that an irrational could be regarded as a "*constant* quantity to which the variable [quantity] *X*, which arises from a rule that contains a number of repetitions of one and the same operation which can be increased to any extent one wishes, can approximate as closely as one desires."[19]

As we will discuss in Sect. 4, Bolzano's later procedure for determining what he would call "measurable numbers" resembles the one first outlined in his notes of 1814. However, in the first place (as noted by Bob van Rootselaar in the introduction to the volume of *BBGA* containing the first of these notes), Bolzano's early procedure "provides a means of deciding whether a given quantity is measurable [...] [,] not a means of constructing a measurable quantity" since, "[f]or Bolzano, the quantities are already there [and] one needs only to determine them by numbers."[20] In the second place, moreover, such a procedure still required some further clarifications in order to operate with numerically determined irrationals, in particular with regard to the difference between these latter and their limits, that is to say, concerning

[17]This procedure could be rooted in the successful use of continuous fractions, by means of which approximations of irrationals, both by excess and by default, could be provided. For a detailed account of continuous fractions at the time, as well as a historical sketch of their use, cf. (Klügel 1808, pp. 43–87; cf. also Dorrego López and Fuentes Guillén, forthcoming).

[18](*BBGA* 2B7/1, p. 35): "*Irrationale, transcendente Größen*"; "sind die *irrationalen* Größen das für die *Zahlen* (Arithmetik), was die *transcendenten* für die Functionen, die *endlichen*, d.h. *algebraischen* Functionen, (Algebra) sind"; "durch keine endliche Menge von *Zahlen* ausgedrückt werden kann; so kann [...] durch keine endliche Menge von Potenzen und Producten ausgedrückt werden."

[19](*BBGA* 2B7/1, p. 35): "In Ansehung beyder aber werfe ich die *Frage* auf: ob man ihre Erklärung nicht dadurch bedeutend verkürzen könnte, daß man statt ihren Werth durch zwey *Grenzgrößen* [...], zu bestimmen vielmehr nur eine einzige gebrauchte"; "*beständige* Größe, der die veränderliche *X*, welche durch eine Regel entsteht, die eine beliebig »zu vermehrende Anzahl von Wiederholungen einer und derselben Operation enthält, so nahe kommen »kann, als man nur immer will." It should be noted that, immediately afterward, Bolzano wrote that "however, sometimes one has to use another quantity *Y* as a help."

[20](van Rootselaar 1995, pp. 27–28): "sie ergibt ein Mittel zu entscheiden, ob eine vorgegebene Größe meßbar sei. Es ist kein Mittel, eine meßbare Größe zu konstruieren. Für Bolzano sind die Größen schon da, man muß sie nur durch Zahlen bestimmen."

the decreasing difference between an irrational quantity and its corresponding rational limits. As Bolzano stated in another note included in his mathematical notebooks and written at the turn of 1815, he had, up to this point, still not been able to "get things clear in his mind" either as regards the concept of the infinite or as regards the concepts of 0 and $\sqrt{-1}$: all of them, he wrote, "denote a kind of nothing," even though "they are essentially different."[21] This last note was to be followed by the discussion of an example showing the nature of the difference between these three concepts; in the end, however, Bolzano did not write it.

Of course, this does not mean that Bolzano did not resort to, for example, the irrationals and zero. For example, in his 1816 work on the binomial theorem (henceforth *BL*),[22] he argued that the validity of the binomial series expansion for $(1 + x)^n$ could also be proved for an irrational value $n = i$, on the basis that such a value could be approximated to by a fraction $\frac{n}{m}$, with both n and m integers, so that "$(1+x)^{\frac{n}{m}}$ comes as close as one might desire to the value $(1 + x)^i$."[23] Thus, considering "$x < \pm 1$" (or, as noted by Paul Rusnock, "$|x| < 1$" (Rusnock 2000, 68)), Bolzano obtained the series

$$(1+x)^{\frac{n}{m}} = 1 + \frac{n}{m}x + \frac{n}{m}\frac{\frac{n}{m}-1}{2}x^2 + \ldots + \frac{n}{m}\frac{\frac{n}{m}-1}{2}\ldots\frac{\frac{n}{m}-r+1}{r}x^r + \Omega^2,$$

where Ω^2 can become smaller than any given quantity (or, from a modern perspective, $\Omega^2 \to 0$), from which, considering that the difference between i and $\frac{n}{m}$ can therefore be made as small as desired, he substituted the latter by the former and obtained the series[24]

$$(1+x)^i = 1 + ix + i\frac{i-1}{2}x^2 + \ldots + i\frac{i-1}{2}\ldots\frac{i-r+1}{r}x^r + \Omega^2.$$

Leaving aside the fact that, as Rusnock has pointed out, there is a subtle mistake in Bolzano's proof—since Bolzano "uses the expansion for $n = -1$ as the basic convergence lemma [,] [b]ut this series diverges for $x = \pm 1$" (Rusnock 2000, p. 69)—there are two things that are particularly interesting about it nonetheless. Firstly, although the meaning of Ω^2 might seem clear, it remains to be explained just what this sign signified for Bolzano. Secondly, at the very end of that work, he stated that the concept of "the *irrationality* of a quantity," along with that of "*imaginary*

[21](*BBGA* 2B7/1, p. 68): "kann ich noch immer nicht ins Reine kommen"; "bezeichnen eine Art von *Nichts*"; "sie doch *wesentlich* verschieden sind."

[22]The title of Bolzano's work is *Der binomische Lehrsatz, und als Folgerung aus ihm der polynomische, und die Reihen, die zur Berechnung der Logarithmen und Exponentialgrößen dienen, genauer als bisher erwiesen*.

[23](Bolzano 1816, p. 76): "$(1+x)^{\frac{n}{m}}$ dem Werthe $(1+x)^i$ so nahe, als man will."

[24]It should be noted, firstly, that in the original the superscript in Ω^2 is placed at the top and that, as Steve Russ wrote, "[a]s often the case with Bolzano, these superscripts only distinguish, they are not powers" (Russ 2004, p. 349). Secondly, in the printed version the substitution of $1 + \frac{n}{m}x$ by $1 + ix$ appears as "1" (cf. Bolzano 1816, p. 77).

expressions" and some others, had yet to be clearly developed and that, in fact, this lack of clarity about these concepts themselves prevented him from addressing some cases in which they were used, for example, those involving the so-called imaginary quantities or "when a negative quantity is to be raised to a power with an irrational exponent."[25]

On the one hand, throughout his works of 1816–17 Bolzano referred to the irrationals as quantities and not as numbers.[26] Such an unequivocal use, then, in these works—which include his *Purely Analytic Proof* (henceforth *RaB*)[27]—of the appellation "quantity" to refer to the irrationals would not be merely a conceptual or even a nominal issue but would have practical, operational implications. On the other hand, the notion of quantities ω and Ω, which he introduced in *BL*, was a key element not only in that work, but also in his works of 1817 and in particular in *RaB*, a work in which he took very significant and ground-breaking steps toward demonstrating highly relevant theorems, such as the one known as the intermediate value theorem (i.e., if a continuous function of x is positive for a value of x and negative for another value, it must be 0 for an intermediate value).

As Bolzano explained in the preface to *BL*, he was opposed to the notion of infinitesimals or quantities that "are supposed *to be* smaller than any [...] *alleged*, i.e. conceivable quantity," instead of which he proposed the use of the notion of variable quantities "*which can become smaller than any given* [*one*]."[28] This reluctance with regard to infinitesimals was nothing strange among mathematicians at the time (cf. Lagrange 1797; du Bourguet 1810). However, as discussed before in connection with his 1804 written exam for a chair at Prague University, Bolzano's criticism had to do not only with what he considered the lack of rigor in the procedures associated with infinitesimals and the "attempted calculation of the infinite," but also with the concept itself, which, he said, was "self-contradictory."[29] Thus, as the first version of his alternative notion to infinitely small quantities explicitly states (a notion that would correspond to the quantities that in §14 of *BL* he designated by the symbol ω, Ω being the "algebraic *sum* or *difference*" of a "(finite) multitude" of ω's),[30] the idea underlying it was that "one can assume an

[25](Bolzano 1816, pp. 143–144; cf. Russ 2004, p. 247): "wenn eine *negative* Größe auf eine Potenz mit *irrationalem* Exponenten erhoben werden sollte"; "*imaginäre*[n] *Ausdrücke*"; "*Irrationalität* einer Größe."

[26]Indeed, in his early mathematical works (1804–17) Bolzano only once used the expression "irrational[e] Zahl," namely in the formulation of one of the last problems in his 1816 work, in the solution of which, however, he again referred to irrational quantities (Bolzano 1816, p. 137).

[27]The full title of Bolzano's work is *Rein analytischer Beweis des Lehrsatzes, daß zwischen je zwey Werthen, die ein entgegengesetztes Resultat gewähren, wenigstens eine reelle Wurzel der Gleichung liege*.

[28](Bolzano 1816, p. V): "schon kleiner *seyn* soll[en], als eine jede [...] *angebliche* d. h. gedenkbare Größe"; "*die kleiner als jede gegebene werden können*."

[29](Bolzano 1816, pp. IV & XI): "versuchte Berechnung des Unendlichen"; "selbst widersprechenden."

[30](Bolzano 1816, p. 15): "algebraische *Summe* oder *Differenz*"; "(endliche) Menge."

even smaller ([or] greater) [quantity] for each already assumed one."[31] In other words, Bolzano stressed the fact that one could, at most, use quantities that "can be" smaller than a "given" one, but not quantities that are *de facto* smaller than any "conceivable" one, while resisting the idea of identifying such quantities (or any quantity) with 0 (cf. Fuentes Guillén and Martínez Adame 2020).

It should be emphasized that at the time, and in spite of the innovative features of the mathematics that he was developing, Bolzano still advocated a traditional notion of number. As he wrote in "On the Concept of Quantity and the Different Kinds Thereof,"[32] dated 1816, "only that which mathematicians usually call a *whole number* deserves to be called a *true* number," while the rest were "not actually numbers, but quantities, or not even quantities."[33] Moreover, in that paper Bolzano pointed out that in previous works, *BL* among them, he had relied on the "common use of language" to refer to numbers and quantities, despite having already "recognized its incorrectness," since he "really feared" that by deviating from it his works would be "completely incomprehensible."[34] As he went on to explain, for him:

> *Any thing X is to be called a quantity (**Quantum**) insofar as it possesses a property, in consideration of which another thing M, called measure, behaves with respect to X in the same way as two divisible things of the same kind behave with respect to each other, one of which is the unit [and] the other an arithmetically determinable whole N, i.e. a thing for which a rule can be given, according to which, for any arbitrary multitude of equal and aliquot parts into which the unit is decomposed, one can determine how many of those parts are contained in N.*[35]

From Bolzano's point of view, such a relation could also be expressed by pointing out that "*X is measured* [. . .] *by N*," the latter being called "the *number* that expresses the quantity of *X*," albeit "very improperly" since "[o]nly in the rarest cases is *N* an actual [or real] number, although it is always something *determinable* by *numbers* (several,

[31](*BBGA* 2B7/1, p. 79): "man zu jedem schon angenommenen ein noch kleineres (größeres) annehmen kann."

[32]The title is "*Uiber den Begriff der Größe und die verschiedenen Arten derselben*."

[33](*BBGA* 2A5, p. 191): "nur dasjenige, was die Mathematiker gewöhnlich eine *ganze Zahl* nennen, den Nahmen einer *wahren* Zahl verdiene"; "sind eigentlich nicht *Zahlen*, sondern *Größen*, oder nicht einmahl *diese*."

[34](*BBGA* 2A5, p. 191): "gewöhnlichen Sprachgebrauch"; "die Unrichtigkeit desselben [. . .] erkannt"; "auch wirklich befürchten mußte, hiedurch ganz unverständlich zu werden."

[35](*BBGA* 2A5, p. 199): "*Größe (**Quantum**) heißt jede Ding X, so fern es irgend eine Eigenschaft besitzt, in Betracht deren ein anderes M, das Maß genannt, sich zu X so verhält, wie sich zwey theilbare Dinge derselben Art verhalten, deren eines die Einheit, das andere ein arithmetisch bestimmbares Ganze N ist, d.h. ein Ding, von dem eine Regel angeblich ist, nach welcher man bey jeder beliebigen Menge gleicher und aliquoter Theile, in die man die Einheit zerlegt, bestimmen kann, wie viele dergleichen in N enthalten sind*." This passage makes it clear that, at least in the case of Bolzano, the appropriate translation for "Größe" is "quantity" and not "magnitude" (from the Latin *magnitūdō*).

often infinitely many)."[36] As will be discussed in the following sections, this is basically the idea of measurement that underlies Bolzano's later project of a theory of quantities and, within it, a theory of numbers. This means that for him, both then and later, "the concept of *quantity* contain[ed] that of *number* as a characteristic."[37]

Interestingly, in his 1816 paper Bolzano maintained that, according to such a definition of quantity and as he had already stated in *BL*, the concept of infinitely small quantities was self-contradictory, while the infinitely great and the imaginaries were "*improperly* so-called" ("*uneigentlich* so genannt") due to certain similarities with quantities (cf. *BBGA* 2A5, pp. 201–203). However, two years later, in a note included in his mathematical notebooks and dated September 9, 1818, he showed himself inclined to accept the notion of infinitely small quantities (cf. *BBGA* 2B9/2, p. 126).

Many years later, in *Paradoxes of the Infinite* (henceforth *PU*),[38] the final version of which dates from the late 1840s and was published posthumously, Bolzano went back to the notion of the measurement of a quantity by another one with equal status standing in a certain ratio to it (cf. Bolzano 1851/1920, pp. 22 & 59) and insisted on the fact that, in a sense, "all numbers [are] also quantities [and] there are even more quantities than numbers," "because also the fractions $\frac{1}{2}, \frac{1}{3}, \frac{2}{3}, \frac{1}{4}, \ldots..$, as well as the so-called *irrational* expressions $\sqrt{2}, \sqrt[3]{2}, \ldots..., \pi, e, \ldots..$ designate quantities."[39] Furthermore, in that work he addressed the discussion that he had left hanging in his 1815 note on the similarities and differences between 0, $\sqrt{-1}$ (both "objectless" quantity ideas or expressions)[40] and the infinitely small quantities, which, he insisted, should not be regarded as equivalent (Bolzano 1851/1920, p. 56).

In particular, Bolzano devoted several paragraphs in *PU* to determining, in a precise manner, the concept of zero[41] and, in connection with this, to discussing the

[36](*BBGA* 2A5, p. 199): "*X werde* (bey dem Maße *M*) *durch N gemessen*"; "die *Zahl*, welche die Größe von *X* ausdrückt"; "sehr uneigentlich"; "Nur in den seltensten Fällen ist *N* eine wirkliche Zahl; wohl aber ist es jederzeit etwas durch *Zahlen* (mehrere, oft selbst unendlich viele) *Bestimmbares*."

[37](*BBGA* 2A5, p. 208): "der Begriff der *Größe* jenen der *Zahl* als ein Merkmahl."

[38]The full title of Bolzano's work is *Paradoxien des Unendlichen herausgegeben aus dem schriftlichen Nachlasse des Verfassers von Dr. Fr. Příhonský*.

[39](Bolzano 1851/1920, p. 21): "alle Zahlen zugleich auch Größen, sondern es gibt noch weit mehr Größen als Zahlen, weil auch die Brüche $\frac{1}{2}, \frac{1}{3}, \frac{2}{3}, \frac{1}{4}, \ldots..$, ingleichen die sogenannten *irrationalen* Ausdrücke $\sqrt{2}, \sqrt[3]{2}, \ldots..\pi, e, \ldots..$ Größen bezeichnen."

[40]Concerning the translation of "gegenstandlos" as "objectless" (*gegenstand-los*), it is worth noting, as Russ does, that Bolzano uses it "in contrast to *gegenständlich* meaning, of an idea, that it does have objects associated with it" (Russ 2004, p. XXIX).

[41]Here Bolzano acknowledges Martin Ohm for "having been the first who drew the attention of the mathematical public to the difficulties in the concept of zero" (Bolzano 1851/1920, p. 55). Interestingly, in the work to which Bolzano refers, Ohm stated that "so würde die 0, als benannte Zahl gedacht, Nichts vorstellen," having established before that a "benannte Zahl" would be "diejenige Zahl, bey welcher wir uns eine völlig bestimmte und genannte Einheit denken," so that "[e]ine Größe *A* wird gemessen, wenn man sie als eine benannte Zahl *aE* ausdrückt, oder doch die Elemente findet, aus denen diese benannte Zahl *aE* leicht gebildet werden kann" (Ohm 1828, pp. 48–49).

idea of infinitely small quantities. Thus, on the one hand, he explained that while 0 could only be considered a quantity in a *translatitious* or figurative sense (*uneigentlichem Sinne*), it could be determined as the "symbol" (*Zeichen*) for which the equations $A - A = 0$ and $A \pm 0 = A$ hold in general (i.e., regardless the quantity expression A corresponds to an actual quantity or is "objectless"), so that $A \times 0 = 0$ (the concept of multiplication) and $B \times \left(\frac{A}{B}\right) = A$ (the concept of division) could be formed, as long as $B \neq 0$ (Bolzano 1851/1920, pp. 50–51 & 56–57).[42] In other words, Bolzano drew attention to the fact that, although strictly speaking 0 only accounts for the absence of a quantity, one might be entitled to consider it as a quantity since, leaving aside division by 0, the four basic operations can be carried out using it.

On the other hand, Bolzano insisted that the notion of infinitely small quantities led to contradictions (Bolzano 1851/1920, pp. 59–60). However, he pointed out that problems could be overcome if, in the expression $\frac{\Delta y}{\Delta x}$, both Δy and Δx were regarded as $=0$, while the corresponding notation for the derivative $\frac{dy}{dx}$ was not considered "as a *quotient* of *dy* by *dx*," that is, not as a ratio between zeros, "but only as a *symbol* of the derivative of *y* by *x*."[43] From Bolzano's point of view, this justified the practice of calculating using such signs inasmuch as these latter were considered "not as signs of actual quantities, but rather as equal to zero," and he added that, "on entirely similar principles," the same could be said about "calculation[s] using so-called *imaginary quantities*,"[44] the values of which he had already identified—along with the value of the "infinitely great"—as non-measurable (cf. Bolzano 1930, p. 16) in a work composed prior to *PU*, namely his *Theory of Functions* (*Functionenlehre*; henceforth *F*).

The following sections will discuss Bolzano's project of a *Pure Theory of Numbers* (*RZ*) in which he presented the notion of "measurable numbers" and which, coupled with *F*, is to be understood within the framework of his more ambitious project of a general theory of quantities. The development of such a project was carried out precisely between the publication of his early mathematical works (i.e., the period 1804–17) and the publication of *PU* (i.e., 1851), in which latter work he noted, as regards his considerations on the legitimacy of making calculations with certain symbols, that, ultimately, such considerations had led to "important truths of the general theory of quantities."[45]

[42]Bolzano noted that 0 should only be used as divisor in identity equations, such as $\frac{A}{0} = \frac{A}{0}$ (Bolzano 1851/1920, pp. 57–58).

[43](Bolzano 1851/1920, p. 67; Russ 2004, p. 639): "als einen *Quotienten* von *dx* in *dy*, sondern nur eben für ein *Symbol* der abgeleiteten von *y* nach *x*."

[44](Bolzano 1851/1920, pp. 69 & 71): "nicht als Zeichen wirklicher Größen, sondern sie vielmehr als der Null gleichgeltend betrachten"; "ganz ähnlichen Grundsätzen"; "sogenannten *imaginären Größen*."

[45](Bolzano 1851/1920, pp. 64 & 69): "*meistens ganz richtige Ergebnisse*"; "wichtige Wahrheiten der allgemeinen Größenlehre."

3 The Conceptual Framework of Bolzano's Measurable Numbers

According to Jan Berg, who is the editor of both the *Introduction to the Theory of Quantities and First Concepts of the General Theory of Quantities* (henceforth *EG*)[46] and *RZ* in *BBGA*, it is known from Bolzano's correspondence that he worked on his project of a theory of quantities from around 1830 onward and that by 1835 he had almost finished writing *EG* and *RZ* (Berg 1975, pp. 9–10; cf. Winter 1933, pp. 213–216; Russ 2004, p. 347). Thus, in order to better understand Bolzano's proposal of "measurable numbers," which he introduced in the seventh and last section of *RZ*, it seems necessary first to shed light on the conceptual groundwork of such a proposal—which Bolzano developed in *EG* and the previous sections of *RZ*—as well as to address some of the reflections on quantities and numbers included in Bolzano's mathematical notebooks from the early 1820s through to the early 1830s.

In an extant note from his mathematical notebooks entitled "Concept and Division of Mathematics," dated May 1830, Bolzano explicitly refers to the fact that, whereas in *BD* he had favored an alternative definition of mathematics,[47] by the time of this note, 20 years later, mathematics had become for him "once again a theory of quantities alone."[48] As noted by Russ in his English translation of Bolzano's mathematical works, the very title "for his mature comprehensive work on mathematics" (i.e., *Größenlehre*) makes it clear that Bolzano had embraced, by this time, once again the traditional definition of mathematics as the "science of quantities" (Russ 2004, p. 347).

Accordingly, Bolzano began *EG* by pointing out that "the word *quantity*" could be understood in both a narrow sense (*enger Sinn*), to refer only to so-called continuous quantities, and a broad sense (*weiter Sinn*), which would include also so-called discrete quantities, and that it was in this latter, broader sense that mathematics could be defined as "a science of quantities," a science which would therefore comprise the theory of numbers, "one of the most important mathematical disciplines."[49] For Bolzano, however, this did not mean that all mathematical disciplines dealt only with quantities, as would be shown by the case of the theory of combinations, which dealt with the combinations of which any given plurality of

[46]The title is *Einleitung in die Größenlehre und erste Begriffe der allgemeinen Größenlehre*.

[47]In 1810 Bolzano defined mathematics as "*eine Wissenschaft* [. . .], *die von den allgemeinen Gesetzen (Formen) handelt, nach welchen sich die Dinge in ihrem Daseyn richten müssen*" (Bolzano 1810, p. 11). For Paola Cantù, referring to Bolzano's *Größenlehre*, "[i]t is exactly for the sake of generality that Bolzano abandons the previous definition of mathematics and modifies the meaning of 'Größe' from quantity to quantity in general, as it was common in the tradition of the *mathesis universalis*" (Cantù 2014, p. 313).

[48](*BBGA* 2B12/1, p. 132): "Mathematik ist mir jetzt wieder nur Größenlehre, und zerfällt zunächst in die reine und angewandte." The title of Bolzano's note is "*Begriff und Eintheilung der Mathematik*." For an earlier note of Bolzano on this subject, cf. (*BBGA* 2B2/1, p. 23).

[49](*BBGA* 2A7, p. 25): "eine Wissenschaft der Größen"; "eine der wichtigsten mathematischen Disciplinen."

objects were susceptible (*BBGA* 2A7, pp. 27–28); this was a consideration, it must be said, that he had already introduced in *BD* (cf. Bolzano 1810, p. 4).

In addition to this, and with respect to the particular disciplines of the general theory of quantities, Bolzano noted that the theory of the infinitely small or great quantities, which for him represented a "special type" (*besondere Gattung*) of quantities, should be regarded as a peculiar but useful part of pure mathematics, of which the theory of numbers (another special type of quantities) would also be a part (cf. *BBGA* 2A8, pp. 33–34). Moreover, he explained that the latter could be used to accurately determine "all other quantities," provided only that—and this was certainly a proviso he intended to abide by in his own work—*numbers* were not considered just in the strict sense of the term, that is, provided that "special forms" (*Arten*) such as rationals and irrationals were also taken into account and thus "the properties of numbers [were] mixed with the properties common to *all* quantities, as well as with those that [were] only common to certain other forms."[50]

But, had Bolzano by this point already sorted out his uncertainties regarding the notions of number and quantity? In a broad sense, he wrote in *EG*, quantity would be every object "belonging to a kind of things such that, for each two, only one of the following two relations to each other can ever hold: they must either be *equal* to one another or one of them must contain a *part equal* to the other."[51] Thus, on the one hand, an irrational i could be regarded either as a quantity equal to a part of a rational quantity from which a certain quantity would have to be subtracted in order to obtain i, or as a quantity to one of whose parts a rational quantity could be equated and to which a certain quantity would have to be added in order to obtain i; whereas, on the other hand, the corresponding irrational number would be the numerical determination of i, which should comply with certain properties common to all quantities and to numbers.

The mathematical notebooks of Bolzano written throughout the previous decade seem very precisely to account for the process which eventually led him to such a stance in his *Größenlehre*. For example, in a note from 1821 he wrote that, while infinite quantities could be determined by saying that "a quantity is ∞ great if every number is a part of it and ∞ small if it is [. . .] $<$ than every fraction," imaginary quantities (*Größen*) such as "$\sqrt{-1}$, $\sqrt{-2}$, etc." should be regarded as "attributes that are determined by the numbers 1, 2. . ., but [. . .] cannot be assigned to actual objects" (in other words, while such expressions somehow involve numbers, there is no real object to which they correspond and so they are "objectless"), both the latter and the

[50](*BBGA* 2A7, p. 34): "aller übrigen Größen"; "wo (wie wir in diesem Buche selbst zu thun gesonnen sind) die Eigenschaften der Zahlen untermischt mit den Eigenschaften, die *allen* Größen gemeinschaftlich, ingleichen auch mit solchen, die nur gewissen anderen Arten (z.B. den irrationalen) Größen zukommen, abgehandelt werden."

[51](*BBGA* 2A7, pp. 25–26): "als gehörig zu einer solchen Art von Dingen betrachten, deren je zwei immer nur eines von folgenden zwey Verhältnissen gegen einander behaupten können: sie müssen entweder einander *gleich* seyn, oder das Eine derselben muß einen dem andern *gleichen Theil* enthalten." Bolzano was to go back to the principle of trichotomy in his theory of measurable numbers (*BBGA* 2A8, pp. 136–137 & 139; cf. Rychlík 1962, p. 5 & 56–59; Berg 1990, p. 151).

former being "*unmeasurable quantities*."[52] Then, in a note written in 1823, he defined quantity as "a collection of parts, among which two parts that are not equal to each other have instead the relation in which one of them contains a part that is equal to the other,"[53] but he noted that such a definition would rule out certain ideas (*Vorstellungen*), so that, in order to include "$0, \infty, \sqrt{-1}, \ldots$," a more general "concept of *quantity* or rather of a quantity *expression* (a quantity *idea*)" would be required.[54] Because of that, in a later note written between 1823 and 1824, Bolzano asked himself if it would not "be easier to say: A *quantity* (in abstracto) is such an *attribute* of a thing which is determinable by the thought of a *sum*, i.e. by the thought of a collection of parts in which no order among the same is perceived,"[55] from which he concluded that the so-called imaginary quantities, zero and the infinite (both great and small) would not be quantities but "mere *quantity ideas*" ("bloße *Größenvorstellungen*") (*BBGA* 2B11/2, p. 91).

Finally, in a note on "[t]he theorem *that factors with modified order give one and the same product*" (written between 1828 and 1829), Bolzano argued that such a theorem was valid not only for whole numbers, but also for fractions and "irrational quantities" such as "$i = \frac{m}{n} + \omega$, where m, n are whole numbers and ω can become as small as one desires," while adding that imaginary quantities "are not actual quantities at all, but only signs that have been obtained according to the rules that apply to all real quantities."[56] And then, in a note on "*imaginary quantities*" (written between 1829 and 1830), he insisted that these latter were not quantities but "*quantity concepts*," inasmuch as they represented a quantity "of which there is none."[57]

[52](*BBGA* 2B11/2, pp. 22–23): "eine Größe ist ∞groß, wenn jede Zahl ein Theil von ihr; und ∞klein, wenn sie ein Theil von jedem Bruch ist oder wie man sagt $<$ als jeder Bruch"; "$\sqrt{-1}, \sqrt{-2}$, etc sind Beschaffenheiten, die durch Zahlen 1, 2... bestimmt werden; obgleich Beschaffenheiten, die keinen wirklichen Gegenständen zukommen können"; "*unermeßlichen Größen*." This note is entitled "*Begriff der Größe*," dated September 1.

[53](*BBGA* 2B11/2, p. 86): "Die *Größe* ist ein Inbegriff von Theilen, zwischen deren je zweyen, die einander nicht gleich sind, das Verhältniß Statt hat, daß der Eine derselben einen dem anderen gleichen Theil enthält." This note is entitled "*Begriff einer Größe*" and is dated March 10, 1823.

[54](*BBGA* 2B11/2, p. 86): "einer *Größe* oder vielmehr eines Größen*ausdrucks* (einer Größen*vorstellung*)." I opted to translate "Vorstellung" by the term "idea," and not "representation," in order to emphasize its mental character and, at the same time, to distinguish it from "Darstellung," which can be associated with a "representation" by signs (cf. *BBGA* 2A8, p. 22). For a detailed account of "Vorstellung" in the work of both Kant and Bolzano, cf. (Rusnock 2000, p. 102ff.).

[55](*BBGA* 2B11/2, p. 91): "Sollte man denn nicht einfacher sagen können: Eine *Größe* (in abstracto) sey eine solche *Beschaffenheit* einer Sache, welche bestimmbar ist durch den Gedanken einer *Summe*, d.h. durch den Gedanken eines Inbegriffs von Theilen, bei welchen auf keine Ordnung unter denselben gesehen wird?" This note is entitled "*Begriff der Größe*" and it is not dated.

[56](*BBGA* 2B12/1, pp. 84–85): "Der Lehrsatz, *daß Faktoren mit veränderter Ordnung einerlei Produkt geben*"; "Irrationalgrößen"; "$i = \frac{m}{n} + \omega$ wo m, n ganze Zahlen, und ω so klein werden kann, als man nur immer will"; "sind nähmlich gar keine wirklichen Größen, sondern nur Zeichen, die nach denjenigen Regeln, welche für alle reellen Größen gelten erhalten worden sind."

[57](*BBGA* 2B12/1, p. 103): "*Imaginäre Größen*"; "*Größenbegriffe*"; "deren es keine gibt."

All this helps to understand the position taken by Bolzano on the notion of number in *RZ* and, in particular, in the first section of this latter work, entitled "On the Concept of Numbers, Their most General Properties and the Manner of Their Designation."[58] There, he began by stating that numbers are sums formed from a unit (i.e., 2, 3, 4, 5, 6, . . .), which meant that, strictly speaking, the "number sequence" (*Zahlenreihe*) was the "*natural sequence of numbers*" or the "*sequence of natural numbers*,"[59] which would be infinite, although in a broad sense one could also consider "objectless ideas of numbers" and, ultimately, numbers could be identified with "whole or actual" (*wirkliche*) ones (*BBGA* 2A8, p. 17). On the one hand, this explains Bolzano's subsequent discussion of several definitions of *number*, ranging from the definition common at the time (i.e., that of Kästner, although he only mentions Stahl) and the traditional definition in which "things of the same kind" was replaced by "units" (Euclid, Kraushaar), through to those definitions in which the meaning of "number" was extended also to fractions (Schröder, Stein) and even to the irrationals, the infinitely great and the infinitely small, but excluded zero and imaginaries (Stevin, Newton) (*BBGA* 2A8, pp. 18–20).

On the other hand, this led Bolzano to declare that by the "appellation" (*Benennung*) of a "number idea" he wished his readers to understand "any idea of the form '[a] number, which has the attributes b', b'', b'''', regardless of whether these attributes can in fact be found combined [*vereinigt*] in a number or not; i.e. regardless of whether this idea has a real [or actual] object or not."[60] Moreover, he made it clear that he would also call these ideas "number concepts for a change" (*zur Abwechslung*), the representation (*Darstellung*) of which was carried out by means of "signs" which he called "number expressions" (*BBGA* 2A8, p. 22). He then went on to write:

> Finally, to abbreviate, in cases where there is no misunderstanding to be worried about, we will also allow ourselves to simply call the number ideas and number expressions *numbers* themselves, and to do so indeed even at times when there are no numbers corresponding to these ideas or signs in reality.[61]

[58]The title is "Von dem Begriffe, den allgemeinsten Beschaffenheiten und der Bezeichnungsart der Zahlen."

[59](*BBGA* 2A8, p. 15): "die *natürliche Reihe der Zahlen*, oder mit Einigen auch *die Reihe der natürlichen Zahlen*."

[60](*BBGA* 2A8, pp. 18–21): "eine jede Vorstellung von der Form: »*Eine Zahl, welche die Beschaffenheiten* b', b'', b'''. . .*hat*,« verstehen wollen, gleichviel ob diese Beschaffenheiten bei einer Zahl in der That vereinigt angetroffen werden können oder nicht; d.h. gleichviel ob diese Vorstellung einen wirklichen Gegenstand hat oder nicht."

[61](*BBGA* 2A8, p. 22): "Zur Abkürzung endlich werden wir uns in Fällen, wo eben kein Mißverstand zu besorgen stehet, erlauben, die Zahlenvorstellungen und Zahlenausdrücke auch schlechtweg *Zahlen* selbst zu nennen, u. dieß zwar zuweilen selbst dann, wenn es dergleichen dieser Vorstellung oder Zeichen entsprechende Zahlen in Wahrheit gar nicht gibt."

After such explanations as these, Bolzano goes on in the second section of *RZ* to address the addition and subtraction of—natural—numbers (which, for him, did not comprise 0 or the unit), and shows that, given two numbers S and M:

(a) with $S > M$, the difference $S - M$ will be another number;
(b) with $S = M$, their difference (i.e., 0) will be an "objectless idea," as he had already pointed out in *EG* (cf. *BBGA* 2A7, p. 164);
(c) with $S < M$, and given the "arbitrary proposition" (*willkürliche Satz*) or "convention" (cf. Russ 2004, p. 106) according to which "in all numerical expressions we want to regard the unit to which they refer as a unit capable of *opposition*," the difference $S - M$ will nevertheless represent an "actual number" (*wirkliche Zahl*), although from an "opposite i.e. negative" (*entgegengesetzt d.h. negativ*) unit (*BBGA* 2A8, pp. 52–53).

In the third section of *RZ* he explains the product (and proves some properties, including distributivity and commutativity) and "quotients" of numbers, introducing the "designation" or "symbol" (*Zeichnung*) $\frac{p}{m}$ (*BBGA* 2A8, p. 67). Moreover, in the fourth section (on *Rationale Zahlen*), at the beginning of which Berg (editor of *RZ* in *BBGA*) notes that there is a marginal note in the manuscript in which Bolzano states that in these sections things could be "shortened by considering *quantities* instead of just numbers,"[62] Bolzano turns to look at number ideas (*Zahlenvorstellungen*) in which only a finite "multitude" (*Menge*)[63] of the four basic operations are to be performed and explains "simple fractions" (*einfache Brüche*), addressing their calculation rules (avoiding division by 0) and stating that an "elementary expression" will be any "number expression" (*Zahlenausdruck*) in which only a finite or infinite multitude of these operations occur (cf. *BBGA* 2A8, pp. 73–84). He does not discuss the latter case in this section (namely, expressions which involve an infinite multitude of the four basic operations), although he gives the following examples:

$$\text{“}1 - 1 + 1 - 1 + 1 - ..\textbf{in inf}:$$

or

$$1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} + ..\textbf{in inf}:\text{”}\ (BBGA\ 2A8, p.73).$$

[62] (*BBGA* 2A8, p. 73 fn. u): "In allen diesen Abschnitten läßt sich Manches verkürzen, indem statt bloßer Zahlen, *Größen* überhaupt betrachtet werden."

[63] Here I agree with both Peter Simons and Russ about the translation of "Menge" as "multitude," and not as "set," which emphasizes its primitive meaning as a "bunch" of something and avoids its association with the set theory developed decades later (cf. Simons 1997, pp. 95–96; Russ 2004, pp. XXVIII–XXIX; see also Ferreirós 2007, pp. XX–XXI & 72–73).

The fifth section of *RZ* focuses on the "Relations of Height Between Rational Numbers,"[64] meaning that form of comparison between different rational numbers whereby one will be "*greater* or *higher*" and the other "*smaller* or *lower*," so that for two unequal rational numbers one is always higher than the other and "there always lies [another] one *between* them," indeed there always lies an infinite "multitude" of such numbers.[65] For Bolzano this section was necessary in order to "justify" the extension of the meaning of that "relation of *being greater*" ("Verhältniß des *Größerseyns*"), constitutive of the "concept of number" "taken as a basis in this theory of numbers," so that it could be applied to rationals, which he regarded as "mere number ideas" with "no [associated] object, because in fact there is no number that is $=\frac{3}{5}$ or $=\frac{2}{5}$ or $=\frac{1}{5}$."[66] Otherwise, he points out, one would be led to consider relations of height involving "objectless" (*gegenstandlos*) number ideas, as in the case of "$1+\sqrt{-1}>1$, which no mathematician will admit" insofar as the combination of numbers and imaginaries would not admit such a relation, or expressions such as "$1+\frac{1}{1+1+1+\text{in inf.}}$," which, not being a "finite elementary number expression," would entail an extension of the concept of number.[67]

Such an extension is performed in the sixth section of *RZ*, entitled "Rational Numbers Which Can Increase or Decrease to Infinity,"[68] where Bolzano explains the "concepts" of these numbers which, he writes, should not "[be confused] with the concepts of an infinitely great and an infinitely small number": whereas the latter

[64]The title is "Verhältnisse der Höhe zwischen den rationalen Zahlen." In his translation of the seventh section of *RZ*, Russ translates "Höhe" as "order" (Russ 2004, p. 395). Undoubtedly, the notion of "height" involves a certain relation of order among the multitude of rational numbers. However, in order to provide a faithful account of Bolzano's proposal and to avoid any possible—and misleading—set-theoretical interpretation, I opted not to translate "Höhe" as "order." Similarly, and with regard to a paragraph of Bolzano's *Theory of Science* (*Wissenschaftslehre*; henceforth *WL*) on the relation of subordination (*Unterordnung*), Jan Šebestík has translated "Höhe" as "*hauteur*" (Šebestík 1992, p. 177; cf. Bolzano 1837, p. 451). Later, Dedekind and Cantor were to use what they called the "height" (*Höhe*) of algebraic numbers in order to enumerate these latter (cf. Cantor 1874, pp. 259–260; Ferreirós 2007, pp. 178–180).

[65](*BBGA* 2A8, pp. 86, 90 & 92): "*größer* oder *höher*"; "*kleiner* oder *niedriger*"; "so gibt es jederzeit eine, die *zwischen* ihnen liegt"; "Die Menge der Rationalzahlen, die zwischen je zwey von einander verschiedenen Rationalzahlen *A* und *Z* eingeschaltet werden können, geht ins Unendliche." Nowadays this can be expressed by saying that the set of rational numbers are densely ordered in the reals. Such an approach, however, is foreign to Bolzano's proposal.

[66](*BBGA* 2A8, p. 87): "ich in dieser Zahlenlehre einmahl zu Grunde gelegt habe"; "bloße Zahlenvorstellungen"; "die keinen Gegenstand haben, weil es in der That keine Zahl gibt, die $=\frac{3}{5}$ oder $=\frac{2}{5}$ oder $=\frac{1}{5}$ wäre." Indeed, Bolzano once again acknowledges Ohm "for having first recognized this need for a particular conceptual determination [*Begriffsbestimmung*] of the signs $>$ and $<$ when applied to general numbers [*allgemeine Zahlen*]" (*BBGA* 2A8, p. 87). It should be noted that, in the paragraph that Bolzano refers to, Ohm discusses the relations of "being greater than" and "being smaller than" between "real numbers" (*reele Zahlen*), which for him, as he explained before, consisted of the integers, fractions and zero (Ohm 1828, pp. 123–124).

[67](*BBGA* 2A8, pp. 87 & 88): "was doch kein Mathematiker zugeben wird"; "endliche[r] elementare[r] Zahlenausdru[ck]."

[68]The title is "Rationale Zahlen, die ins Unendliche zu- oder ab-nehmen können."

involve "thinking" of a "multitude that *consists* of infinitely many units," the former involve thinking of variable numbers that "*can* take on infinitely many values, including those that are greater [or smaller] than any other given number."[69] Consequently, from Bolzano's point of view, whereas the "multitude of clear ideas that can be cultivated over time in the mind of a thinking being" would be a number idea that *can* increase to infinity while "being and always remaining finite,"[70] "the multitude of points lying on a given line," thought "as a number," would "form the (admittedly self-contradictory) concept of an infinitely great number."[71] Or, as he later explained in *WL*, no "attempted enumeration" (*versuchten Abzählung*) of the members of an infinite multitude of points on a bounded line could ever be achieved (Bolzano 1837, p. 413).

The idea of rational numbers that *can* increase or decrease to infinity is a very interesting one not only because the concept of such numbers, along with Bolzano's criticism of self-contradictory concepts of number, reveals a link with Bolzano's earlier works (cf. Sect. 2), but also because of what he goes on to explain about the former in this section of *RZ*. For him, the idea associated with a "sign" (*Zeichen*) designating a *number* that increases or decreases to infinity was a "multi-form number idea" (*mehrförmige Zahlenvorstellung*), given that it involves "infinitely many values," none of which would be the greatest or smallest (*BBGA* 2A8, pp. 95–96). This meant that, as he had already explained in the first section of that work, such a number idea and its concept would comprise infinite numbers and thus a particular sign would be required to denote said number idea, while, for example, a seven-form number concept would be that of the number between 3 and 11, or 21 and 29, comprising in each case seven different numbers (4, 5, 6, 7, 8, 9, 10 and 22, 23, 24, 25, 26, 27, 28, respectively; cf. *BBGA* 2A8, p. 24).

As a consequence, in the case of the aforementioned number idea involving infinitely many small values, Bolzano introduced an arbitrary proposition or convention (*willkürliche Satz*) according to which the signs "ω, Ω, ω^1, ω^2, etc. [denote]

[69](*BBGA* 2A8, p. 95): "verwechsel[t] [werden] mit den Begriffen einer *unendlich großen* und *unendlich kleinen* Zahl"; "eine Menge denke, die aus unendlich vielen Einheiten *bestehet*"; "die der Werthe unendlich viele und darunter auch solche annehmen *kann*, die größer als eine jede andere gegebene Zahl sind" (emphasis added in "bestehet" and "kann").

[70]It is interesting to note the subtle contrast between Bolzano's stance on this issue and the proof of Dedekind's theorem 66 in his *Was sind und was sollen die Zahlen?*, where the latter stated that "the totality S of all things that can be the object of my thought is infinite" (Dedekind 1888, p. 17): whereas for Dedekind this proves that there *exist* "infinite systems" (*unendliche Systeme*), as in the case of "my world of thoughts," for Bolzano the number idea of one's own clear ideas *can* increase to infinity but remains finite. Nevertheless, as Dedekind himself pointed out in a footnote with regard to (Bolzano 1851/1920, pp. 13–14), Bolzano does consider "infinite multitudes" (cf. Bolzano 1817a, pp. 4–6).

[71](*BBGA* 2A8, p. 95): "[d]ie Menge der klaren Vorstellungen, welche sich in dem Gemüthe eines Denkenden Wesens mit der Zeit ausbilden können, ist und bleibt immer endlich"; "die Menge der Punkte, die in einer gegebenen Linie liegen; und denken wir uns sonach diese Menge als eine Zahl; so bilden wir uns den (freylich sich selbst widersprechenden) Begriff einer unendlich großen Zahl."

numbers that can decrease indefinitely."[72] The theorem that follows this proposition, which deals with "the algebraic sum of a finite and non-variable multitude of rational numbers $\omega^1, \omega^2, \ldots \omega^n$," makes it clear that, at least at that point, those signs stand for rational numbers that decrease and thus vary to infinity, which in turn allows Bolzano to hold that each non-variable rational number is to be enclosed by a pair of variable numbers that "can come as close to each other as one desires."[73] In other words, as the proof (*Beweis*) of the latter theorem shows, the non-variable rational number A would be the limit to which the pair of rational numbers

$$X = A - \frac{1}{2N} \text{ and } Y = A + \frac{1}{2N}$$

would approximate, with N denoting a number that can become as great as one desires (*BBGA* 2A8, p. 99), a procedure which resembles that which he had already proposed in his mathematical notebooks as a procedure for determining an irrational quantity. As it will be discussed in the following section, it is with reference to the proposition about enclosed non-variable numbers that, in the last section of *RZ*, Bolzano goes back to the possibility pointed out at the beginning of this book's fourth section regarding numerical expressions in which an infinite multitude of the four basic operations occur, which he calls "infinite quantity concepts."

4 Bolzano's *meßbare Zahlen*

As pointed out by Berg, whereas the final title that Bolzano assigned to the seventh section of *RZ* was "*Infinite Quantity Concepts* (Quantity Expressions),"[74] he had initially used the expression "Infinite Number Concepts" (*Unendliche Zahlenbegriffe*; *BBGA* 2A8, p. 100 fn. m). In this section, Bolzano sets out to consider expressions that represent numerical concepts involving an infinite multitude of basic operations, that is, infinite quantity expressions, such as the sum of the infinite "multitude of all actual [or real] numbers," the expression of which would be "1 + 2 + 3…in inf.," or even such as the sum of the fractions (*Brüche*) "$\frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16} + ..$**in inf**:," which arises by the division of the unit by 2 and the multiplication of the denominators of the subsequent fractions by -2.[75]

[72](*BBGA* 2A8, p. 97): "*Willk. S.* Zahlen, die ins Unendliche abnehmen können, wollen wir zur Abkürzung zuweilen durch Zeichen wie ω, Ω, ω^1, ω^2, u.s.w. andeuten."

[73](*BBGA* 2A8, pp. 97 & 98): "Die algebraische Summe aus einer endlichen und unveränderlichen Menge von Rationalzahlen $\omega^1, \omega^2, \ldots \omega^n$"; "Zu jeder unveränderlichen Rationalzahl A gibt es ein Paar veränderliche Zahlen, die sie als ihre Grenzen zwischen sich einschließen (d.h. deren die Eine höher, die andern niedriger ist) während sie selbst einander so nahe rücken können, als man nur immer will."

[74]The title is "*Unendliche Größenbegriffe*. (Größenausdrücke)."

[75](*BBGA* 2A8, p. 100): "die Menge aller wirklichen Zahlen." A similar statement can be found in (Bolzano 1851/1920, p. 20).

However, Bolzano notes in §3 that an infinite number concept does not require that the idea of every one of the operations that it involves be comprised in it as "singular constituent parts," in which case it would be "unthinkable for a finite mind such as ours."[76] This remark is connected with his previous and subsequent discussion of concepts and determinable objects. For example, in *BD* (1810) he established that composite concepts were decomposable (*zerlegbaren*) and definable, unlike simple concepts (e.g., a point) or "indeterminate or infinite" concepts (*unbestimmte oder unendliche*; concepts of the form "[e]*verything which is not A* [...] *is also not M*"; Bolzano 1810, pp. 43, 56–57 & 84–85), so that, in the case of a concept composed of an "infinite number of parts" (*unendlich vielen Theilen*), this would not be definable (*BBGA* 2A8, p. 101). Later, in *The Three Problems* (henceforth *DP*; 1817),[77] he introduced the notion of an infinite multitude of quantities and explained that such a concept was not contradictory and indeed that such a multitude could be "determinable" (*bestimmbar*) given a rule (or law) or a finite multitude of rules that determines all its parts, as in the case of the functions "fx, $\overline{f}x$, $\overline{\overline{f}}x$, ...," which "vary according to the law of continuity," or a straight line, "determined by the mere specification of its two endpoints and by a single law."[78] As he explained further, in such cases "only the *multitude* of its parts is indeterminable, but not the multitude itself, if there is a rule that determines every single one of those parts."[79] And, finally, when addressing, in *PU*, the "paradox" whereby, according to the concept established for them, the—natural—numbers would constitute an infinite multitude of all the finite multitudes that said numbers are, he pointed out that this multitude was determined by "the *rule of formation*" according to which "each of its terms has a *succeeding one*."[80]

More importantly, it is in §5 that Bolzano posits for the first time the property that, as he explains in §6, will allow him to consider what he calls "measurable expressions," namely:

> *Theo*[rem]. Among the infinite number concepts there are also some that are of such a nature that, for any arbitrary actual number q that we want to regard as the denominator of a

[76](*BBGA* 2A8, p. 101): "eigenthümlichen Bestandtheile"; "und eben deßhalb für einen endlichen Verstand, wie es der unsrige ist, undenkbar."

[77]The full title of Bolzano's work is *Die drey Probleme der Rectification, der Complanation und der Cubirung, ohne Betrachtung des unendlich Kleinen, ohne die Annahmen des Archimedes, und ohne irgend eine nicht streng erweisliche Voraussetzung gelöst; zugleich als Probe einer gänzlichen Umstaltung der Raumwissenschaft, allen Mathematikern zur Prüfung vorgelegt*.

[78](Bolzano 1817a, p. 4): "nach dem Gesetze der Stetigkeit ändern." For Bolzano's use of superscripts, cf. footnote 24.

[79](Bolzano 1817a, p. 6): "nur die *Menge* seine Theile unbestimmbar, nicht aber er selbst, wenn anders irgend ein Gesetz vorhanden ist, das jeden einzelnen aus diesen Theilen bestimmt"; "durch die bloße Angabe ihrer zwey Endpunkte und durch ein einziges Gesetz [...] bestimmt."

[80](Bolzano 1851/1920, p. 21; cf. Russ 2004, p. 611): "Denn nach dem, in der Erklärung jener Reihe (§8) angegebenen *Bildungsgesetze* derselben hat jedes ihrer Glieder wieder ein *folgendes*."

> fraction, a numerator p can be found which is again a positive or negative actual number, or sometimes even a zero, [and] with the outcome that we obtain the two equations $S = \frac{p}{q} + P$ and $S = \frac{p+1}{q} - P^1$, in which the sign S denotes the infinite number expression, but the P and P^1denote a pair of strictly positive number expressions or, [in the case of] the former, sometimes even a mere zero.[81]

As Bolzano explains further in the following paragraph, this "means of determining infinite number concepts" was in fact very useful, since it implied "infinitely many operations" that would otherwise be impossible for us.[82] Moreover, he says, such a means could be used to "*determine or measure by approximation*," that is, "*up to a* $\frac{1}{q}$," "every not only infinite but also finite number expression S," which he calls "measurable or estimable" (*meßbar* oder *ermeßlich*).[83] Therefore, whereas in the case of rational numbers the "*measuring*" (*messenden*) fraction $\frac{p}{q}$ would be "*complete* or *perfect*" (*voll* oder *vollkommen*), so that the "complement" (*Ergänzung*) P would consequently be $=0$, in other cases (leaving aside the "unmeasurable or inestimable" expressions, that is, those for which the aforementioned equations do not occur) one would require not only the measuring fraction plus a complement to measure S but also the "*next greater* fraction" (*nächst*[e] *größer*[e] Bruch) $\frac{p+1}{q}$ (*BBGA* 2A8, p. 105). In other words, those equations would constitute the rules that would allow one to determine numerically a certain quantity, either completely or approximately.

In order to better understand Bolzano's proposal, let us consider the concrete case of $\sqrt{2}$, an example of a non-rational measurable expression (or "number," as he states in §7) and an example, moreover, which, as discussed in Sect. 2, he had addressed years earlier in his mathematical notebooks. He is no longer here, as he was back in 1814, providing some rules for finding out if a quantity is measurable; instead, he is requiring that the aforementioned equations be satisfied in order to determine or measure the number expression S, without, however, identifying the latter with anything specific, as for example Cantor (with a fundamental sequence of

[81](*BBGA* 2A8, p. 102; cf. Russ 2004, pp. 358–359): "*Lehrs*. Unter den unendlichen Zahlenbegriffen gibt es auch einige, die von einer solchen Beschaffenheit sind, daß sich zu jeder beliebigen wirklichen Zahl q, die wir als Nenner eines Bruches betrachten wollen, ein Zähler p, der abermahls eine positive oder negative wirkliche Zahl, oder zuweilen auch eine Null ist, mit dem Erfolge auffinden läßt, daß wir die beyden Gleichungen erhalten $S = \frac{p}{q} + P$ und $S = \frac{p+1}{q} + P^1$, in welchen das Zeichen S den unendlichen Zahlenausdruck, die P und P^1 aber ein Paar durchaus positive Zahlenausdrücke oder das erstere zuweilen auch eine bloße Null bedeutet."

[82](*BBGA* 2A8, pp. 103–104): "dieß Mittel zur Bestimmung unendlicher Zahlenbegriffe"; "unendlich vielen Verrichtungen."

[83](*BBGA* 2A8, p. 104): "*näherungsweise bestimmen oder messen*"; "*bis auf ein* $\frac{1}{q}$"; "jeden, nicht nur unendlichen, sondern auch endlichen Zahlenausdrucke S." Here I follow Russ' translation of "ermeßlich" as "estimable"—in measure—and therefore of "unermeßlich" as "inestimable" (Russ 2004, p. 361). According to the corresponding entry in the last volume of the *Deutsches Wörterbuch* by Jacob and Wilhelm Grimm, "*ermeszlich*" meant "*mensurabilis*" (Grimm and Grimm 1862, p. 915).

rational numbers)[84] and Dedekind (with cuts)[85] were to do a few decades later. Thus, given $S = \sqrt{2}$, one would be able to measure it up to $\frac{1}{100}$ by means of, on the one hand, the measuring fraction $\frac{141}{100}$ plus the complement P and, on the other hand, $\frac{142}{100}$ (the next greater fraction) from which P^1 should be subtracted, with $P + P^1 < \frac{1}{100}$. Clearly, one would be able to carry out such a measurement as far as desired, so that, following the "visualization" proposed by Russ and Trlifajová, one would always be able to approximate more closely to the rational division marks enclosing its value on a line of length $>S$ (cf. Russ and Trlifajová 2016, p. 43).

Throughout the following paragraphs Bolzano proves several theorems, including the following: that "[a]ny *rational number* is a [complete] measurable number" and vice versa (§7); that "[i]f A is measurable, then $-A$ is also measurable" (§10); and that "there are [...] not two different [numerators] p^1 and p^2" of a pair of measuring fractions with the same q as denominator and which correspond to the same number expression S so that there are two different pairs of what could be called measuring equations (although this is not Bolzano's terminology) corresponding to S (§11).[86] Then, however, in the theorem of §21 and the definition of §22, and with reference to an addendum (*Zusatz*) to the previous theorem in which he had pointed out that the numbers

$$A = 1 - \frac{1}{1 + 1 + 1 + \ldots \textbf{ in inf.}} \text{ and } B = 1$$

have different measuring fractions (§20; cf. *BBGA* 2A8, pp. 111–112), Bolzano notes that "[a]mong the infinite number concepts there are also some" that "represent" numbers that can be called "*infinitely small*," such as

$$S = \frac{1}{1 + 1 + 1 + \ldots \textbf{ in inf.}},$$

and which, "according to the concepts [introduced] so far" (Bolzano once more refers to (*BBGA* 2A7, p. 164)), should not be considered as $= 0$.[87] In other words, such number concepts were those which, "in the attempted process of measuring"

[84] A fundamental sequence $a_1, a_2, \ldots a_n, \ldots$ of rational numbers has the property that the difference $|a_{n+m} - a_n|$ becomes as small as desired as n increases, b (a numerical quantity or *Zahlengrösse*) being the limit of the sequence and B (the totality of such numerical quantities) being the domain of real numbers (Cantor 1872, pp. 123–124).

[85] A Dedekind's cut decomposes all rational numbers into two classes, such that each rational number in the class to the left is smaller than each one in the class to the right, the cut being either a rational or an irrational number (Dedekind 1872, pp. 19–21).

[86] (*BBGA* 2A8, pp. 105–107; cf. Russ 2004, pp. 361 & 363): "Jede *Rationalzahl* ist eine meßbare Zahl, und zwar läßt sich ein volles Maß für sie angeben"; "Ist A meßbar, so ist auch $-A$ meßbar"; "gibt es [...] nicht zwey von einander verschiedene Zahlen p^1 und p^2, welche als Zähler des messenden Bruches."

[87] (*BBGA* 2A8, pp. 112–113): "Unter den unendlichen Zahlenbegriffen gibt es auch einige"; "vorstell[en]"; "*unendlich kleine*"; "nach den bisherigen Begriffen."

and with the numerator of the measuring fraction = 0 (so that the measuring fraction is $\frac{0}{q} + P^1 = P^1$ or, following Bolzano's initial notation, $= P$), "the two equations $S = P^1 = \frac{1}{q} - P^2$ [or $-P^1 = -\frac{1}{q} + P^2$, for negative S] hold, where q is taken to be as great as one desires."[88]

Bolzano goes on to say, first of all, that he will call a "*finite* number" (*endliche* Zahl, which should not be confused with the appellation "finite expression") any non-infinitely-small measurable number (end of §22), and, secondly, that infinitely small numbers are not "actual numbers" (*wirkliche Zahlen*; §23). Then, in the theorem of §26 and the definition of §27, he notes that, conversely, "[a]mong the infinite number concepts there are also some" for which, "in the attempted process of measuring," "there is a p for every q, such that one of the two equations $S = \frac{p}{q} + P^1 = \frac{p+1}{q} - P^2$ is satisfied, but not both of them at once,"[89] infinite number concepts the representation of which he calls "infinitely great" positive or negative numbers, depending on whether they satisfy the first or second equation, respectively (*BBGA* 2A8, p. 114). Examples of these *numbers* would be those designated by the expression $S = 1 + 2 + 3 + 4 + \ldots$ **in inf**. and, for negative S, $-1 - 2 - 3 - 4 - \ldots$ **in inf**. (cf. *BBGA* 2A8, p. 114). However, unlike the infinitely small numbers, the infinitely great *numbers* would be "unmeasurable" (*unermeßlich*) inasmuch as they would not comply with the requirement of the two measuring equations set out in §§5–6 (cf. *BBGA* 2A8, p. 115).

Interestingly, Bolzano points out that there would, nevertheless, still also be unmeasurable numbers that are not infinitely great, such as the *number* represented by the expression $1 - 1 + 1 - 1 + \ldots$ **in inf**. and 0 (§§29–30; cf. *BBGA* 2A8, p. 115). Thus, and at least up to this point in *RZ*, his theory of numbers (in the broad sense of this term) would not entirely correspond to our modern continuum of real numbers. This inasmuch as it comprises:

(a) the unit, that is, 1;
(b) the numbers in the strictest sense of the term, that is, 2, 3, 4, 5, 6, . . .;
(c) the negative numbers;
(d) the rational numbers;
(e) the non-rational measurable numbers, which so far seem to hint at our irrational numbers but also include the infinitely small numbers;

[88](*BBGA* 2A8, p. 113): "bey dem versuchten Geschäfte des Messens"; "die beyden Gleichungen $S = P^1 = \frac{1}{q} - P^2$ bestehen, q werde so groß als man nur immer will genommen." Bolzano introduces the denomination of "infinitely small *negative* number" (unendlich kleine *negative* Zahl) and its corresponding measuring equations in this very same paragraph.

[89](*BBGA* 2A8, pp. 112–114): "Unter den unendlichen Zahlenbegriffen gibt es auch einige"; "bey dem versuchten Geschäfte des Messens [. . .] für welche die beyden Gleichungen $S = P^1 = \frac{1}{q} - P^2$ bestehen, q werde so groß als man nur immer will genommen"; "für jedes q wohl ein p gibt, das Einer der beyden Gleichungen $S = \frac{p}{q} + P^1 = \frac{p+1}{q} - P^2$, keines aber, das beyden zugleich entspräche."

(f) the unmeasurable numbers, such as the infinitely great numbers, 0 and what nowadays would be look on as "divergent series."

Furthermore—although, as it must once again be emphasized, this holds true of Bolzano's proposal in *RZ* only up to this point, namely §30 of the seventh section—his "measurable numbers" would not strictly correspond either to our modern continuum of real numbers, since they would include the infinitely small numbers but not 1 and 0, or to our nonstandard reals, since Bolzano's measurable numbers would indeed not include 1, 0 or the infinitely great numbers.

In the following paragraphs Bolzano focuses on operations involving infinitely great and small numbers, without saying anything further about $1 - 1 + 1 - 1 + \ldots$ **in inf**. and suchlike expressions. To mention just a few results, in §32 he proves that the sum of an infinitely great and a rational number is a number of the first kind; in §§34–35 he proves that the sum of two, or of a "finite multitude" (*endlich*[e] *Menge*) of either infinitely small numbers or infinitely great numbers of the same sign, is infinitely small or infinitely great, respectively; in §36 he states that the difference between a pair of infinitely great numbers can be zero (if they are equal), infinitely small (if an infinitely small number is added to one or the other of them), finite (if a finite number is added to one or the other of them), or even infinitely great (if an infinitely great number is added to one or the other of them); in §§37–38 he proves that the product of an infinitely small or great number by a finite one (thus excluding 0) or by another infinitely small or great number is infinitely small or great, respectively; in §39 he proves that the product of a finite multitude of what he calls finite numbers cannot be either infinitely small or infinitely great, while in §40 he proves that the quotient of a finite number divided by another finite number cannot be either infinitely small or infinitely great; and in §44 he states that the "signs" (*Zeichen*) P^1 and P^2 that appear in the measuring equations are also measurable numbers (cf. *BBGA* 2A8, pp. 115–122).

But then in §53, after arguing that the sum, the difference (although he neglects this case) or the product of two—or of a finite multitude of—measurable numbers must necessarily be another measurable number (§§45–46 & 49–50), Bolzano states that, "according to [the] concepts [introduced] so far," there are number expressions that cannot be compared with one another, that is, between which there obtains no relation of equality or of height.[90] As he goes on to say, such would be the case, for example, of

$$A \text{ and } A + \frac{1}{1 + 1 + \ldots \textbf{ in inf.}}$$

since, according to a definition set out in the fifth section of *RZ*, the difference $A - B$, with $A > B$ and with both of these being rational numbers, "can be reduced to a

[90](*BBGA* 2A8, p. 128): "nach unsern bisherigen Begriffen."

fraction of the form $+\frac{m}{n}$, where m and n denote actual numbers,"[91] which is not the case here since

$$A + \frac{1}{1+1+\ldots \textbf{ in inf.}} - A = \frac{1}{1+1+\ldots \textbf{ in inf.}},$$

with n (i.e., $1+1+\ldots$ **in inf.**) not being an actual number. As a consequence, in §54 he poses the "problem" (*Aufg*[abe]) of investigating whether the previously discussed concepts could be extended in order to allow us to establish such a relation, and he presents the following solution: given any two finite or infinite number expressions A and B, if both are measurable and if "for any arbitrary q, the same positive or negative p is always found for both expressions A and B, which satisfies the equations $A = \frac{p}{q} + P^1 = \frac{p+1}{q} - P^2$ and $B = \frac{p}{q} + P^3 = \frac{p+1}{q} - P^4$,"[92] with P^1 and P^3 zero or positive expressions and P^2 and P^4 positive expressions, then $A = B$; but if the difference between those two number expressions is positive and not infinitely small, then the one being subtracted will be smaller than the other (cf. *BBGA* 2A8, pp. 133–134).

The problem with such a solution, as Bolzano notes in an additional sheet which was not included in the 1962 edition of *RZ* (cf. Rychlík 1962) and which indicates that §54—and by extension the definition in §55, as well as perhaps some other paragraphs—should be rewritten (*BBGA* 2A8, p. 129 fn. n), arises when one considers that "numbers that differ only by an infinitely small [number?] can behave differently in the process of measuring."[93] This would be the case, for example, of the sum of

$$.33333\ldots \text{ and } .66666\ldots,$$

which, according to Bolzano's initial formulation of the relations of equality and height, would be

$$= .99999\ldots \text{ and so } < 1,$$

which in turn would result in

$$\frac{1}{3} + \frac{2}{3} < 1.$$

[91] (*BBGA* 2A8, p. 128; cf. Russ 2004, p. 390): "auf einen Bruch von der Form $+\frac{m}{n}$ bringen läßt, wo m und n wirkliche Zahlen bedeuten."

[92] (*BBGA* 2A8, p. 131): "zu jedem beliebigen q immer dasselbe positive oder negative p für beyde Ausdrücke A und B vorfindet, welches die Gleichungen $A = \frac{p}{q} + P^1 = \frac{p+1}{q} - P^2$ und $B = \frac{p}{q} + P^3 = \frac{p+1}{q} - P^4$ erfüllet."

[93] (*BBGA* 2A8, p. 130): "Zahlen, die sich nur um ein unendlich Kleines unterscheiden, können sich bei dem Geschäfte des Messens verschiedentlich verhalten."

Or, following Bolzano, this would also be the case for

$$1 \text{ and } 1 - \frac{1}{1+1+\ldots \textbf{ in inf.}},$$

which, "for every measuring fraction q, give the numerators $p = q$ and $p = q - 1$ [respectively]"[94] and yet should be regarded as equal. Because of this, he adds, if the difference between A and B, "considered absolutely," "behaves like zero," "one finds that the numerator of the measuring fraction [is] $=0$, and so [...] $A = B$."[95]

First of all, it should be stressed that Bolzano's corrections and amendments, such as the one just presented, are evidence of a work the final version of which he did not manage to finish. Secondly, the amendment introduced in §54 not only allows Bolzano to revisit the case posited in §20, namely

$$A \neq B, \text{with } A = 1 - \frac{1}{1+1+1+\ldots \textbf{ in inf.}} \text{ and } B = 1,$$

and state that

$$A + J = A,$$

with J an infinitely small number or $=0$ (*BBGA* 2A8, p. 136). Such an amendment, as he explains further in the note of §58, involves reconsidering the notion of infinitely small numbers insofar as, "in the process of measuring," they "behave" (he uses the noun *Verhalten*) as "equal to zero," even though they are not, and thus, he says, in order to distinguish them from zero in the strict sense of the term, they should be called "*relative* or *respective* zero."[96]

As pointed out by Detlef Laugwitz in his second paper on *RZ*, this last formulation of the equality relation between measurables is crucial in order to overcome some significant difficulties in Bolzano's theory (cf. Laugwitz 1982, p. 669), although, as noted by Berg and—following him—Rusnock, it may at the same time pose some difficulties, in particular due to Bolzano's reference to the difference $A - B$ "considered absolutely" (cf. *BBGA* 2A8, pp. 134–135 fn. 64; Rusnock 2000, p. 185). Moreover, as pointed out by Rusnock, "[t]he condition on P^1 reveals an important weakness in Bolzano's approach" (Rusnock 2000, p. 182), not only from the modern perspective of how our real numbers must behave, but also from the perspective of what Bolzano's own theory of numbers dictates. As noted by Russ and Trlifajová, whereas according to §§45–46 the sum of a finite multitude of measurable numbers will also be a measurable number (so, from a modern point of view, there is closure under addition), problems emerge when one considers an

[94](*BBGA* 2A8, p. 130): "bei jedem messenden Bruche q, den Zähler $p = q$, und $p = q - 1$ geben."
[95](*BBGA* 2A8, p. 130): "absolut betrachtet"; "wie Null sich verhält"; "man zu Jedem auch noch so großen Nenner q den Zähler des messenden Bruches $= 0$ findet, und somit [...] daß $A = B$ sey."
[96](*BBGA* 2A8, p. 136): "bey dem Geschäfte des Messens"; "Null gleichgelten"; "*relative* oder *beziehungsweise* Null."

expression that Bolzano quotes in §2 as an example of an infinite quantity expression, namely "$\frac{1}{2}-\frac{1}{4}+\frac{1}{8}-\frac{1}{16}+\ldots$ **in inf.**" (*BBGA* 2A8, p. 100; Russ and Trlifajová 2016, p. 49). Following Russ and Trlifajová, we might interpret such an expression "as the sequence of partial sums [so that] we obtain the sequence $\frac{1}{2}, \frac{1}{4}, \frac{3}{8}, \frac{5}{16}, \ldots$ that converges to $\frac{1}{3}$" (Russ and Trlifajová 2016, p. 49), but for which the two corresponding measuring equations cannot be given. Nonetheless, if this type of expression is unmeasurable, the sum of "$A = 2-2+\frac{1}{2}-\frac{1}{2}+\frac{1}{8}-\frac{1}{8}+\ldots$ in inf." and "$B = -1+\frac{1}{2}+\frac{1}{4}+\frac{1}{8}+\ldots$ in inf.," "$A+B = 1-\frac{3}{2}+\frac{3}{4}-\frac{3}{8}+\frac{3}{16}-\ldots$ in inf.," would likewise be unmeasurable and, as a consequence, measurable numbers would not be closed under addition (Russ and Trlifajová 2016, p. 49).[97]

Whereas from a modern perspective it may be desirable to *repair* Bolzano's proposal in such a way that his "measurable numbers" turn out to be equivalent to our real numbers, we consider that it would be a more faithful reading of *RZ* to understand it as a transitional work that was not leading inexorably to the modern post-Weierstraßian or nonstandard frameworks.[98] It is undeniable that Bolzano himself was struggling to overcome some problems in his theory of numbers, as is shown by a handwritten note that he added at the very end of *RZ*:

> *For the theory of measurable numbers*
> Should it not be possible to simplify the theory of measurable numbers if one establishes the definition of them so that A is called measurable if one has 2 equations of the form $A = \frac{p}{q} + P = \frac{p+n}{q} - P$, where for the same n, q can be increased to infinity [or indefinitely]?[99]

In his first work on *RZ*, which was based on the 1962 edition, Laugwitz suggests an amendment in line with those which Bolzano introduced but which were only included in the second edition of that work (as in the case of the note just quoted), whereby "[a]n expression A is called measurable if, for every natural (or 'actual') number q, there is an integer $p = p(q)$, so that $\frac{p}{q} < A < \frac{p+2}{q}$."[100] Berg interprets the last of Bolzano's amendments as meaning that a measurable number expression corresponds "to a sequence S $(=\langle S_n\rangle)$ of rational numbers in such a way that, for every natural number q, there is an integer $p(q, S)$ so that, for all n, holds $S_n =$

[97] Previously, Rusnock posed the example of "$1-\frac{3}{2}+\frac{3}{4}-\frac{3}{8}+\frac{3}{16}-\ldots+\frac{3\cdot(-1)^n}{2^n}$ which gives rise to the sequence of values 1, $-\frac{1}{2}, \frac{1}{4}, -\frac{1}{8}, \frac{1}{16}, \ldots,$" a sequence that converges to zero and that would not be measurable even though "it can be obtained as the sum or difference of two expressions each of which is measurable" (Rusnock 2000, p. 182).

[98] For similar stance with regard to both the modern post-Weierstraßian and nonstandard interpretations of Augustin-Louis Cauchy's analytical proposal, cf. (Lützen 2003, p. 164).

[99] (*BBGA* 2A8, p. 168): "*Zur Lehre von den meßbaren Zahlen*
Sollte die Lehre von den meßbaren Zahlen nicht vielleicht vereinfacht werden können, wenn man die Erklärung derselben so errichtet, daß A meßbar heißt, wenn man 2 Gleichungen von der Form, $A = \frac{p}{q} + P = \frac{p+n}{q} - P$ hat, wo bey einerlei n, q ins Unendliche zunehmen kann?"

[100] (Laugwitz 1965, p. 407): "Ein Ausdruck A heißt meßbar, wenn es zu jeder natürlichen (oder „wirklichen") Zahl q eine ganze Zahl $p = p(q)$ gibt, so daß $\frac{p}{q} < A \frac{p+2}{q}$."

$\frac{p(q,S)}{q} + P_n(q,S) = \frac{p(q,S)+m}{q} - P_n(q,S)$, where m is a natural number and $\langle P_n(q, S)\rangle$ is a purely positive sequence."[101] Similarly, and following (Rychlík 1962) and (van Rootselaar 1964), who also suggested such an interpretation of Bolzano's measurable numbers, Rusnock proposes that A be considered as measurable "iff for all q there is exactly one integer p and number concepts $P_1 \gtrsim 0$ and $P_2 > 0$ such that $A = \frac{p}{q} + P_1 = \frac{p+1}{q} - P_2$" (Rusnock 2000, p. 186). And, finally, Russ and Trlifajová suggest that Bolzano's definition of measurable numbers can be repaired either by considering the numerator p in both the measuring fraction and the next greater fraction of the measuring equations as a rational number, or by interpreting that Bolzano "generally considered number expressions with oscillating values and approaching a rational number as being equal to that rational number" (Russ and Trlifajová 2016, p. 50).[102]

Undoubtedly, each of those proposals has its advantages; but they all involve certain conjectures regarding issues that are not entirely clear or explicit in Bolzano's theory. In particular, whereas the consideration of measurable numbers as sequences of rational numbers would be "in harmony with Bolzano's remarks on infinite series from the paper on the binomial theorem" (Rusnock 2000, p. 181), where—from a modern point of view—Bolzano treated infinite series in a finite manner by focusing on their partial sums or finite segments of them (cf. Rusnock 2000, p. 63; Russ 2004, p. 144), it should be stressed that the latter does not explicitly endorse such an interpretation in *RZ*. So, while this chapter is not intended to demean the challenging and praiseworthy work of reinterpreting Bolzano's theory, it rather concurs with the suggestion of both Spalt and Šebestík that this theory should be understood, first and foremost, "on its own terms,"[103] that is, "in its specificity, including its stylistic peculiarities."[104]

Thus, on the one hand, in the case of convergent (in modern terminology) infinite number expressions with alternating values, Bolzano—as Rusnock has already suggested—seems to have "never fully mastered the use of inequalities in

[101](*BBGA* 2A8, p. 168 fn. 77): "entspricht nun eine Folge S ($=\langle S_n\rangle$) von rationalen Zahlen derart, daß es für jede natürliche Zahl q eine ganze Zahl $p(q, S)$ gibt, so daß für alle n gilt: $S_n = \frac{p(q,S)}{q} + P_n(q,S) = \frac{p(q,S)+m}{q} - P_n(q,S)$, wobei m eine natürliche Zahl und $\langle P_n(q, S)\rangle$ eine rein positive Folge ist."

[102]Russ and Trlifajová base the second interpretation on an example provided by Bolzano in §45, "which could be interpreted as non-monotonic sequences," namely "$A + B = \frac{p^1+p^2}{q} + \frac{1}{q} - \Omega^1 + P^{13} = \frac{p^1+p^2+2}{q} - \frac{1}{q} + \Omega^2 - P^{14}$," from which "$A + B = \frac{p^1+p^2+1}{q}$" (there would be a mistake here, either in the manuscript or in the 1976 edition, since the numerator is written "$p^1 + p^1 + 1$"; *BBGA* 2A8, p. 123; Russ and Trlifajová 2016, pp. 50–51; Russ 2004, p. 384).

[103](Spalt 1991, p. 68): "Sie [Bolzano's Zahlenlehre] muß nur in ihrem eigenen Recht verstanden werden."

[104](Šebestík 1992, p. 358): "l'historien doit de prime abord restituer une théorie du passé dans sa spécificité, y compris dans ses particularités stylistiques; c'est ensuite seulement qu'il peut tenter un rapprochement avec la pratique mathématique de notre temps."

conjunction with absolute values, and never seems to have understood the behaviour of alternating series" (Rusnock 2000, p. 183). On the other hand, as regards the infinitely great and other unmeasurable *numbers* (i.e., those that cannot be placed in a relation of equality or height), such as the unmeasurable *number* represented by the divergent (in modern terminology) number expression $1 - 1 + 1 - 1 + \ldots$ **in inf.** (§§29–30), Bolzano says very little more about these throughout the whole of the rest of *RZ*. First, in §62 he notes that "we are not entitled, *even according to the broader concepts now established*," to maintain that all infinite number expressions can be placed in a relation of equality or height, as shown by "the difference $B - A = 1 - 2 + 3 - 4 + 5 - \ldots$ **in inf.**," with A being "an arbitrary expression."[105] Then, in §69 he points out that it can be said that every positive or negative infinitely great number will be greater or smaller than any "actual number" (*wirkliche Zahl*), respectively (*BBGA* 2A8, p. 138), so that

(a) it can be considered that every positive or negative measurable number lies between 0 and a positive or negative infinitely great number, respectively (theorem of §78; *BBGA* 2A8, p. 140);
(b) given two numbers L and R, and a "property B [that] is to belong to all measurable numbers from L to R," if both are infinitely great and one is positive and the other negative, then B will belong to all measurable numbers; but if one of them is $=0$ and the other a positive or negative infinitely great number, B will belong to all positive or negative measurable numbers, respectively (theorem of §89).[106]

Throughout the remaining paragraphs of the seventh section of *RZ*, proceeding in a way similar to the way in which he proceeds in the previous sections with regard to natural numbers, integers and rationals (cf. Sect. 3; Šebestík 1992, pp. 355–356), Bolzano discusses the extension of several properties to measurable numbers (cf. Russ and Trlifajová 2016, p. 45). For example, he states that

$$\text{"[i]f } A > B \text{ and } B > C, \text{ then also } A > C\text{"} \quad (\S 63)$$

and that[107]

[105](*BBGA* 2A8, p. 137; cf. Russ 2004, p. 396): "wir *selbst nach den jetzt aufgestellten weiteren Begriffen* nicht berechtiget sind"; "der Unterschied $B - A = 1 - 2 + 3 - 4 + 5 - \ldots$ **in inf.**"; "beliebiger Ausdruck."

[106](*BBGA* 2A8, p. 142; Russ 2004, p. 403): "die Beschaffenheit B allen meßbaren Zahlen von L bis zu R ein- oder ausschließlich zukommen soll." Bolzano's formulation of this theorem contains a fairly subtle mistake since, strictly speaking, he says at the beginning of the paragraph that if L and R are infinitely great numbers, with one of them positive and the other negative, and the property B belongs "to all measurable numbers from L to R, inclusively or exclusively," then it belongs to all measurable numbers. However, it is clear that L and R cannot be counted among the measurable numbers and thus L and R cannot be included among "all measurable numbers."

[107](*BBGA* 2A8, pp. 137 & 139): "Wenn $A > B$ und $B > C$, so ist auch $A > C$"; "entweder $A = B$ oder $A > B$ oder $A < B$."

"either $A = B$ or $A > B$ or $A < B$" (theorem of §73),

a proposition which, as in other cases, is false with his first formulation of the equality relation (cf. Russ 2004, p. 399 fn. q; *BBGA* 2A8, pp. 134–135 fn. 64). In addition to this, he takes up once again some important theorems which he had already addressed in *RaB*, such as the theorem on what nowadays is called a least upper bound property (§109) and that about what—depending on whether or not Bolzano's infinitesimals are considered to be equivalent to 0—can be considered equivalent to so-called Cauchy's convergence criterion (§107). Nevertheless, inasmuch as the elucidation of the extent to which Bolzano succeeds to ground these properties in a rigorous manner (from his own point of view) in *RZ* is something that requires and deserves a thorough study,[108] whereas the objective of this section has been to address the insights and uncertainties with regard to the number continuum underlying his notion of "measurable numbers," readers are referred to (Spalt 1991), (Šebestík 1992) and (Rusnock 2000) for a careful assessment of Bolzano's discussion of such theorems.

5 Final Remarks

In his introduction to the 1976 edition of *RZ*, Berg pointed out a dilemma faced by the scholar of Bolzano's theory of numbers: either one updates Bolzano's proposal to bring it into line with present-day knowledge, thereby running the risk of misinterpreting some of its basic characteristics, or, if one attempts to be faithful to Bolzano's proposal, some of such characteristics remain unclear (cf. Berg 1976, p. 8). This chapter has attempted to cast light upon Bolzano's insights and uncertainties regarding the number continuum by paying attention not only conceptual framework of *RZ*, but also to the introductory volume to his general theory of quantities (i.e., *EG*), his mathematical notebooks and some other of his works, both those published during his lifetime and those published only posthumously. Moreover, this chapter has tried to provide a more faithful assessment of *RZ* by showing how Bolzano's stance on numbers evolved from his student days through to his maturity, when he wrote this latter work.

It should be pointed out, however, that there are some volumes of Bolzano's *Größenlehre* and *Miscellanea Mathematica* (comprising, indeed, those notebooks which cover the period from 1830 onward) which have not yet been published and which might provide further evidence regarding certain aspects of *RZ*. Coupled with this, it is worth noting that, due to its limited scope, this chapter has left out of account certain interesting and not uncontroversial issues that are either addressed in *RZ* or linked to it. For example, this chapter did not delve into Bolzano's

[108] In her presentation at the symposium "Bolzano's Mathematics and the General Methodology of the Sciences," which was organized by Steve Russ and held as part of the 16th CLMPST, in Prague, Anna Bellomo examined §107 and provided appealing evidence in favor of a non-set-theoretical interpretation of *RZ* by focusing on Bolzano's reasoning "in terms of parts and wholes."

characterization of numbers as abstract (the property or nature to which the numbers are due) and concrete (the "actual multitude of things"), or "nominated" (*benannte* or *genannte*; e.g., "the concept three points") and "unnominated" (*unbenannte* or *ungenannte*; in themselves, e.g., "the concept three," so there is no unnominated number idea that has only one object, because "one" is not a number), these latter being those which are "primarily" (*vornehmlich*) studied in the "pure theory of numbers" (cf. *BBGA* 2A8, pp. 19–26). For a careful study of these topics, readers are referred to (Benis-Sinaceur 1975) and (Šebestík 1992, pp. 345–350).

Likewise, this chapter has not engaged in any deeper discussion of Bolzano's distinction between multitudes and collections (not sets), for which readers are referred to (Simons 1997), nor of Bolzano's vindication of the so-called part-whole principle (cf. Trlifajová 2018). Regarding this last issue: (a) in *PU*, Bolzano defended the idea that an infinite multitude is greater than those infinite multitudes contained as parts of it (cf. Bolzano 1851/1920, pp. 26–27 & 30–31); (b) in *WL*, he stated that in the "infinite series of concepts [of whole numbers] [. . .] n, n^2, n^4, n^8, . . .," "every succeeding [concept] is always subordinated to [i.e., smaller than] the preceding one";[109] and (c) he is said to have retracted his previous stance on the part-whole principle in a letter dated a few months before his death (cf. Mancosu 2009, p. 625). Paolo Mancosu has challenged the interpretation according to which "Bolzano saved his mathematical soul in extremis and joined the rank of the blessed Cantorians by repudiating his previous sins," and he has pointed out that "recent mathematical work gives us theories that can (cum grano salis) be seen as formally capturing (parts of) the intuitive concept of infinity found in [. . .] all those who believed that the size of the natural numbers is larger than the size of the even numbers" (Mancosu 2009, pp. 626–627). Instead, and based not only on the passages alluded to but also on a paper by Bolzano dated 1840–41, Rusnock and Šebestík have recently argued that "[m]aintaining the whole–part principle would thus appear to force Bolzano" to pay a price that he presumably would not have been willing to pay (Rusnock and Šebestík 2019, pp. 537–538).

There is a well-known passage—"well-known" at least among Bolzano's scholars—toward the end of the preface to *RaB* where, with reference to his theorem on what today is designated as a "least upper bound," Bolzano claims that, according to a "correct concept of *quantity*," "the thought [or idea] of an i which is the greatest of those [quantities] of which it may be said that all those standing below it possess the property M, is the thought [or idea] of a real, i.e. of an *actual* quantity."[110] From the point of view expressed in this chapter, the fact that in this passage Bolzano refers to i as a "quantity" and not as a "number," whereas in §109 of *RZ* he refers to it as a "measurable number," not only constitutes evidence of both a terminological and a

[109](Bolzano 1837, p. 474): "unendlichen Reihe von Begriffen"; "ist also jeder folgende immer den vorhergehenden untergeordnet."

[110](Bolzano 1817a, p. 23): "für Jeden, der einen richtigen Begriff von *Größe* hat, [. . .] daß der Gedanke eines i, welches das größte derjenigen ist, von denen gesagt werden mag, daß alle unter ihm stehende die Eigenschaft M besitzen, der Gedanke einer reellen d.h. *wirklichen* Größe sei."

conceptual change, but ultimately points to the substratum on which his later notion of "measurable numbers" was to rest, namely that of quantities. Therefore it may be concluded that, on the one hand, from his early works onward Bolzano showed "a profound insight into the nature of [quantities]" (Russ 2004, p. 150)—indeed, one would even want to be entitled to say "into the nature of *numbers*"—which eventually led him to the development of his notion of "measurable numbers." On the other hand, however, even in the case of the latter notion, which reflects a transition to a non-traditional notion of numbers and represents "a surprising achievement for its time" (Russ 2004, p. 348), one still cannot help but note significant traits of a not-yet-modern understanding of the number continuum, of quantities and of mathematics itself.

In this sense, Šebestík's remark that the relevance of Bolzano's theory of numbers can be better appreciated if it is compared both with later and with earlier proposals in this subject seems to be extremely appropriate (cf. Šebestík 1992, p. 385). Following Šebestík, it is worth considering, for example, "Kästner's decomposition of irrational numbers,"[111] first published in 1758. For the latter, irrational—algebraic—numbers, "which originate from roots, can be approximated to just as closely as one desires," inasmuch as they are composed of both a rational part and of another part that can be considered "an innumerable multitude of infinitely small parts."[112] Such an approach, which was not novel,[113] certainly had its shortcomings, starting with the fact that Kästner only referred to the algebraic irrationals and took for granted the operations on them (Šebestík 1992, pp. 353–355). Nonetheless, as pointed out by Šebestík, Kästner's presentation can be regarded as a step forward, inasmuch as he would seem to have intended to develop "[a]ll the concepts of arithmetic" on the basis of the notion of whole numbers.[114]

The ending of "the paradigm of the science of quantity" (to echo Epple's expression mentioned in the introduction), which was still strongly advocated in the early nineteenth century and which, as has been shown to some extent in this chapter, entailed profound changes, was actually a protracted process which went on well beyond Bolzano's own lifetime, extending for the whole of that century. As a consequence, remnants of that previous understanding of mathematics as *Größenlehre* were to continue to prevail, in one way or another, in several key proposals that are usually linked to the development of the modern notion of real

[111](Šebestík 1992, p. 353): "Lorsque nous parlerons de la représentation bolzanienne des «grandeurs mesurables», on devra se rappeler la décomposition des nombres irrationnels selon Kästner."

[112](Kästner 1786, pp. 126–127; cf. Šebestík 1992, pp. 352–353): "Irrationalzahlen, die von Wurzeln herrühren, kann man sich, so weit man will, nähern"; "eine unzählige Menge unendlich kleiner Theile."

[113]In the mid-1810s, Bolzano explicitly rejected such an approach, which was still common at the turn of the nineteenth century (cf. van Rootselaar 1995, p. 28; Šebestík 1992, p. 355), because otherwise "one would arrive at the *consideration of the infinite*" ("käme man da in die *Betrachtung des Unendlichen*"; *BBGA* 2B6/2, p. 195).

[114](Kästner 1786, p. [4]): "Alle Begriffe der Arithmetik gründen sich meines Erachtens auf die von ganzen Zahlen." Cf. (Šebestík 1992, pp. 52 & 54).

numbers. A couple of examples shall be mentioned. Firstly and as noted by Ferreirós, whereas Weierstraß continued to differentiate between, on the one hand, numbers in the strict sense of the term and, on the other, quantities—leading to "[h]is theory of rational and irrational numbers [which dates from the 1860s] [being] formulated as a theory of 'numerical [quantities]'"—, there nevertheless lies "under [such a] traditional denomination [. . .] an abstract conception of [quantities]" (Ferreirós 2007, pp. 64–65 & 125). Secondly, as pointed out by Epple, whereas in his *Theorie der complexen Zahlensysteme* Hermann Hankel intended to develop a formal concept of real numbers following "the British tradition of Peacock and de Morgan," he nevertheless claimed that "[t]he irrational require[d] for its systematic treatment the concept of quantity"[115] and that irrationals, therefore, should be developed "within the theory of quantities."[116]

Nevertheless, as the works of Dedekind, Cantor, and Heine show, by the 1870s the notion of number had changed significantly. Hence Dedekind's insistence in 1872 that the "gradual extension of the concept of number" should be carried out without using "foreign ideas," such as that of "measurable quantities."[117] As he was later to write, in the preface to the first edition of *Was sind und was sollen die Zahlen?*, even though he agreed that the "ancient conviction" that an "irrational number [could be] understood as a ratio of measurable quantities" was ultimately "the source" of any attempt at a theory of irrational numbers, for Dedekind there was an essential difference between his own theory based on cuts and certain earlier proposals.[118] In particular, Dedekind disagreed with Jules Tannery's claim that the latter's theory (which the former recognized as equivalent to his) represented "the development of [the] idea originating from J. Bertrand [. . .] of defining an irrational number by indicating all rational numbers which are smaller and all those which are greater than the number to be defined."[119] As he went on to explain, Joseph Bertrand's proposal, according to which any "incommensurable number" "is necessarily placed between two [commensurable numbers], $\frac{x}{n}$ and $\frac{x+1}{n}$, and [the integer]

[115](Epple 1996, pp. 6–7; cf. Hankel 1867, p. 47): "die britische Tradition Peacocks und de Morgans"; "Das Irrationale verlangt zu seiner systematischen Fassung den Grössenbegriff."

[116]The third and fourth sections of Hankel's work are entitled "Die reellen Zahlen in ihrem formalen Begriffe" and "Die reellen Zahlen in der Grössenlehre," respectively (Hankel 1867, pp. 35 & 48), while the full title of that work is *Theorie der complexen Zahlensysteme insbesondere der gemeinen imaginären Zahlen und der Hamilton'schen Quaternionen nebst ihrer geometrischen Darstellung*.

[117](Dedekind 1888, p. X): "die shrittweise Erweiterung der Zahlbegriffes"; "fremdartiger Vorstellungen"; "der meßbaren Größen."

[118](Dedekind 1888, p. XIV): "diese uralte Ueberzeugung"; "die irrationale Zahl als Verhältniß meßbarer Größen auffaßt"; "die Quelle."

[119](Dedekind 1888, pp. XIII–XIV): "die Entwickelung eines von Herrn J. Bertrand herrührenden Gedankens nennt, welcher in dessen *Traité d'arithmétique* enthalten sei und darin bestehe, eine irrationale Zahl zu definiren durch Angabe aller rationalen Zahlen, die kleiner, und aller derjenigen, die größer sind als die zu definirende Zahl."

n can be taken great enough, so that their difference $\frac{1}{n}$ is as small as desired,"[120] was still a proposal which "ha[d] recourse to the existence of measurable quantities" and "present[ed] some essential gaps."[121]

Bolzano's proposal of "measurable numbers," which was unknown to all these mathematicians, certainly constitutes a step forward, made already within the first half of the nineteenth century, in the elucidation of the number continuum. However, several crucial steps remained still to be taken, beginning with the abandonment of the substratum of quantities and by extension of the core notion of variable quantities (cf. Fuentes Guillén and Martínez Adame 2020). The position defended in this chapter, therefore, is that a proper assessment of Bolzano's theory of numbers should always take into account its original setting and, as fruitful as such an "updating" approach may sometimes appear to be, should always avoid dislocating this theory by reinterpreting it within a modern, post-Weierstraßian or nonstandard framework.

Acknowledgments The author would like to thank Steve Russ, José Ferreirós and Carlos Álvarez for their very helpful remarks and suggestions, as well as Michèle Friend and Bharath Sriraman for all their support for the publication of this chapter. He would also like to thank Davide Crippa for his help in obtaining some of the documents cited in this chapter, as well as Alejandrina Viesca Ramírez for her careful revision of it and Alexander Reynolds for his excellent proofreading.

Funding This chapter was made possible thanks to the support by the Postdoctoral Scholarship Program of the Dirección General de Asuntos del Personal Académico (DGAPA) and the Faculty of Sciences at Universidad Nacional Autónoma de México, as well as thanks to the support for the grant project "Mathematics in the Czech Lands: From the Jesuit Teaching to Bernard Bolzano" (GA ČR 19-03125Y) and the support by the Centre for Science, Technology and Society Studies of the Filosofický ústav Akademie věd České republiky.

Abstract

The theory of elliptic integrals and functions was a major research topic during the nineteenth century. Great mathematicians such as Euler, Lagrange, and Legendre made important contributions in this field. The Norwegian mathematician Niels Henrik Abel revolutionized this theory as he introduced novel ideas and approaches. Specifically, he proved what is called Abel's addition theorem which is a sweeping extension of previous addition theorems for elliptic integrals obtained in the eighteenth century.

This chapter provides an elementary review of addition theorems for elliptic integrals before 1830 with special focus on Abel's addition theorem. An important aim of the chapter is to bring out the intuition behind the various methodological approaches. The chapter also contains a short review of Abel's life with special reference to his contribution to the theory of elliptic integrals and beyond.

Keywords

Elliptic integrals · Hyperelliptic integrals · Abelian integrals · Elliptic functions · Addition theorems · Theory of transformations · Multiplication of elliptic integrals

1 Introduction

The life of the Norwegian mathematician Niels Henrik Abel (1802–1829) was short and dramatic. Nevertheless, he was able to make pathbreaking contributions in several fields within mathematics. A major part of Abel's research was on the theory of elliptic functions and integrals. He revolutionized this theory as he introduced new ideas and approaches that later served as the starting point for seminal works by mathematicians such as Karl Theodor Wilhelm Weierstrass (1815–1897) and Georg Bernhard Riemann (1826–1866), among many others. One of Abel's most important achievement is his addition theorem.

The mathematician Carl Gustav Jacob Jacobi (1804–1851) described Abel's theorem as *"die grosste mathematische Entdeckung unserer Zeit, obgleich erst eine kunftige grosses Arbeit ihre ganze Bedeutung aufweise könne" ("the greatest mathematical discovery of our time, even though only a great work in the future will reveal its full significance").* The most general and complete exposition of the addition theorem is given in Abel's famous Paris memoir. Due to a number of unfortunate circumstances, it was first published 12 years after his death (Abel 1841).

An integral is called elliptic if the integrand is a rational function of u and y where y^2 is a polynomial in u of degree three or four, $p(u)$, (say). Specifically, when $p(u) = (1 - u^2)(1 - k^2u^2)$ where $k^2 < 1$ is a constant, one obtains what is called an elliptic integral of the first kind. The purpose of this chapter is to give a brief elementary review of the development of the theory of elliptic integrals before 1830 with focus on Abel's addition theorem. Special emphasis is placed on bringing out the key idea and intuition of Abel's approach by means of elementary calculus. Accordingly, this exposition should be accessible to a general audience interested in the development of mathematics but who only have just an elementary knowledge about calculus.

A number of survey articles and books on Abel's work cover the addition theorem. Some of them are simple without the ambition to cover essential details of the mathematical developments and proofs whereas others require considerable

background knowledge of mathematics. The works of Houzel (1986, 2004) and Sørensen (2004) provide deeper analyses and deal with Abel's entire work within several areas. The paper written by Huntington Barnum (1910) discusses aspects of the theory of elliptic integrals and Abel's addition theorem, but it is not that much easier to read than Abel's original papers. The same might be said about the work by Houzel (2004). The paper written by Mittag-Leffler (1923) provides a nice introduction to the theory of elliptic integrals and early works on addition theorems. He also compares aspects of Abel's work with the approach Weierstrass developed to study elliptic functions and integrals. However, he does not go through the details of the proof of Abel's addition theorem. Hopefully, this chapter will fill a gap.

This chapter starts by showing how elliptic integrals emerged historically from problems in geometry and mechanics. During the seventeenth century, it became clear that this type of integrals could not be expressed on closed form by elementary functions. Subsequently, it was discovered that this type of integrals possesses specific invariance properties and the theory of such integrals became a central research area by the end of the eighteenth century. Before Abel, it was Giulio Carlo Fagnano (1682–1766), Leonhard Euler (1707–1783), Joseph Louis Lagrange (1736–1813), and Adrien-Marie Legendre (1752–1833) who were the main contributors to this theory.

However, when Abel entered the scene, he introduced a totally new and powerful approach that enabled him to generalize the theory far beyond the previous contributions. Consider, for example, a set of m elliptic integrals of the first kind with the same parameter k and a constant lower integration limit and upper limits x_j, $j = 1, 2, \ldots, m$. As will be discussed in detail in Sect. 4, Abel' s approach starts by making a change of variable where the variable of integration u (say) is transformed to z by $u = r_j(z)$ where $r_j(z)$ is chosen as the root of a suitably selected polynomial $\psi(u)$ (say), where one or several of the coefficients of $\psi(u)$ is allowed to depend on z. The upper integration limit is changed from x_j to z_1 (say) where z_1 does not depend on j. After this change of variable, Abel shows that the integrand of the j-th elliptic integral can be expressed as $r'_j(z)/\sqrt{p\left(r_j(z)\right)} = q\left(r_j(z)\right)/\psi'\left(r_j(z)\right)$, where $q(u)$ is a polynomial with degree less than the degree of $\psi(u)$ minus one. According to the theorem of partial fraction decomposition, the sum over j of the fractions $\{q(r_j(z))/\psi'(r_j(z))\}$ is equal to zero and therefore the sum of the corresponding elliptic integrals becomes equal to a constant. In other words, an addition theorem for this special case has been established.

The chapter is organized as follows: Section 2 contains a description of what is meant by elliptic integrals and we discuss examples of how elliptic integrals arise in selected applications in mechanics and geometry. Section 3 contains a review of the theory of elliptic integrals before Abel's contribution. In Sect. 4, several versions of Abel's addition theorem are presented, including examples. Section 5 contains a short review of Abel's life with special reference to his contribution to the theory of elliptic integrals and extensions.

2 Elliptic, Hyperelliptic, and Abelian Integrals

The class of elliptic integrals can be described as follows: let $p(x)$ be a polynomial of degree three or four and $R(x, y)$ be a rational function of x and y, i.e., $R(x, y)$ is a quotient with numerator and denominator that are polynomials in x and y. An integral of the form

$$\int R\left(x, \sqrt{p(x)}\right)dx$$

it is called an *elliptic integral*. The historical reason for this is that when calculating the arch length of an ellipse, one gets an integral of this type. After Gottfried Wilhelm Leibniz (1646–1716) and Isaac Newton (1642–1727) had developed the field of infinitesimal calculus in the 1660s, and Johannes Kepler (1571–1630) had established the laws of celestial mechanics, intensive research into pure as well as applied mathematics, such as mechanics and spherical geometry (navigation), followed. Because Kepler established that planets move around the sun according to elliptic orbits, the calculation of the length of these orbits corresponds to the calculation of the arch length of an ellipse. According to Hoffman (1949), Leibniz contacted Newton and the mathematician James Gregory (1638–1675) in 1675, asking whether it would be possible for him to compute the arch length of an ellipse. Leibniz was told that this problem could only be solved approximately, not in an exact way. At the time, Leibniz thought that he himself would be able to solve this problem, but he eventually realized that he could not. Much later, it was Joseph Liouville (1809–1882) who proved that elliptic integrals cannot be expressed by elementary functions.

When the degree of the polynomial $p(x)$ is greater than 4, the above integral is called hyperelliptic. Abel considered hyperelliptic integrals as well as much more general cases called Abelian integrals. An Abelian integral has the form

$$\int R(x, y(x))dx$$

where $y(x)$ is an algebraic function. Remember that an algebraic function $y(x)$ is the root of a polynomial in y, $P(x, y)$, (say) where the coefficients are polynomials in x with integer coefficients. In other words, the algebraic function $y(x)$ is determined by $P(x, y(x)) = 0$.

Example 2.1. Arch Length of an Ellipse
Consider the problem of computing the arch length of an ellipse. Recall that the arch length, $s(u,v)$, from $x = u$ to $x = v$ of a differentiable function $y = f(x)$ can be computed by means of the formula

$$s(u, v) = \int_u^v \sqrt{1 + f'(x)^2}dx. \tag{1}$$

Recall also that the ellipse with parameters a and b can be expressed by

$$\left(\frac{x}{a}\right)^2 + \left(\frac{y}{b}\right)^2 = 1. \tag{2}$$

From (2), it follows by applying (1) that

$$s(u,v) = \frac{1}{a}\int_u^v \frac{a^4 + (b^2 - a^2)x^2}{\sqrt{(a^2 - x^2)(a^4 + (b^2 - a^2)x^2)}}dx. \tag{3}$$

As mentioned above, Liouville's work has made clear that the integral in (3) cannot be "solved" in the sense that it can be expressed by elementary functions. It may be instructive to see how the integral in (3) can be transformed to an elliptic integral of the second kind (see Sect. 3.5). Assume first that $b > a$. Let us make a change of variable, $x \to z, x = a\sqrt{1 - z^2}$. Then $dx = -az(1 - z^2)^{-1/2}dz$. The corresponding transformed integral limits become $z_1 = \sqrt{1 - (u/a)^2}$ and $z_2 = \sqrt{1 - (v/a)^2}$. As a result, it follows from (3) that

$$s(u,v) = ab\int_{z_1}^{z_2} \frac{(1 - k^2z^2)dz}{\sqrt{(1 - z^2)(1 - k^2z^2)}}$$

where $k^2 = (b^2 - a^2)/b^2$. The last integral is an elliptic integral of the second kind with $m = -k^2$. In the case where $b < a$, the proof is similar.

Example 2.2. Oscillation of the Pendulum

There is another well-known problem in mechanics that also leads to an elliptic integral, namely: the analysis of the oscillation of the simple pendulum. Let g denote the acceleration due to gravity, l the length of the pendulum cord, and $\theta(t)$ the angle between the y-axis and the pendulum cord at time t. The challenge is to establish how $\theta(t)$ depends on t. By applying the standard laws of mechanics, one can show, see for example, (Stephenson 1960), that the following differential equation holds:

$$\theta''(t) = -\frac{g}{l}\sin\theta(t). \tag{4}$$

By multiplying (4) by $2\theta'(t)$, it follows that

$$2\theta''(t)\theta'(t) = -\frac{2g}{l}\sin(\theta(t))\theta'(t). \tag{5}$$

The left-hand side of (5) is the derivative of $\theta'(t)^2$and the right-hand side is the derivative of

$$2\cos(\theta(t))g/l.$$

Hence

$$\theta'(t)^2 = \kappa\cos\theta(t) + c \tag{6}$$

where c is a constant and $\kappa = 2g/l$. Let α denote the greatest angle between the y-axis and the pendulum cord: that is, the angle for which $\theta'(t) = 0$. From this, we obtain $c = -\kappa\cos\alpha$. By solving the differential equation in (6) and by making the change of variable $u = \cos\theta(t)$, it follows that the inverse solution can be written as

$$t(\theta) = \int_{\cos\theta}^{1} \frac{du}{\sqrt{(1-u^2)(u-\cos\alpha)\kappa}} \tag{7}$$

where $t(\theta)$ is the time at which the pendulum cord makes an angle θ with the vertical axis. Note that this integral is an elliptic integral. The integral in (7) can be transformed into an elliptic integral of the first kind (see Sect. 3.5) by making the change of variable $u \to z$, $u = 1 + (\cos\alpha - 1)z^2$, which gives

$$\int_{\cos\theta}^{1} \frac{du}{\sqrt{(1-u^2)(u-\cos\alpha)\kappa}} = \sqrt{\frac{2}{x}} \int_{h(\theta)}^{1} \frac{dz}{\sqrt{(1-z^2)(1-0.5(1-\cos\alpha)z^2)}}$$

where

$$h(\theta) = \sqrt{\frac{1-\cos\theta}{1-\cos\alpha}} = \frac{\sin(0.5\theta)}{\sin(0.5\alpha)}.$$

This last integral is an elliptic integral of the first kind with $k^2 = 0.5(1-\cos\alpha)$.

Example 2.3. The Arch Length of the Lemniscate

A third example where an elliptic integral occurs is when computing the arch length of the lemniscate. The graph of the lemniscate has the same form as the infinity sign, instead of w, and can be expressed in Cartesian coordinates by the following formula

$$\left(x^2 + y^2\right)^2 = x^2 - y^2$$

or in polar coordinates as

$$r(\theta)^2 = \cos(2\theta).$$

Here, only the case where $\theta \in [-\pi/4, \pi/4]$ is considered where θ is the angle between the x-axis and the radius $r(\theta)$ from the origin to the graph. Since $x = r(\theta)\cos\theta$ and $y = r(\theta)\sin\theta$, this implies that $dx = (r'(\theta)\cos\theta - r(\theta)\sin\theta)d\theta$ and $dy = (r'(\theta)\sin\theta + r(\theta)\cos\theta)d\theta$, so that

$$\sqrt{1+\left(\frac{dy}{dx}\right)^2}dx = \sqrt{dx^2+dy^2} = \sqrt{r'(\theta)^2 + r(\theta)^2}d\theta = \frac{d\theta}{\sqrt{\cos(2\theta)}} = \frac{d\theta}{r(\theta)}.$$

Thus, the arch length $s(\theta_0)$ which corresponds to the angle from 0 to θ_0 is given by

$$s(\theta_0) = \int_0^{\theta_0} \frac{d\theta}{r(\theta)}.$$

By the change of variable $\theta \to r, r = \sqrt{\cos 2\theta}$, one gets

$$dr = -\frac{\sin(2\theta)}{\sqrt{\cos(2\theta)}}d\theta = -\frac{\sqrt{1-\cos^2(2\theta)}}{\sqrt{\cos 2\theta}}d\theta = -\frac{\sqrt{1-r^4}}{r}d\theta$$

which yields

$$s(\theta_0) = \int_0^{\theta_0} \frac{d\theta}{r(\theta)} = -\int_1^{r_0} \frac{dr}{\sqrt{1-r^4}} = \int_{r_0}^{1} \frac{dr}{\sqrt{1-r^4}} \tag{8}$$

where $r_0 = \sqrt{\cos 2\theta_0}$. By making the change of variable $r \to w, r = \sqrt{1-w^2}$, it follows that

$$s(\theta_0) = \frac{1}{\sqrt{2}} \int_0^{\sin 2\theta_0} \frac{dw}{\sqrt{(1-w^2)(1-0.5w^2)}}.$$

This last integral is an elliptic integral of the first kind with $k^2 = 0.5$.

3 Early Approaches to Addition Theorems

By addition theorems, we mean theorems on how the sum or product of two or several functions (integrals) of given arguments can be expressed as a function of the same type with argument that is an explicit function of the given arguments. Familiar examples are the logarithm, exponential, and trigonometric functions.

3.1 Addition Theorems for Inverse Trigonometric Functions

The inverse trigonometric functions are special cases of elliptic integrals, cf. Sects. 1 and 2. One example of an addition theorem is given by

$$\arcsin x + \arcsin z = \arcsin\left(x\sqrt{1-z^2} + z\sqrt{1-x^2}\right), \tag{9}$$

for $xz \leq 0$ or $x^2 + z^2 \leq 1$,

$$\arcsin x + \arcsin z = \pi - \arcsin\left(x\sqrt{1-z^2} + z\sqrt{1-x^2}\right), \tag{10}$$

for $x > 0$, $z > 0$, $x^2 + z^2 > 1$, and

$$\arcsin x + \arcsin z = -\pi - \arcsin\left(x\sqrt{1-z^2} + z\sqrt{1-x^2}\right), \tag{11}$$

for $x < 0$, $z < 0$, $x^2 + z^2 > 1$, where

$$\arcsin x = \int_0^x \frac{du}{\sqrt{1-u^2}}.$$

Thus, arcsin$x$ is an elliptic integral of the first kind with $k = 0$. The addition theorem in (9), (10), and (11) can be proved by applying the well-known formula

$$\sin(u+v) = \sin u \cos v + \cos u \sin v$$

where $u = \arcsin x$ and $v = \arcsin z$. A similar addition theorem holds for the integral

$$arctgx = \int_0^x \frac{du}{1+u^2}.$$

By the change of variable, $u \to z$, $u = z(1-z^2)^{-1/2}$, the integral above becomes

$$\int_0^x \frac{du}{1+u^2} = \int_0^{x\left(1+x^2\right)^{-1/2}} \frac{dz}{\sqrt{1-z^2}}$$

which demonstrates that arctg$x$ can be expressed by an elliptic integral of the first kind with $k = 0$.

It can easily be demonstrated that the following addition theorem, namely

$$\text{arctg}x + \text{arctg}z = \text{arctg}\left(\frac{x+z}{1-xz}\right)$$

holds for $xz < 1$, and an analogous formula holds for $xz > 1$.

3.2 Development of the Theory of Elliptic Integrals in the Eighteenth and early Nineteenth Century

Since it seemed impossible to reduce elliptic integrals to elementary functions, mathematicians started to investigate what might be called the intrinsic properties of these transcendental functions. Note that in the eighteenth and early nineteenth century, elliptic integrals were often called elliptic functions, in contrast to the terminology established after Abel and Jacobi where the inverse of elliptic integrals are called elliptic functions. In the eighteenth century, the properties of the trigonometric and inverse trigonometric functions were well known by Euler and others, including the addition relations reviewed in Sect. 3.1. It is not known if Euler was led to his approach in the study elliptic integrals by considering the properties of the inverse trigonometric functions reviewed in Sect. 3.1, but it may very well have been so. To elaborate on this point, consider the relation in (9) and let

$$y = x\sqrt{1-z^2} + z\sqrt{1-x^2} \tag{12}$$

where z now is a given constant. By differentiation, it follows from (9) that

$$\frac{dy}{\sqrt{1-y^2}} = \frac{dx}{\sqrt{1-x^2}}. \tag{13}$$

The solution of (13) is given by $y = \sin(\arcsin x + C)$ which is equivalent to

$$y = \sin(\arcsin x + \arcsin z)$$

where $z = \sin C$. But it is known from (9) that y is also given by (12), which implies that x and y are related by the second-degree polynomial equation

$$x^2 + y^2 - 2\alpha xy - \beta = 0 \tag{14}$$

where α and β are constants, $\beta = z^2$ and $\alpha^2 + \beta = 1$. In other words, the solution (y) of (13) can be expressed as an algebraic function of x.

As mentioned above, it was Fagnano and Euler who were the first to study elliptic integrals systematically, see Ayoub (1984). When Euler started his investigations of elliptic integrals, inspired by the results obtained by Fagnano, his point of departure was the differential equation

$$\frac{dy}{\sqrt{1-y^4}} = \frac{dx}{\sqrt{1-x^4}}. \tag{15}$$

Euler's conjecture was that the solution of (15) would satisfy the polynomial equation

$$x^2 + y^2 + \beta x^2 y^2 - 2\alpha xy - \beta = 0 \tag{16}$$

where α, and β, are constants. In fact, he proved that this is so with $\beta > 0$ and $\alpha^2 + \beta^2 = 1$. Since the differential equations in (13) and (15) are quite similar, Euler's conjecture might very well have been motivated by the fact that the solution of (13) is determined by (14). Apart from the term $\gamma x^2 y^2$, the latter equation is identical to (16). Subsequently, Euler studied more general differential equations of the same type where the terms under the radicals of (15) were general polynomials of degree four, to be discussed below.

Among the approaches to addition theorems of elliptic functions in the nineteenth century, it is the approach of Lagrange (1766–9) that appears to be the most interesting one. His method is constructive whereas the approaches of Fagnano (1718), Euler (1761), and Legendre (1825–1828) were based on conjectures of how the addition theorem might look like.

In this context, it is worth mentioning that John Landen (1719–1790) obtained what is known as Landen's theorem (Landen 1775). Landen's theorem expresses the length of the arc of a hyperbola in terms of the lengths of the arcs of two ellipses. For details, see Cayley (1961) who goes through Landen's result. It seems, however, that Landen did not establish addition theorems explicitly and did not fully realize the value of his discovery (Mittag-Leffler 1923).

Both Euler and Lagrange tried in vain to extend their approaches to more general situations where the terms under the radicals of (15) were polynomials of a higher degree than the fourth. Much later, Richelot (1842) demonstrated how Lagrange's approach can be used to prove more general addition theorems.

After Euler and Lagrange, Legendre continued research on the theory of elliptic integrals. Although he produced a different proof of Euler's addition theorem, he did not come up with fundamental new ideas beyond those of Euler and Lagrange. One of his major results was that the demonstration that all elliptic integrals can be reduced to the three fixed canonical forms given in Sect. 3.5 below.

3.3 Results Obtained by Fagnano

Fagnano wrote several papers that dealt with integrals that had geometric interpretations but could not be expressed by elementary functions. In 1718, he published the following remarkable relation for the arch length of the lemniscate (Fagnano 1718; compare Example 2.3),

$$2s(x) = s\left(\frac{2x\sqrt{1-x^4}}{1+x^4}\right) \tag{17}$$

for $x \in [-1, 1]$,where $s(u)$ is as defined in (8). The problem of establishing (17) is equivalent to showing that

$$y = \frac{2x\sqrt{1-x^4}}{1+x^4} \tag{18}$$

is a solution of the differential equation

$$\frac{dy}{\sqrt{1-y^4}} = \frac{2dx}{\sqrt{1-x^4}}.$$

Apparently, it was the following problem formulated by John Bernoulli (1667–1748) that motivated Fagnano in his investigations, namely: what is the curve with the property that the time taken for a particle to traverse the curve is proportional to the distance from a given point? The solution of this problem yields the integral given in (8). Fagnano's result in (17) can in fact be viewed as a special case within the theory of transformations of elliptic integrals. This topic was to become central in the competition between Abel and Jacobi. Although Fagnano demonstrated that (18) was a solution to (14), he was not able to find the general solution to this differential equation. For further discussion on Fagnano's work on elliptic integrals, see Ayoub (1984).

3.4 Results Obtained by Euler

Euler first saw Fagnano's work on 23 December 1751, which explains why Jacobi referred to this date as the birth of elliptic functions. According to Ayoub (1984), it was then that Euler was asked to examine the collected papers of Fagnano, who was being put forward for membership of the Berlin Academy. Euler had already encountered elliptic integrals through his work on elasticity and had published several papers on the topic before 1751. He had also written papers on the rectification of the ellipse, which leads to an elliptic integral, see Example 2.3. Ayoub (1984) notes that Euler had apparently not written anything about addition theorems for elliptic integrals before reading the work of Fagnano. Subsequently, Euler (1761) obtained the general solution to (15) and he established the following addition theorem

$$s(x) + s(y) = s\left(\frac{x\sqrt{1-y^4} + y\sqrt{1-x^4}}{1+x^2y^2}\right) \tag{19}$$

which generalizes (17), since (19) implies (17) when $x = y$. In the same paper, Euler demonstrated that the approach applied to prove (19) can also be applied to prove addition theorems for more general integrals $F(x)$ of the form

$$F(x) = \int_0^x \frac{du}{\sqrt{p(u)}}$$

where $p(x)$ is a polynomial of degree three or four.

Next, consider Euler's proof of his addition theorem in the case with $p(x) = 1 + ax^2 + bx^4$ where a and b are real constants such that $p(x) > 0$, $x \in [0, c]$, for some constant c. It will be clear that the corresponding addition theorem can be obtained by solving the differential equation

$$\frac{dy}{\sqrt{1 + ay^2 + by^4}} = \frac{\varepsilon dx}{\sqrt{1 + ax^2 + bx^4}} \tag{20}$$

where y is an unknown function $f(x)$ (say), and ε is equal to 1 or -1. Here, it is sufficient to consider the case with $\varepsilon = 1$. However, it will be convenient to consider the case with $\varepsilon = -1$ below when discussing Legendre's approach. With $\varepsilon = 1$, the equation in (20) becomes equivalent to $F(y) = F(x) + C$ where C is a constant and y is a function of x and C. Thus, the solution can be expressed as $y = F^{-1}(F(x) + C)$. Without loss of generality, we can write $C = F(z)$, where z is a constant. Hence, (20) becomes equivalent to

$$F(y) = F(x) + F(z) \tag{21}$$

where now y is a function of x and z. Euler (1761) proved that the solution of (20) also satisfies the equation

$$a\left(x^2 + y^2\right) = 2\beta xy + \gamma x^2 y^2 + \delta \tag{22}$$

where α, β, γ, and δ are constants. We shall next prove this. By creating the total differential of (22), one obtains

$$\alpha(xdx + ydy) = \beta(xdy + ydx) + \gamma\left(xy^2 dx + x^2 ydy\right)$$

which is equivalent to

$$\left(\alpha x - \beta y - \gamma xy^2\right)dx + \left(\alpha y - \beta x - \gamma x^2 y\right)dy = 0. \tag{23}$$

When solving (22) for x and y, respectively, two possible solutions are

$$x = \frac{\beta y - \sqrt{\alpha\delta + \left(\beta^2 - \alpha^2 - \gamma\delta\right)y^2 + \alpha\gamma y^4}}{\alpha - \gamma y^2} \tag{24}$$

and

$$y = \frac{\beta x + \sqrt{\alpha\delta + \left(\beta^2 - \alpha^2 - \gamma\delta\right)x^2 + \alpha\gamma x^4}}{\alpha - \gamma x^2} \tag{25}$$

There are in fact four possible solutions of (22) of x (y) in terms of y (x). However, it is essential for the subsequent results to pick from among these solutions the largest one for x and the smallest one for y.

From the equations above, by multiplying by the respective denominators in (24) and (25), it follows that

$$\alpha x - \beta y - \gamma x y^2 = -\sqrt{\alpha\delta + (\beta^2 - \alpha^2 - \gamma\delta)y^2 + \alpha\gamma y^4} \tag{26}$$

and

$$\alpha y - \beta x - \gamma x^2 y = \sqrt{\alpha\delta + (\beta^2 - \alpha^2 - \gamma\delta)x^2 + \alpha\gamma x^4}. \tag{27}$$

By inserting (26) and (27) into (23), one obtains

$$\frac{dy}{\sqrt{\alpha\delta + (\beta^2 - \alpha^2 - \gamma\delta)y^2 + \alpha\gamma y^4}} = \frac{dx}{\sqrt{\alpha\delta + (\beta^2 - \alpha^2 - \gamma\delta)x^2 + \alpha\gamma x^4}} \tag{28}$$

which proves that the relation in (23) in fact represents a solution of (20) with $\alpha\delta = 1$, $a = \beta^2 - \alpha^2 - \gamma\delta$, $b = \alpha\gamma$ and $\alpha = 1/z$. Hence, $\delta = z$, $\gamma = bz$, and $\beta = \sqrt{a + z^{-2} + bz^2}$ where z is an arbitrary variable that for the moment is kept fixed. By using the above notation, it follows that (25) can be expressed as

$$y = \frac{x\sqrt{1 + az^2 + bz^4} + z\sqrt{1 + ax^2 + bx^4}}{1 - bz^2x^2}. \tag{29}$$

Above, z is treated as a constant, but since the relations above hold for any value of z, one can treat z as a free variable. From (29) and (21), it is therefore the case that

$$F\left(\frac{x\sqrt{1 + az^2 + bz^4} + z\sqrt{1 + ax^2 + bx^4}}{1 - bz^2x^2}\right) = F(x) + F(z). \tag{30}$$

Note that the equation in (19) is a special case of (30). By letting $a = -(1 + k^2)$ and $b = k^2$, the addition equation in (30) can be reduced to

$$H\left(\frac{x\Delta(z) + z\Delta(x)}{1 - k^2z^2x^2}\right) = H(x) + H(z) \tag{31}$$

where $H(x)$ denotes the (definite) elliptic integral of the first kind and $\Delta(x)^2 = (1 - x^2)(1 - k^2x^2)$. Thus, an addition theorem for elliptic integrals has been established. Note that when $z = x$ in (31), an extension of Fagnano's invariance relation in (17) is obtained.

Moreover, Euler (1761) demonstrated that the same technique as above works for solving differential equations of the type

$$\frac{mdx}{\sqrt{p(x)}} = \frac{ndy}{\sqrt{q(y)}} \tag{32}$$

where m and n are integers, and $p(x)$ and $q(x)$ are general fourth-order polynomials in x that are not necessarily equal. The solutions of (32) constitutes part of the theory of transformations, see Cayley (1961). For example, if in (32), $m = n = 1$, and $p(x) = (1 - \alpha^2x^2)(1 - \beta^2x^2)$, then the differential $dx/\sqrt{p(x)}$ is carried into a differential of the same form $dy/\sqrt{q(y)}$ by means of the transformation

$$y = \frac{x}{1 + \alpha\beta x^2}$$

where $q(y) = \left(1 - \alpha_1^2y^2\right)\left(1 - \beta_1^2y^2\right), \alpha_1 = \alpha + \beta$ and $\beta_1 = 2\sqrt{\alpha\beta}$. Similarly, Landen (1775) and Mittag-Leffler (1923) discovered a similar result, namely that when $m = n = 1, \alpha_1 = \alpha + \sqrt{\alpha^2 - \beta^2}$ and $\beta_1 = \alpha - \sqrt{\alpha^2 - \beta^2}$, then

$$y = x\sqrt{\frac{1 - \alpha^2x^2}{1 - \beta^2x^2}}.$$

Recall that part of Euler's method is the trick of letting the coefficients of the original differential equation in (20) be suitable functions of the free variable z. At the outset, this variable is understood to be fixed, but it becomes clear later that it may vary freely since the corresponding differential equation is supposed to hold for *any* value of z. Although this observation is trivial, it is nevertheless very important because it makes it possible to express y in the symmetric relation given in (29), which is a key element in the statement of the corresponding addition theorem. Below it will be shown that in Abel's approach also a similar trick of allowing one or several coefficients to depend on a free variable is essential for establishing Abel's addition theorem.

3.5 Lagrange's Approach

Lagrange introduced a method for solving a specific type of differential equations that can be applied constructively to obtain the addition theorem for elliptic integrals (Cayley 1961). Lagrange's approach for solving (20) with $\varepsilon = 1$ starts with the introduction of a new variable t, defined by

$$t = t(x) = \int_0^x \frac{du}{\sqrt{p(u)}}. \tag{33}$$

Equations (20) and (33) imply that

$$dt = \frac{dx}{\sqrt{p(x)}} = \frac{dy}{\sqrt{p(y)}} \tag{34}$$

and

$$\frac{dx}{dt} = \sqrt{p(x)} \text{ and } \frac{dy}{dt} = \sqrt{p(y)}. \tag{35}$$

By differentiating the first equation in (35) with respect to t, it follows that

$$\frac{d^2x}{dt^2} = \frac{d(dx/dt)}{dx} \cdot \frac{dx}{dt} = \frac{d\left(\sqrt{p(x)}\right)}{dx} \cdot \frac{dx}{dt}$$

$$= \frac{2ax + 4bx^3}{2\sqrt{p(x)}} \cdot \sqrt{p(x)} = ax + 2bx^3.$$

Similarly, it follows from (35) that

$$\frac{d^2y}{dt^2} = ay + 2by^3.$$

At this point, it becomes convenient to introduce the notation $r = x + y$ and $q = x - y$. By means of this notation, one gets

$$\frac{d^2q}{dt^2} = \frac{d^2x}{dt^2} - \frac{d^2y}{dt^2} = aq + \frac{b}{2}\left(q^3 + 3r^2q\right) \tag{36}$$

and

$$\frac{dr}{dt} \cdot \frac{dq}{dt} = \left(\frac{dx}{dt} + \frac{dy}{dt}\right) \cdot \left(\frac{dx}{dt} - \frac{dy}{dt}\right) = \left(\frac{dx}{dt}\right)^2 - \left(\frac{dy}{dt}\right)^2$$

$$= a\left(x^2 - y^2\right) + b\left(x^4 - y^4\right) = arq + \frac{b}{2}rq\left(r^2 + q^2\right). \tag{37}$$

From (36) and (37), it follows that

$$r\frac{d^2q}{dt^2} - \frac{dr}{dt} \cdot \frac{dq}{dt} = arq + \frac{brq^3}{2} + \frac{3r^3q}{2} - arq - \frac{brq^3}{2} - \frac{br^3q}{2} = br^3q. \tag{38}$$

By dividing both sides of (38) by $r^3$and multiplying both sides by 2 dq/dt lead to

$$\frac{2}{r^2}\cdot\frac{d^2q}{dt^2}\cdot\frac{dq}{dt}-\frac{2}{r^3}\left(\frac{dq}{dt}\right)^2\cdot\frac{dr}{dt}=2br\cdot\frac{dq}{dt}. \tag{39}$$

Equation (39) can readily be integrated, which gives

$$\frac{1}{r^2}\cdot\left(\frac{dq}{dt}\right)^2=bq^2+K \tag{40}$$

where K is an arbitrary constant. When inserting for r, q, and dq/dt, as functions of x and y, into (40) and applying the equation in (35), the resulting equation becomes

$$\left(\frac{\sqrt{p(x)}-\sqrt{p(y)}}{x+y}\right)^2=b(x-y)^2+K. \tag{41}$$

Equation (41) expresses the relationship between x and y in implicit form. It is, however, possible to simplify this equation considerably. After multiplication on both sides of (41) by $(y+x)^2$and rearranging, it is obtained that

$$-2\sqrt{p(x)p(y)}=(y+x)^2\left(K+(x-y)^2b\right)-2-a\left(x^2+y^2\right)-b\left(x^4+y^4\right). \tag{42}$$

By raising both sides of (42) to the power of 2 yields

$$\begin{aligned}0&=\left((y+x)^2\left(K+(x-y)^2b\right)-2-a\left(x^2+y^2\right)-b\left(x^4+y^4\right)\right)^2\\&\quad-4\left(1+ax^2+bx^4\right)\left(1+ay^2+by^4\right)\\&=\left(a^2-4b\right)\left(y^2-x^2\right)^2+K^2(y+x)^4-2aK(y+x)^2\left(x^2+y^2\right)\\&\quad-4K(y+x)^2-4bK(y+x)^2x^2y^2.\end{aligned} \tag{43}$$

Note that the right-hand side of (43) has $(y+x)^2$ as a common factor. By dividing through and rearranging, (43) can be reduced to

$$\alpha\left(x^2+y^2\right)=2\beta xy+\gamma x^2y^2+\delta \tag{44}$$

where $\delta=4K$, $\beta=a^2-4b-K^2$, $\gamma=4bK$, and $\alpha=K^2-4b+a^2-2aK$.

Equation (44) represents the solution y as a function of x, of the differential equation in (20). Note that the equation (44) is equivalent to the equation (22). This means that there are no other solutions to Euler's differential equation (20) than the one Euler postulated and subsequently verified. The rest of the analysis proceeds in the same way as Euler's deductions.

3.6 Results Achieved by Legendre

As mentioned above, it was Legendre who most systematically and extensively conducted research on elliptic integrals before Abel and Jacobi. In his monumental three-volume work, *Traité des fonctions elliptiques et des intégrales éulériens,* which was published in the period 1825–1828, Legendre presented what was the state of the theory of elliptical integrals (which he called elliptic functions) at that time, and he also discussed a number of applications in geometry and mechanics. Furthermore, he has given a comprehensive contribution to numerical analysis that leads to practical approximation formulas that could be used to calculate numerical values of various functions, such as the Gamma function and elliptical integrals. In volume 2 of Legendre's work, there are approximately 141 pages with tables calculated with a precision of between 10 and 15 decimals. It thus is an impressive amount of work that has been put into making these tables. Some of the results presented by Legendre in 1825–1828 were previously published by Legendre (1793) and Legendre (1811–1817). In 1825, Legendre proved that elliptic integrals can always be expressed by linear combinations of elementary functions and the following three types of elliptic integrals, namely:

$$\int \frac{dx}{\sqrt{(1-x^2)(1-k^2x^2)}}, \int \frac{(1-k^2x^2)dx}{\sqrt{(1-x^2)(1-k^2x^2)}}, \text{and} \int \frac{dx}{(1-nx^2)\sqrt{(1-x^2)(1-k^2x^2)}}$$

where k and n are constants and $|k| \leq 1$. In Legendre's classification, such integrals are called elliptic integrals of the first, second, and third kind, respectively.

In Chapter 6 of Legendre (1825), a proof is given of the addition theorem established by Euler and Lagrange for elliptic integrals. He shows that Euler's differential equation in (20) with $a = 1$, $b = -(1 + k^2)$, $c = k^2$ and $\varepsilon = -1$ can, by making the substitution $x = \sin \varphi$ and $y = \sin \psi$, the differential equation becomes

$$\frac{d\psi}{\sqrt{1-k^2 \sin^2\psi}} + \frac{d\varphi}{\sqrt{1-k^2 \sin^2\varphi}} = 0. \tag{45}$$

Here, it is understood that ψ is a function of φ. The problem now is to solve (45), that is, to establish the relationship between φ and ψ. By integrating (45), it follows that

$$G(\psi) + G(\varphi) = C \tag{46}$$

where

$$G(\varphi) = \int_0^{\phi} \frac{dv}{\sqrt{1-k^2 \sin^2 v}}$$

and C is a constant. As with Euler, Legendre's proof is based on conjecture about what a solution of (45) might look like. Specifically, Legendre's conjecture was that the relationship between y and q can be expressed by

$$\cos\varphi\cos\psi - \cos\mu = (\sin\varphi\sin\psi)\sqrt{1-k^2\sin^2\mu} \tag{47}$$

where μ is a constant. The equation in (47) is equivalent to each of the equations

$$\cos\psi - \cos\mu\cos\varphi = (\sin\mu\sin\varphi)\sqrt{1-k^2\sin^2\psi} \tag{48}$$

and

$$\cos\varphi - \cos\mu\cos\psi = (\sin\mu\sin\psi)\sqrt{1-k^2\sin^2\varphi}. \tag{49}$$

The simplest way of verifying that (47), (48), and (49) are equivalent is to raise both sides of the equations to the power of 2 and then make suitable rearrangements. By dividing (46) by $\sin\varphi\sin\psi$ and subsequently differentiating with respect to ψ, treating φ as a function of ψ, one gets

$$\frac{1}{\sin\varphi}(\cos\psi - \cos\mu\cos\varphi) + \frac{d\psi/d\varphi}{\sin\psi}(\cos\varphi - \cos\mu\cos\psi) = 0.$$

Moreover, by using (47) and (48), it follows that

$$\frac{d\varphi}{\sin\varphi}\cdot(\sin\mu\sin\varphi)\sqrt{1-k^2\sin^2\psi} + \frac{d\psi}{\sin\psi}\cdot(\sin\mu\sin\psi)\sqrt{1-k^2\sin^2\varphi} = 0$$

which reduces to the differential equation in (45). By letting $\varphi = 0$, it follows from (47) that $\psi(0) = \mu$, implying that $C = G(\mu)$. If one instead considers μ as a function of φ and ψ, determined by (48) and (49), it follows that one can establish addition theorems by solving the equations in (48) and (49) for μ. Specifically, by dividing the equation in (47) by the equation in (48) $\sin\mu$ cancels on the right-hand side and one can solve for $\cos\mu$, which yields

$$\cos\mu = \frac{(\sin\psi\cos\psi)\Lambda(\varphi) - (\sin\varphi\cos\varphi)\Lambda(\psi)}{(\sin\psi\cos\varphi)\Lambda(\varphi) - (\sin\varphi\cos\psi)\Lambda(\psi)} \tag{50}$$

where

$$\Lambda(\varphi) = \sqrt{1-k^2\sin^2\varphi^2}.$$

By multiplying the denominator and numerator of (50) by $(\sin\psi\cos\varphi)\Lambda(\varphi) - (\sin\varphi\cos\psi)\Lambda(\psi)$ and rearranging, we get that

$$\cos\mu = \frac{\cos\varphi\cos\psi - (\sin\varphi\sin\psi)\Lambda(\varphi)\Lambda(\psi)}{1 - k^2\sin^2\varphi\sin^2\psi} \tag{51}$$

Similarly, it is possible to show that

$$\sin\mu = \frac{(\sin\varphi\cos\psi)\Lambda(\psi) + (\sin\psi\cos\varphi)\Lambda(\varphi)}{1 - k^2\sin^2\varphi\sin^2\psi} \tag{52}$$

and

$$tg\mu = \frac{(tg\varphi)\Lambda(\psi) + (tg\psi)\Lambda(\varphi)}{1 - (tg\varphi tg\psi)\Lambda(\varphi)\Lambda(\psi)}. \tag{53}$$

Next, make the change of variable back to the original variables: that is, $\varphi \to x$ and $\psi \to y$, where $\varphi = \arcsin x$ and $\psi = \arcsin y$. Accordingly, $G(\varphi) = H(x)$, $G(\psi) = H(y)$, and $G(\mu) = H(\sin\mu)$, where $H(x)$ is the elliptic integral of the first kind where the integration goes from zero to x. Thus, it is possible to write (46) as $H(x) + H(y) = H(\sin\mu)$. Furthermore, (52) can be expressed as

$$\sin\mu = \frac{x\Delta(y) + y\Delta(x)}{1 - k^2x^2y^2}$$

which is equivalent to the result in (31).

Legendre has also given an alternative proof in which he shows that the relations in (46) to (49) follow from spherical geometry, and more specifically, the relations between the sides of a triangle on the surface of a ball with respective lengths φ, ψ, and μ. In addition to being of independent interest, this proof also provides a good illustration of how problems within spherical geometry lead to elliptic integrals.

4 Abel's Addition Theorem: An Elementary Exposition

When Abel began working on the theory of elliptic integrals, his approach was radically different from previous contributions in this field. His results are not limited to elliptic integrals but also extend to hyperelliptic integrals and the much more general case of Abelian integrals. The next section discusses the addition theorem in the elliptic and hyperelliptic case.

4.1 The Addition Theorem for Elliptic and Hyperelliptic Integrals

Consider an integral of the form given by

$$F(x) = \int_c^x \frac{du}{\sqrt{p(u)}}$$

where $p(u)$ is a polynomial of degree higher than 2 and c is a constant. When the degree of $p(u)$ is equal to 3 or 4, F reduces to an elliptic integral. As discussed above, Euler, Lagrange, and Legendre proved the addition theorem

$$F(x_1) + F(x_2) = F(x_3)$$

where x_3 is a particular algebraic function of (x_1, x_2) where (x_1, x_2) are two arbitrary distinct (real) variables subject to the condition that $p(x_j) > 0, j = 1, 2$. In the general case, $p(x)$ may be negative, have complex roots, and have complex coefficients. It is, however, beyond the scope of this chapter to analyze the complex case. In this section, integrals of the form

$$F(x, a) = \int_c^x \frac{\mu(u)du}{(u-a)\sqrt{p(u)}}$$

will also be treated, where a is a constant smaller than c and $\mu(u)$ is a polynomial such that the degree of $\mu(u)^2$ is less than the degree of $p(u)$.

As will be clear shortly, the method of partial fraction decomposition of rational functions plays a key role in Abel's approach. It was Gottfried Leibniz (1646–1716) and Johann Bernoulli (1667–1748) who, independently, in 1702 discovered the method known as partial fraction decomposition of rational functions, which is stated in Lemma 1 below. Abel was of course familiar with this result.

Lemma 1
(Partial Fraction Decomposition)

Let $A(x)$ and $B(x)$ be polynomials where the degree of $B(x)$ is less than the degree of $A(x)$.

Furthermore, assume that all the roots $x_1, x_2, \ldots, x_K$ of $B(x)$ are distinct and different from the roots of $A(x)$. Then

$$\sum_{j=1}^{K} \frac{A(x_j)}{(x - x_j)B'(x_j)} = \frac{A(x)}{B(x)}. \tag{i}$$

If $B(0) \neq 0$ and $A(x) = xg(x)$, then

$$\sum_{j=1}^{K} \frac{g(x_j)}{B'(x_j)} = 0. \tag{ii}$$

A proof of Lemma 1(i) is given in several mathematical textbooks, see, for example, Miller et al. (1990). The proof of Lemma 1(ii) follows by letting $x = 0$ in (i).

The next theorem is a special case of Abel's general addition theorem.

Theorem 1
Let $f(x)$, $\varphi(x)$, and $p(x)$ be polynomials where the degree of $p(x)$ is greater than 2, let $x_j, j = 1, 2, \ldots, K$ be the roots of the polynomial $f(x)^2 - \varphi(x)^2 p(x)$ and let $\varepsilon_j = \pm 1$ be determined by

$$f(x_j) = \varepsilon_j \varphi(x_j) \sqrt{p(x_j)}.$$

If all the roots $\{x_j\}$ are real, distinct, and different from zero, and $p(x) > 0$ for $x \in [c, \max_j x_j]$, then

$$\sum_{j=1}^{K} \varepsilon_j F(x_j) = C \tag{54}$$

where C is a constant.

As demonstrated below, some of the roots $\{x_j\}$ can be chosen freely, but not all. Note that the roots $\{x_j\}$ must either satisfy $f(x_j) = \varphi(x_j)\sqrt{p(x_j)}$ or $f(x_j) = -\varphi(x_j)\sqrt{p(x_j)}$. The role of ε_j is thus to identify which of these two relations applies. Note also that the degree of the polynomial $p(x)$ can be greater than 4 which means that Theorem 1 holds in the hyperelliptic case. This shows that Abel's result is far more general than the previous contributions by Euler, Lagrange, and Legendre.

A very brief summary of Abel's approach goes as follows. A key step is the introduction of an auxiliary variable z and the change of variable, $u = r_j(z)$, where $r_j(z)$ is a suitable function of z. This change of variable implies that it is possible to express the integrand of the elliptic integral $F(x)$, namely $r'_j(z)/\sqrt{p(r_j(z))}$, as a rational function in $r_j(z)$ where the denominator is the derivative of a specific polynomial of which $r_j(z)$ is a root. Since the root $r_j(z)$ depends on z one or several coefficients of this polynomials must depend on z. Then, by Lemma 1(ii) (providing the conditions of Lemma 1(ii) are met), the sum of the integrands becomes zero, which implies that the sum of the corresponding integrals in (54) becomes a constant. The auxiliary variable z is only needed in the proof and does not have to be included in the statement of Theorem 1.

In the following, the exposition of the proof is broken up in a number of additional Lemmas.

Lemma 2
Let $u = r_j(z), j = 1, 2, \ldots, K$ be differentiable functions such that $x_j = r_j(v)$ where $\{x_j\}$ are given. Then

$$\sum_{j=1}^{K} \varepsilon_j F(x_j) = \sum_{j=1}^{K} \varepsilon_j \int_c^{x_j} \frac{du}{\sqrt{p(u)}} = \int_{v_0}^{v} \xi(z)dz + \widetilde{C} \tag{55}$$

where

$$\xi(z) \equiv \sum_{j=1}^{K} \frac{\varepsilon_j r'_j(z)}{\sqrt{p(r_j(z))}} \tag{56}$$

and $v_0, \widetilde{C}$ are constants.

The proof of Lemma 2 follows readily by the change of variable, $u = r_j(z)$, where the function $r_j(z)$ is unspecified (but differentiable) apart from the condition that $x_j = r_j(v)$. The constant $\widetilde{C}$ is given by

$$\widetilde{C} = \sum_{j=1}^{K} \int_{v_{0,j}}^{v_0} \frac{r'_j(z)dz}{\sqrt{p(r_j(z))}}$$

where $c = r_j(v_{0j})$.

Although the integral on the right side of (55) does not immediately appear to represent a simplification of the original integral, it has the advantage that the original sum of integrals in (54) can be expressed as a single integral.

The next lemma shows that after a suitable choice of the function $\{r_j(z)\}$, one can get rid of the square root in the integrand of the elliptic integral and express $\sqrt{p(r_j(z))}$ as a rational function of $r_j(z)$.

Lemma 3
Let $f(x, z)$ and $\varphi(x, z)$ be polynomials in x of degrees m_1 and m_2, respectively, where at least one of the coefficients of $f(x, z)$ and/or $\phi(x, z)$ depend on a free variable z. If $r_j(z), j = 1, 2, \ldots, K$ are the roots (distinct and real) of the polynomial $\psi(x, z) = f(x, z)^2 - \varphi(x, z)^2 p(x)$ where $K = \max(2m_1, 2m_2 + q)$, then

$$\frac{\varepsilon_j}{\sqrt{p(r_j(z))}} = \frac{\varphi(r_j(z))}{f(r_j(z))}. \tag{57}$$

If q is the degree of $p(x)$, then the first $m_1 + m_2 + 1$ roots of $\psi(x)$ can be chosen freely whereas the remaining $K - m_1 - m_2 - 1 = \max(m_1 - m_2, m_2 - m_1 + q) - 1$ roots become functions of the first $m_1 + m_2 + 1$ roots.

Proof of Lemma 3:

For simplicity, the variable z is suppressed in the proof. Note that (57) is equivalent to $f(r_j)^2 - p(r_j)\varphi(r_j)^2 = 0$ which is equivalent to stating that (57) implies that $\{r_j\}$ are the roots of $\psi(x)$. A key question is which constraints (if any) the roots of the polynomial $\psi(x)$ must satisfy. Let $f = a_0 + a_1 x + \ldots + x^{m_1}$ and $\varphi = b_0 + b_1 x + \ldots b_{m_2} x^{m_2}$ where the coefficient a_{m_1} is normalized such that $a_{m_1} = 1$. Furthermore, (55) implies that

$$a_0 + a_1 r_j + \ldots + r_j^{m_1} = \varepsilon_j \left(b_0 + b_1 r_j + \ldots + b_{m_2} r_j^{m_2} \right) \sqrt{p(r_j)} \tag{58}$$

for $j = 1, 2, \ldots, K$. In (58), there are $m_1 + m_2 + 1$ unknown coefficients, namely the coefficients of the polynomials f and φ. Hence, the proof of Lemma 3 is complete.

In the following, the notation $g'_k(x, z)$ means the partial derivative of the function g with respect to argument k, $k = 1, 2$.

The next lemma is of crucial importance because it shows that after the change of variable and a suitable choice of the functions $\{r_j(z)\}$, it is possible to express the integrand of $F(x)$ as a rational function of $\{r_j(z)\}$ such that Lemma 1 can be applied.

Lemma 4

Letf (x, z) and $\varphi(x, z)$ be polynomials in x where one or several coefficients depend on a free variable z and let $\psi(x, z) = f(x, z)^2 - \varphi(x, z)^2 p(x)$. Then

$$\frac{\varepsilon_j r'_j(z)}{\sqrt{p(r_j(z))}} = \frac{2\theta(r_j(z), z)}{\psi'_1(r_j(z), z)} \tag{59}$$

where

$$\theta(x, z) = -f(x, z)\varphi'_2(x, z) + \varphi(x, z) f'_2(x, z). \tag{60}$$

Proof of Lemma 4:

By differentiating the equation $\psi(r_j(z), z) = 0$ with respect to z, it follows that

$$\psi'_1(r_j(z), z) r'_j(z) + \psi'_2(r_j(z), z) = 0. \tag{61}$$

From (59) and (60), and the fact that Lemma 3 yields

$$p(r_j(z)) = f(r, (z), z)^2 / \varphi(r_j(z), z)^2,$$

it follows that

$$= \frac{2\theta\left(r_j(z),z\right)}{\psi_1'\left(r_j(z),z\right)r_j'(z)} = -\frac{2\theta\left(r_j(z),z\right)}{\psi_2'\left(r_j(z),z\right)}$$

$$= -\frac{2\theta\left(r_j(z),z\right)}{2f\left(r_j(z),z\right)f_2'\left(r_j(z),z\right) - 2p\left(r_j(z)\right)\varphi\left(r_j(z),z\right)\varphi_2'\left(r_j(z),z\right)}$$

$$= \frac{\varphi\left(r_j(z),z\right)f_2'\left(r_j(z),z\right) - f\left(r_j(z),z\right)\varphi_2'\left(r_j(z),z\right)}{f\left(r_j(z),z\right)f_2'\left(r_j(z),z\right) - f\left(r_j(z),z\right)^2\varphi\left(r_j(z),z\right)^{-2}\varphi\left(r_j(z),z\right)\varphi_2'\left(r_j(z),z\right)}$$

$$= \frac{\varphi\left(r_j(z),z\right)}{f\left(r_j(z),z\right)} = \frac{\varepsilon_j}{\sqrt{p\left(r_j(z)\right)}}.$$

Hence, the proof of Lemma 4 is complete.

The results obtained above shows that it is possible to express $\xi(z)$, given in (56), as

$$\xi(z) \equiv \sum_{j=1}^{K} \frac{\varepsilon_j r_j'(z)}{\sqrt{p\left(r_j(z)\right)}} = \sum_{j=1}^{K} \frac{2\theta\left(r_j(z),z\right)}{\psi_1'\left(r_j(z),z\right)}. \tag{62}$$

The right side of (62) is particularly interesting because it has the structure that enables the use of Lemma 1(ii). However, to be able to do so, it must be the case that $\psi(0, z) \neq 0$ which means that zero cannot be a root of $\psi(x, z)$. Furthermore, the degree of $\theta(x, z)$ (as a polynomial in x) must be less than or equal to the degree of $\psi(x, z)$ (as a polynomial in x) minus 2. The next lemma establishes the properties needed for the application of Lemma 1(ii).

Lemma 5
The degree of θ is lower than or equal to the degree of ψ minus 2.

Proof of Lemma 5
Since both $f_2'(x, z)$ and $\phi_2'(x, z)$ do not have constant terms, it follows from (60) that $\theta(0, z) = 0$. Recall that q is the degree of $p(x)$, m_1 the degree of $f(x, z)$, and m_2 the degree of $\varphi(x, z)$ (as polynomials in x). Then the degree of ψ becomes equal to $\max(2m_1, 2m_1 + q)$. For the condition of Lemma 1(ii) to hold the inequality, $\max(2m_1, 2m_2 + q) \geq m_1 + m_2 + 2$ must hold which is equivalent tomax $(m_1 - m_2, q - (m_1 - m_2)) \geq 2$. Since $q \geq 3$, this inequality is evidently fulfilled for all $m_1 - m_2 \leq 0$ and for $m_1 - m_2 \geq 2$. Furthermore, it also holds when $m_1 - m_2 = 1$. This means that the inequality $\max(2m_1, 2m_2 + q) \geq m_1 + m_2 + 2$ holds for all integer values of m_1 and m_2.

Thus, we have proved that (54) also holds in the hyperelliptic case, that is, when $q > 4$. This completes the proof of Lemma 5.

From the Lemmas 1, 2, 3, 4, and 5, it follows that $\xi(z) = 0$. It thus follows from (57) and (59) that

$$\sum_{j=1}^{k} \varepsilon_j F(x_j) = \widetilde{C} + \sum_{j=1}^{K} \varepsilon_j F(c_j) \equiv C.$$

Hence, the proof of Theorem 1 is complete.

Let x_K be a root that corresponds to $\varepsilon_K = -1$. From Theorem 1, the next Corollary follows.

Corollary 1

Assume that the degree of $p(x)$ is equal to 3 or 4. Then

$$F(x_K) = \sum\nolimits_{j=1}^{K-1} \varepsilon_j F(x_j) + C$$

where C is a constant, $\varepsilon_j = \pm 1$ is determined such that $f(x_j) = \varepsilon_j \varphi(x_j)\sqrt{p(x_j)}, j = 1, 2, \ldots, K-1$ and x_K is determined by $f(x_K) + \varphi(x_K)\sqrt{p(x_K)} = 0$.

Next, consider the addition theorem for the integral $F(x, a)$. To this end, the following lemma is needed.

Lemma 6

Let $h_1(z)$ and $h_2(z)$ be two differentiable functions and κ a positive constant. Then

$$\int \frac{(h_2(z)h_1'(z) - h_1(z)h_2'(z))dz}{h_2(z)^2 - h_1(z)^2\kappa} = C + \frac{1}{2\sqrt{\kappa}} \log\left(\left|\frac{h_2(z) + h_1(z)\sqrt{\kappa}}{h_2(z) - h_1(z)\sqrt{\kappa}}\right|\right)$$

where C is a constant.

The proof of Lemma 6 follows immediately by differentiation of the right side of the equation stated in Lemma 6. By means of Lemma 1(i) and Lemma 2, Abel (1828d) used the same approach as in the proof of Theorem 1 to prove the following result.

Theorem 2

Let $f(x)$, $\varphi(x)$, and $p(x)$ be polynomials, let x_j, $j = 1, 2, \ldots, K$, be the roots of the polynomial $f(x)^2 - \varphi(x)^2 p(x)$, with $p(x_j) > 0$, and let $\varepsilon_j = \pm 1$ be determined by $f(x_j) = \varepsilon_j \varphi(x_j)\sqrt{p(x_j)}$. If all the roots $\{x_j\}$ are distinct, real, and different from zero, then

$$\sum_{j=1}^{m} \varepsilon_j F(x_j, a) = C - \frac{\mu(a)}{\sqrt{p(a)}} \log\left(\left|\frac{f(a) + \varphi(a)\sqrt{p(a)}}{f(a) - \varphi(a)\sqrt{p(a)}}\right|\right) \tag{63}$$

where C is a constant.

Proof of Theorem 2

By proceeding in the same way as in the proof of Theorem 1, it turns out that similarly to (59), it is possible to express the integrand of the left side of (63) as

$$\sum_{j=1}^{K} \frac{\varepsilon_j \mu(r_j(z)) r_j'(z)}{(a - r_j(z))\sqrt{p(r_j(z))}} = \sum_{j=1}^{K} \frac{2\mu(r_j(z))\theta(r_j(z), z)}{(a - r_j(z))\psi_1'(r_j(z), z)}. \tag{64}$$

Due to Lemma 1(i), (59), and (60), the right side of (64) equals

$$\frac{2\mu(a)\theta(a,z)}{\psi(a,z)} = 2\mu(a)\left(f(x,z)\varphi_2'(x,z) - \varphi\left(\frac{x,z) f_2'(x,z))dz}{f(a,z)^2 - p(a)\varphi(a,z)^2}.\right.$$

Using Lemma 6, with $\kappa = \sqrt{p(a)}$, $h_2(z) = f(a, z)$, and $h_1(z) = \varphi(a, z)$, we therefore obtain that

$$\int \frac{2\mu(a)\theta(a,z)dz}{\psi(a,z)} = C - \frac{\mu(a)}{\sqrt{p(a)}} \log\left(\left|\frac{f(a,z) + \varphi(a,z)\sqrt{p(a)}}{f(a,z) - \varphi(a,z)\sqrt{p(a)}}\right|\right)$$

from which (63) follows. Note that in Theorem 2, the dependence of the functions f and φ, on the free variable z is suppressed. This completes the proof.

4.2 A More General Version of Abel's Addition Theorem

A great advantage of Abel's approach is that it applies to much more general cases than the ones discussed.

Consider now the addition theorem for Abelian integrals of the form

$$G(x) = \int_c^x \frac{\mu(u)du}{y(u)}$$

where $\mu(x)$ is a polynomial of degree t and $y(x)$ is a root of the equation $Q(y) - p(x) = 0$, where $Q(y)$ is a polynomial of degree m that has constant coefficients and does not contain a constant term. Moreover, $p(x)$ is a polynomial in x with degree q which is equal to or greater than 3. The question to be investigated here is whether one can, similarly to the results obtained in the previous section, write

$$\sum\nolimits_{j=1}^{K} G(x_j) = C \tag{65}$$

where C is a constant and where some of the distinct real numbers $x_1, x_2, \ldots, x_K$ can be chosen freely whereas the remaining numbers are algebraic functions of the former ones. When $Q(y) = y^2$, the problem reduces to the case considered in Sect. 4.1. In the same way as the approach used in Sect. 4.1, one attempts to express $y(r_j(z))$ on the following form

$$y\big(r_j(z)\big) = f\big(r_j(z), z\big)/\varphi\big(r_j(z), z\big) \tag{66}$$

where $r_j(z)$, $j = 1, 2, \ldots, K$, are the roots of a suitable polynomial, $\phi(x, z)$ and $f(x, z)$ are polynomials in x of degrees m_2 and m_1. As above, it is understood that at least one of the coefficients of these polynomial depends on a free variable z. This means that the polynomials φ and f must satisfy the equation

$$p\big(r_j(z)\big) = Q\left(\frac{f\big(r_j(z), z\big)}{\varphi\big(r_j(z), z\big)}\right). \tag{67}$$

Let $\psi(x, z)$ be defined as

$$\psi(x, z) = \varphi(x, z)^m \left(Q\left(\frac{f(x, z)}{\varphi(x, z)}\right) - p(x)\right). \tag{68}$$

Since Q has degree m, $\psi(x, z)$ becomes a polynomial in x. Let $r_j(z)$, $j = 1, 2, \ldots, K$, be the roots of $\psi(x, z)$ where, as above, K is the degree of $\psi(x, z)$ which is given by $K \equiv \max(mm_1, mm_2 + q)$. By differentiation with respect to z and subsequently inserting the root $r_j(z)$ into (68), (67) and (68) imply that

$$\psi_2'\big(r_j(z), z\big) = \varphi\big(r_j(z), z\big)^{m-2} Q'\left(\frac{f\big(r_j(z), z\big)}{\varphi\big(r_j(z), z\big)}\right)\theta\big(r_j(z), z\big) \tag{69}$$

where, as above,

$$\theta(x, z) = \varphi(x, z) f_2'(x, z) - \varphi_2'(x, z) f(x, z).$$

It thus follows from (69) that

$$\frac{r_j'(z)}{y\big(r_j(z)\big)} = r_j'(z)\varphi\big(r_j(z), z\big)/f\big(r_j(z), z\big) = \frac{r_j'(z)\Lambda\big(r_j(z), z\big)}{\psi_2'\big(r_j(z), z\big)} = -\frac{\Lambda\big(r_j(z), z\big)}{\psi_1'\big(r_j(z), z\big)} \tag{70}$$

where

$$\Lambda\left(r_j(z),z\right)=\frac{\varphi\left(r_j(z),z\right)\psi_2'\left(r_j(z),z\right)}{f\left(r_j(z),z\right)}$$
$$=\varphi\left(r_j(z),z\right)^{m-1}Q'\left(\frac{f\left(r_j(z),z\right)}{\varphi\left(r_j(z),z\right)}\right)\theta\left(r_j(z),z\right)/f\left(r_j(z),z\right).$$

Since the polynomial Q does not contain a linear term, $\Lambda(x, z)$ becomes a polynomial in x. Furthermore, it is easily verified that the degree of $\mu(x)\Lambda(x, z)$, which may be denoted by T, is given by

$T = t + m_2 + (m - 1)m_1$. As discussed in Sect. 4.1, one must have that $T \leq K - 2$ in order for Lemma 1 to apply. This requirement implies that t, m_1, and m_2 must satisfy the inequality

$$2 + t + m_2 + (m - 1)m_1 \leq \max\left(mm_1, mm_2 + q\right) \tag{71}$$

for given values $q \geq 3$, $t \geq 0$ and $m \geq 4$. Equation (71) will not always hold, in contrast to the corresponding case analyzed in Sect. 4.1. When (71) holds, then Lemma 1(ii) implies that

$$\sum_{j=1}^{K}\frac{\Lambda\left(r_j(z),z\right)}{\psi_1'\left(r_j(z),z\right)}=0$$

which, according to (70), implies that

$$\sum_{j=1}^{K}\frac{\mu\left(r_j(z)\right)r_j'(z)}{y\left(r_j(z)\right)}=0. \tag{72}$$

In the same way as in the derivation of Theorem 1, we obtain the equation in (65) where $x_1, x_2, \ldots, x_K$ satisfy the equation

$$Q\left(\frac{\mu\left(x_j\right)f\left(x_j\right)}{\varphi\left(x_j\right)}\right)=p\left(x_j\right) \tag{73}$$

for $j = 1, 2, \ldots, K$. Thus, it has been demonstrated that the more general version of Abel's addition theorem, expressed in (65), can be obtained by the same approach as the one applied for the case of elliptic and hyperelliptic integrals. It is, however, beyond the scope of this chapter to investigate how many of the roots $x_1, x_2, \ldots, x_K$ can be chosen freely and how the remaining roots depend on the polynomials Q and p.

The version of the addition theorem discussed in this section is, however, only a special case of Abel's most general version of his theorem.

4.3 Abel's Addition Theorem in Its Most General Form

A summary of Abel's addition theorem in its most general form will be presented in this section, but without going through the proof. Let $y = y(x)$ be the algebraic function determined by

$$Q(x, y) = 0 \tag{74}$$

where $Q(x, y)$ is a polynomial in y of degree n with coefficients that are polynomials in x. Furthermore, let

$$V(x, y) = r_0(x) + r_1(x)y + \ldots + r_{n-1}(x)y^{n-1}$$

be another polynomial in y of degree $n - 1$ where the coefficients $\{r_j(x)\}$ are polynomials in x and let $\{\beta_k\}$ denote the coefficients of $\{r_j(x)\}$. Assume that

$$V(x, y) = 0. \tag{75}$$

When both (74) and (75) hold, y can be eliminated and it follows that x must satisfy an equation $\rho(x) = 0$ (say) where $\rho(x)$ is a polynomial in x of degree K with constant coefficients.

Theorem 3 *Let $x_j, j = 1, 2. \ldots, K$, be the roots of $\rho(x)$ and define*

$$M(x) = \int_0^x R(u, y(u))du$$

where $R(x, y)$ is a rational function in (x, y). Then

$$\sum_{j=1}^{\mu} M(x_j) = v_0 + \sum_{j=1}^{\eta} c_j \log w_j$$

where $\{w_j\}$ are rational functions of $\{\beta_s\}$ and $\{c_j\}$ are constants.

When $Q(x, y) = Q(y) - p(x)$ where $Q(y)$ is a polynomial in y with constant coefficients, $p(x)$ is a polynomial in x with constant coefficients and $R(x, y) = \mu(x)/y$, then Theorem 3 reduces to the result discussed in Sect. 4.2.

The proof of Theorem 3 is given in the article "Mémoire sur une propriété générale d'une classe très étendue des fonctions transcendantes" (Abel 1841). An extremely compact version of the proof is given in the article "Démonstration d'une propriété général d'une certaine classe de fonctions transcendantes" (Abel 1829b).

4.4 Elliptic Integrals and Multiplication

From trigonometry, it is well known that $\sin(my)$ can be expressed as a function of $\sin(y)$ by a simple algebraic formula where m is a natural number. Abel proved that similar formulas hold for elliptic integrals. As reviewed above, Fagnano obtained multiplication formulas, such as the one given in (17).

He also considered cases of complex multiplication, see Ayoub (1984).

Let $H(x)$ denote the elliptic integral of the first kind, namely

$$H(x) = \int_0^x \frac{du}{\Delta(u)}$$

where $\Delta(u) = \sqrt{(1-u^2)(1-k^2u^2)}$, and k is a real constant, $|k| < 1$. In the addition theorems above the roots $\{x_f\}$ were assumed to be distinct. However, by letting $x_1 \to x_2$, (say) it becomes clear that the corresponding limiting version of Theorem 1 will hold when two or several roots are equal, because the functions involved are continuous.

Corollary 2
Let $m > 1$ be an integer. Then

$$mH(x) = H(y)$$

where the relation between x and y is determined by

$$f(u)^2 - \varphi(u)^2\Delta(u)^2 = \left(u^2 - x^2\right)^m\left(u^2 - y^2\right). \tag{76}$$

One can determine the coefficients in the polynomial on the left-hand side of (76) and subsequently determine y as function of x. However, Abel used an alternative approach that is considerably simpler (Abel 1929a, pp. 256–258).

Corollary 3
Let g_m be defined by

$$H(g_m(x)) = mH(x).$$

Then g_m is given recursively by

$$g_{m+1}(x) = -g_{m-1}(x) + \frac{2g_m(x)\Delta(x)}{1 - k^2x^2g_m(x)^2}, \tag{77}$$

$$g_{2m-1}(x) = \frac{g_m(x)^2 - g_{m-1}(x)^2}{x\left(1 - k^2 g_m(x)^2 g_{m-1}(x)^2\right)} \tag{78}$$

and

$$g_{2m}(x) = \frac{2g_m(x)\Delta(g_m(x))}{1 - k^2 g_m(x)^4} \tag{79}$$

where $g_0(x) = 0$, $g_1(x) = x$. *The function* g_m *is rational when* m *is odd and has the form* $\xi(x)\Delta(x)$ *when* m *is even, where* $\xi(x)$ *is rational.*

Proof of Corollary 3

From Corollary 2, it follows, for natural numbers m and r that

$$H\left(g_{m+r}\right) = (m+r)H(x) = mH(x) + rH(x) = H(g_m) + H(g_r)$$

which implies that

$$H\left(g_{m+r}\right) = H(g_m) + H(g_r). \tag{80}$$

From (80) and the addition theorem, it follows that

$$g_{m+r} = \frac{g_m\Delta(g_r) + g_r\Delta(g_m)}{1 - k^2 g_r^2 g_m^2} \tag{81}$$

Note furthermore that $H(-x) = -H(x)$. From (80), it also follows that

$$H(g_m) = H(g_{m-r}) + H(g_r)$$

which is equivalent to

$$H(g_{m-r}) = H(g_m) - H(g_r) = H(g_m) + H(-g_r). \tag{82}$$

Hence, (81) and (82), with g_r replaced by $-g_r$, yields

$$g_{m-r} = \frac{g_m\Delta(g_r) - g_r\Delta(g_m)}{1 - k^2 g_r^2 g_m^2} \tag{83}$$

for $m > r$. By letting $r = 1$ in (82) and (86), one obtains

$$g_{m+1} = \frac{g_m\Delta(x) + x\Delta(g_m)}{1 - k^2 x^2 g_m^2} \tag{84}$$

and

$$g_{m-1} = \frac{g_m \Delta(x) - x\Delta(g_m)}{1 - k^2 x^2 g_m^2}. \tag{85}$$

When adding together the expressions in (84) and (85), the following recursion formula for $\{g_m\}$ is obtained, namely

$$g_{m+1} = -g_{m-1} + \frac{2g_m \Delta(x)}{1 - k^2 x^2 g_m^2}. \tag{86}$$

By calculating $g_2, g_3, \ldots$, it becomes clear that g_m is rational when m is odd and has the form $\xi(x)\Delta(x)$ when m is even, where $\xi(x)$ is rational. Furthermore, by multiplying the expressions in (81) and (85), one obtains

$$g_{m+r} g_{m-r} = \frac{g_m^2 - g_r^2}{1 - k^2 g_m^2 g_r^2}. \tag{87}$$

By letting $r = m - 1$ in (85), one gets $g_{m-r} = g_1 = x$, so that (87) gives

$$g_{2m-1} = \frac{g_m^2 - g_{m-1}^2}{x\left(1 - k^2 g_m^2 g_{m-1}^2\right)}.$$

Furthermore, by letting $r = m$ in (81) follows, due to $g_1 = x$, that

$$g_{2m} = \frac{2g_m \Delta(g_m)}{1 - k^2 g_m^4}.$$

Hence, the proof is complete.

4.5 Examples

To fix ideas, we shall discuss a few examples on elliptic and hyperelliptic integrals in this section.

Example 4.5.1
Let $f(x) = bx + x^3$, $\varphi(x) = d$, and $p(x) = 1 + \gamma_1 x^2 + \gamma_2 x^4 + \gamma_3 x^6$, where a, γ_1, γ_2, γ_3, b, and d are constants. The results achieved in Sect. 4.1 and 4.2 will now be applied to work out the details of the addition theorem for the hyperelliptic integral

$$F(x) = \int_0^x \frac{du}{\sqrt{p(u)}}.$$

Notice that $f(x)^2 - \varphi(x)^2 p(x)$ is of degree 6 implying that this polynomial has 6 roots. Note also that this polynomial contains solely odd powers so that it is a cubic

polynomial in x^2. According to Theorem 1, the roots of $\psi(x)$ are determined by the equations

$$f(x_j) - \varepsilon_j \varphi(x_j)\sqrt{p(x_j)} = bx_j + x_j^3 - \varepsilon_j d\sqrt{p(x_j)} = 0, \tag{88}$$

$j = 1, 2, \ldots, 6$, and these equations link the given polynomial $p(x)$, the roots $x_j, j = 1, 2, \ldots, 6$, and the coefficients b and d together. With no loss of generality, let $\varepsilon_1 = \varepsilon_2 = \varepsilon_6 = 1$ and $\varepsilon_3 = \varepsilon_4 = \varepsilon_5 = -1$. Moreover, since the roots are determined by three equations in x^2, we can put $x_4 = -x_1, x_5 = -x_2$, and $x_6 = -x_3$. Let x_1 and x_2 be given values. From (88) for $j = 1, 2$, it follows that b and d are determined by

$$b = b(x_1, x_2) = \frac{x_1^3\sqrt{p(x_2)} - x_2^3\sqrt{p(x_1)}}{x_2\sqrt{p(x_1)} - x_1\sqrt{p(x_2)}} \tag{89}$$

and

$$d = d(x_1, x_2) = \frac{x_2x_1^3 - x_1x_2^3}{x_2\sqrt{p(x_1)} - x_1\sqrt{p(x_2)}}. \tag{90}$$

From (88) and (89) and (90), it follows that the root x_3 is determined by the equation

$$b(x_1, x_2)x_3 + x_3^3 = -d(x_1, x_2)\sqrt{p(x_3)}$$

where it is understood that the expressions for b and d given in (90) and (91) are inserted. Consider next how to obtain a simplified explicit formula for x_3 as a function of x_1 and x_2. Specifically, an alternative way to determine x_3 is to use that the constant term of the polynomial $f(x)^2 - \varphi(x)^2p(x)$ equals the product of the roots of the polynomial. Since the products of the roots equals $x_1x_2x_3x_4x_5x_6 = -(x_1x_2x_3)^2$ and the constant term of the polynomial is equal to d^2, it follows that

$$x_3 = \frac{d(x_1, x_2)}{x_1x_2} = \frac{x_1^2 - x_2^2}{x_1\sqrt{p(x_2)} - x_2\sqrt{p(x_1)}} = \frac{x_1\sqrt{p(x_2)} + x_2\sqrt{p(x_1)}}{1 - \gamma_2x_1^2x_2^2 - \gamma_3x_1^2x_2^2(x_1^2 + x_2^2)}. \tag{91}$$

The third equality in (91) follows by multiplying the numerator and the denominator of the expression in the middle above by $x_1\sqrt{p(x_2)} + x_2\sqrt{p(x_1)}$. By making the change of variable $u \to -w$ yields that $F(-x) = -F(x)$. Hence, the addition theorem implies that

$$C = \sum_{j=1}^{6} \varepsilon_j F(x_j) = F(x_1) + F(x_2) - F(x_3) - F(x_4) - F(x_5) + F(x_6). \tag{92}$$

The constant C becomes equal to zero due to the property that $F(0) = 0$. Hence, from (92) it follows that

$$\begin{aligned} 0 &= F(x_1) + F(x_2) - F(x_3) - F(x_4) - F(x_5) + F(x_6) \\ &= F(x_1) + F(x_2) - F(x_3) - F(-x_1) - F(-x_2) + F(-x_3) \\ &= 2F(x_1) + 2F(x_2) - 2F(x_3) \end{aligned}$$

which yields

$$F(x_1) + F(x_2) = F(x_3) \tag{93}$$

where x_3 is given by (92). By letting $x_1 = x_2 = x$ and $y = x_3$, it follows from (91) by using l'Hopital's rule and (93) that if y is given by

$$y = \frac{2x\sqrt{p(x)}}{1 - \gamma_2 x^4 - 2\gamma_3 x^6}.$$

and

$$F(y) = 2F(x).$$

Example 4.5.2
When $\gamma_1 = -1 - k^2$, $\gamma_2 = k^2$, and $\gamma_3 = 0$, it follows that $p(x) = (1 - x^2)(1 - k^2x^2)$ where k is a constant, $|k| < 1$, and $F(x)$ becomes an elliptic integral of the first kind. In this case, the equation in (91) reduces to

$$x_3 = \frac{x_1\sqrt{p(x_2)} + x_2\sqrt{p(x_1)}}{1 - k^2x_1^2x_2^2}$$

which, combined with (93), yields the addition theorem for elliptic integrals of the first kind.

Example 4.5.3
This example is a slightly modified version of the example discussed in a letter Abel wrote on 6 August 1826 to August Leopold Crelle (1780–1855), editor and founder of the *Journal für die reine und angewandte Mathematik*, see Abel (2012). In this letter, Abel mentions an application of his addition theorem to the hyperelliptic integral

$$F(x) = \int_b^x \frac{du}{\sqrt{p(u)}}$$

where $p(x) = a + a_1x + a_2x^2 + a_3x^3 + a_4x^4 + a_5x^5 + x^6$ and $a, a_1, \ldots, a_5$ are given numbers such that $p(x)$ is positive on a suitable set. Thus, the integral above is a hyperelliptic integral. However, Abel provides no details in his letter of how he achieved his results; this task is left to the reader. Here, a proof is provided of the assertion put forward in Abel's letter by applying the addition theorem.

Let

$$\begin{aligned}\psi(x) &= \left(c + c_1x + c_2x^2 + x^3\right)^2 - p(x)\\ &= c^2 - a + (2cc_1 - a_1)x + \left(c_1^2 + 2cc_2 - a_2\right)x^2 + (2c + 2c_1c_2 - a_3)x^3\\ &\quad + \left(2c_1 + c_2^2 - a_4\right)x^4 + (2c_2 - a_5)x^5 \end{aligned} \tag{94}$$

where c, c_1, and c_2 are free coefficients (variables). From this it follows that $\psi(x)$ has only five roots ($K = 5$) because the term x^6 cancels. Let x_1, x_2, x_3, y_1, and y_2 denote the roots of $\psi(x)$. As in the examples given above, the free coefficients c, c_1, and c_2 can be expressed as functions of x_1, x_2, and x_3 by solving the equations $\psi(x_j) = 0$, for $j = 1, 2, 3$, which implies that the free coefficients must satisfy the linear equations

$$c + c_1x_j + c_2x_j^2 = \sqrt{p(x_j)} - x_j^3$$

for $j = 1, 2, 3$. The remaining roots y_1 and y_2 are not free variables but determined by $\psi(y_j) = 0$ for $j = 1, 2$, after the coefficients c, c_1, and c_2 have been determined as functions of x_1, x_2, and x_3. From (94) it follows by using the relationship between roots and coefficients in a polynomial that

$y_1 + y_2 = \frac{2c_1 + c_2^2 - a_4}{a_5 - 2c_2} - x_1 - x_2 - x_3$ and $y_1y_2 = \frac{c^2 - a}{(a_5 - 2c_2)x_1x_2x_3}$ which imply that y_1 and y_2 are roots of the equation

$$y^2 - \left(\frac{2c_1 + c_2^2 - a_4}{a_5 - 2c_2} - x_1 - x_2 - x_3\right)y + \frac{c^2 - a}{(a_5 - 2c_2)x_1x_2x_3} = 0. \tag{95}$$

Hence y_1 and y_2 can be determined by solving the quadratic equation in (95). As a result, Theorem 1 gives

$$F(x_1) + F(x_2) + F(x_3) = C - F(y_1) - F(y_2)$$

where C is a constant. Thus, the claim expressed in Abel's letter is verified.

Recall that in the hyperelliptic case where $p(x)$ has degree q, $q \geq 5$, it is, in contrast to the elliptic case, not generally possible to specify $K - 1$ independent roots with the K-th root being an algebraic function of the independent roots, as we have seen in the current example. However, in special cases of hyperelliptic integrals, such as in Example 4.5.1, it is still possible to obtain a similar addition theorem as in the case with elliptic integrals.

Example 4.5.4
Let $Q(y) = y^3, f(x) = b + x, \varphi(x) = d, \mu(x) = 1$, and $p(x) = 1 + \alpha x^2 + \beta x^4$. Consider the Abelian integral

$$L(x) = \int_c^x \frac{du}{\sqrt[3]{p(u)}}.$$

Note that $L(x)$ is not an elliptic integral because the integrand contains the cubic root of a polynomial $p(x)$. In this case

$$\psi(x) = f(x)^3 - \varphi(x)^3 p(x) \tag{96}$$

which is a polynomial of degree 4. In this case, $K = 4$ and $T = 2$ so that (71) is fulfilled. From (73), it follows that the roots must satisfy the equation

$$b + x_j = d\sqrt[3]{p(x_j)} \tag{97}$$

for $j = 1, 2, 3, 4$. From (97), it follows that the coefficients b and d are determined by

$$b = b(x_1, x_2) = \frac{x_1\sqrt[3]{p(x_2)} - x_2\sqrt[3]{p(x_1)}}{\sqrt[3]{p(x_1)} - \sqrt[3]{p(x_2)}} \text{ and } d = d(x_1, x_2)$$
$$= \frac{x_1 - x_2}{\sqrt[3]{p(x_1)} - \sqrt[3]{p(x_2)}}. \tag{98}$$

Moreover, the constant term in the polynomial $-\psi(x)/\beta d^3$ turns out to be equal to $(d(x_1, x_2)^3 - b(x_1, x_2)^3)/\beta d(x_1, x_2)^3$ and the coefficient associated with the x^3 is equal to $-1/\beta d(x_1, x_2)^3$.

By utilizing the relationship between the roots and the coefficients of a polynomial, it follows that $x_3 + x_4 = \frac{1}{\beta d(x_1,x_2)^3} - x_1 - x_2$ and $x_3 x_4 = \frac{d(x_1,x_2)^3 - b(x_1,x_2)^3}{x_1 x_2 \beta d(x_1,x_2)^3}$ which implies that x_3 and x_4 are functions of (x_1, x_2), and they are determined by the quadratic equation

$$x_j^2 + \left(x_1 + x_2 - 1/\beta d(x_1, x_2)^3\right)x_j - \frac{b(x_1, x_2)^3 - d(x_1, x_2)^3}{x_1 x_2 \beta d(x_1, x_2)^3} = 0 \tag{99}$$

for $j = 3, 4$, where b and d are given in (98). Consequently, the following addition theorem

$$\sum_{j=1}^{4} L(x_j) = C$$

has been established where C is a constant and the roots x_1 and x_2 can be selected freely whereas the remaining two roots x_3 and x_4 are determined by (99). Consider next the special case where $x_1 = x_2 = x$. To examine this case, it is convenient to let $x_1 \to x_2$ in the formulas in (98) and then apply l'Hopital's rule. Hence $b(x,x) = \frac{3+\alpha x^2-\beta x^4}{2\alpha x+4\beta x^3}$ and $d(x,x) = \frac{3p(x)^{2/3}}{2\alpha x+4\beta x^3}$.

Furthermore, (99) implies that x_3 and x_4 are given by the roots of the quadratic polynomial

$$x_j^2 + \left(2x - 1/\beta d(x,x)^3\right)x_j - \frac{b(x,x)^3 - d(x,x)^3}{x^2\beta d(x,x)^3} = 0$$

for $j = 3, 4$.

Example 4.5.5
From Corollary 3 with $m = 2$ and $m = 3$, respectively, it follows that

$$H(y_2) = 2H(x) \text{ and } H(y_3) = 3H(x)$$

where

$$y_2 = \frac{2x\Delta(x)}{1-k^2x^4} \text{ and } y_3 = \frac{3x - \left(4+4k^2\right)x^2 + 6k^2x^5 - k^4x^9}{1 - 6k^2x^4 + 4k^2\left(1+k^2\right)x^6 - 3k^4x^8}.$$

5 A Short Review of Abel's Work on Elliptic Integrals and the Addition Theorem

Several biographers have written about Niels Henrik Abel: see, for example, Ore (1957), Stubhaug (2000), and Sørensen (2004). Sørensen (2004) also provides an overview of the state of mathematics at the turn of the eighteenth century. Here, a brief review of selected parts of Abel's life and work is provided which have relevance to his contribution to the theory of elliptic integrals and elliptic functions.

Abel's life was short and dramatic. He was born in 1802 near the town of Stavanger in Norway. In 1804, his father was appointed pastor at Gjerstad, near the town of Risør, and the family moved there. In 1815, he entered the Cathedral School in Christiania at the age of 13. (Oslo was called Christiania at that time). A new mathematics teacher, Bernt Michael Holmboe (1795–1850), was appointed in 1818 and he set the students' mathematical tasks to do at home. He quickly became aware of Abel's talent and encouraged him to study mathematics at an advanced level. Abel entered the university in Christiania in 1821. At that time, he was already the foremost mathematician in Norway. He had studied all the latest mathematical literature in the university library and had also started work on his own mathematical

problems, such as the solution to the general quintic equation in radicals. In a letter dated 21 May 1821 from Carl Ferdinand Degen (1766–1825), professor of mathematics at the University of Copenhagen to Christopher Hansteen (1784–1873), professor of astronomy and geophysics at the University of Christiania, the content of which was made known to Abel, Degen wrote that such a talented young manas Abel should devote himself to the theory of "elliptic transcendents" (elliptic integrals), adding that he would "discover Magellanian thoroughfares to large portions of a vast analytical ocean." This almost prophetic statement might well have been influential for the direction of Abel's work.

From 1823 to 1826, Abel wrote three papers where one was published in 1826 in *Magazin for Naturvidenskaberne* (Journal of the Natural Sciences), Norway's first scientific journal, which had been co-founded by Hansteen at the University of Christiania. This paper was later translated into French and published in Abel (2012a). The two other papers where not published before Abel's death (Abel 2012b, c). In the summer of 1823, he was awarded a scholarship that allowed him to make his first trip abroad, to Copenhagen. From the letters he wrote to his former teacher Holmboe, it is clear that he had started to work on the theory of elliptic integrals and had already achieved new results. It would appear that the article "Petite contribution à la théorie de quelques fonctions transcendantes"(Abel 2012a) is the first article he published that, among other topics, concerns elliptic and hyperelliptic integrals. In a letter to Degen dated 2 March 1824, Abel writes about the progress he has made since the last time they met in Copenhagen, in the summer of 1823. From this letter and a paper that Abel wrote a short time afterwards, it seems that he had already by that time formulated the most general version of his addition theorem (Skau 2011).

In his article "Petite contribution à la théorie de quelques fonctions transcendantes" (2012a), Abel starts by discussing the integral

$$\int \frac{\varphi(x)\exp(\ f(x))dx}{x-a}$$

where a is a constant, $f(x)$ is a rational function, and $\varphi(x)$ has the form

$$\varphi(x) = \kappa(x+\alpha_1)^{\beta_1}(x+\alpha_2)^{\beta_2}\cdot\cdot(x+\alpha_r)^{\beta_r},$$

where $\alpha_1, \alpha_2, \ldots, \beta_1, \beta_2, \ldots, \boldsymbol{\kappa}$, are given coefficients and neither of the functions f and φ depends on a. By ingenious manipulations, including suitable operations (differentiation and integration), Abel obtains a set of surprising equations that can be applied to produce a number of amazing results. For example, when $p(x) = \gamma_0 + \gamma_1 x + \cdots + \gamma_s x^s$, where $\gamma_1, \gamma_2, \ldots$ are given coefficients and s is an integer, he obtains as a special case

$$\int \frac{dx}{(x-a)\sqrt{p(x)}} = \frac{1}{2\sqrt{p(a)}}\sum_n\sum_m (m-n)\gamma_{n+m+2}\int \frac{a^m da}{\sqrt{p(a)}}\cdot\int \frac{x^n dx}{\sqrt{p(x)}} \qquad (100)$$

for s greater than 2 and x being a root of p. Consider, for example, the case where $p(x) = (1 - x^2)(1 - k^2x^2) = \Delta(x)^2$. Then $\gamma_0 = 1$, $\gamma_1 = \gamma_3 = 0$, $\gamma_2 = -1 - k^2$ and $\gamma_4 = k^2$, which by (100) yields

$$\int \frac{dx}{(x-a)\Delta(x)} = \frac{k^2}{2\Delta(a)} \int \frac{da}{\Delta(a)} \cdot \int \frac{x^2 dx}{\Delta(x)} - \frac{k^2}{2\Delta(a)} \int \frac{a^2 da}{\Delta(a)} \cdot \int \frac{dx}{\Delta(x)}. \tag{101}$$

Since

$$\int \frac{dx}{(x^2 - a^2)\Delta(x)} = \int \frac{dx}{2a(x-a)\Delta(x)} - \int \frac{dx}{2a(x+a)\Delta(x)},$$

it follows immediately from (101) (by successively changing the sign of a) that

$$\int \frac{dx}{(x^2 - a^2)\Delta(x)} = \frac{k^2}{2a\Delta(a)} \int \frac{da}{\Delta(a)} \cdot \int \frac{x^2 dx}{\Delta(x)} - \frac{k^2}{2a\Delta(a)} \int \frac{a^2 da}{\Delta(a)} \cdot \int \frac{dx}{\Delta(x)}. \tag{102}$$

The equation in (102) shows that Legendre's elliptic integral of the third kind can be expressed in a simple way by elliptic integrals of the first and second kind when x is a root of p.

In 1825, Abel was awarded a second scholarship to travel abroad. The plan was to visit Carl Friedrich Gauss (1777–1855) in Gottingen and then continue on to Paris, which at that time was the leading center for mathematics. He initially intended to travel with four of his friends. However, when he got as far as Copenhagen, he changed his mind, following his friends to Berlin instead, having decided to visit Gauss and go on to Paris afterwards. For some unknown reason, though, he never met with Gauss. On the way, he visited the astronomer Heinrich Christian Schumacher (1780–1850) in Altona, now a district of Hamburg. Schumacher was at that time the editor of *Astronomische Nachrichten*, where Abel and Jacobi published important papers. He then spent 4 months in Berlin, where he became well acquainted with August Leopold Crelle (1780–1885). Crelle was about to establish a new mathematical journal, *Journal für die reine und angewandte Mathematik*, which would become very important for the dissemination of Abel's work. Crelle also became a close personal friend. In the journal's first year, Abel contributed seven articles. However, he saved what he regarded as his most important work, the Paris memoir, for the French Academy of Sciences.

Abel revolutionized the theory of elliptic integrals by proposing to study elliptic functions instead of elliptic integrals. The elliptic functions may be defined as the inverse of corresponding elliptic integrals. More precisely, let

$$H(x,k) = \int_0^x \frac{du}{\sqrt{(1-u^2)(1-k^2u^2)}} \tag{103}$$

denote the elliptic integral of the first kind with k as parameter. Then the corresponding elliptic function, say $g(y, k)$, is defined as the inverse of the integral $H(x, k)$: that is $H(g(y, k), k) = y$ for $y \in [0, 1]$. The elliptic functions can be viewed as a generalization of the trigonometric functions. To realize this, note that when $k = 0$, then $H(x, 0)$ reduces to arcsin$x$. The so-called Jacobian elliptic functions were introduced by Jacobi and the notation *sny*, *cny*, *dny*, and *tny* proposed by Christoph Gudermann (1798–1852) is nowadays common for elliptic functions. Specifically, $sny = g(y, k)$, $cn^2y = 1 - sn^2y$, $dn^2y = 1 - k^2sn^2y$, and $tny = sny/cny$. When $k = 0$, *sny*, cny, and *tny* reduce to the trigonometric functions sin$y$, cos$y$, and tg$y$, respectively. An addition theorem for elliptic functions that is dual to Euler and Legendre's addition theorem for elliptic integrals can be expressed as

$$sn(y + v) = \frac{snycnvdnv + snvcnydny}{1 - k^2sn^2ysn^2v}.$$

Note that $sn(y + v)$ reduces to the usual addition formula for $\sin(y + v)$ when $k = 0$.

Another area in which fierce competition between Abel and Jacobi took place was the theory of transformations. This theory includes the study of solutions (transformations) $\omega(x)$, say, satisfying

$$H(\omega(x), k) = bH(x, k') + C$$

where H is given in (103), k and k' are the respective parameters, which may be equal or different, and b and C are constants. The transformation omega(x) will of course depend on b, k, and k', but this is suppressed in the notation here. Note that Corollaries 2 and 3 can be viewed as part of the theory of transformations in the case where $k = k'$. See Stubhaug (2000) and Sørensen (2004) for more details about the rivalry between Abel and Jacobi.

In Paris, Abel continued his work on his memoir, which he finished in October 1826 and submitted to the academy on 30 October. It was to be reviewed by Augustin-Louis Cauchy (1789–1857) and Legendre. Unfortunately, the Paris memoir, regarded as Abel's masterpiece, was put aside among Cauchy's papers and forgotten. In early 1827, Abel returned to Berlin, where he stayed several months before returning to Norway. In Berlin, he completed an extensive paper which was published in two parts (Abel 1827, 1828a). In it he does not, however, apply his addition theorem but rather the one established by Euler and Legendre. In this paper, Abel develops the theory of elliptic functions and obtains many new results, and he also discusses the theory of transformations and complex multiplication. He also considered ways to solve for *sny* when $sn(my)$ is given, where m is an integer. As an example of multiplication of elliptic functions, one can show that

$$sn(3y) = \frac{3sny - \left(4 + 4k^2\right)sn^2y + 6k^2sn^5y - k^4sn^9y}{1 - 6k^2sn^4y + 4k^2\left(1 + k^2\right)sn^6y - 3k^4sn^8y}.$$

The continuation of the article "Recherches sur les fonctions elliptiques" (Abel 1827) was finished and published in the following year (Abel 1828a). By May 1827, Abel was back in Norway. Jacobi wrote a paper on the theory of transformations of elliptic integrals in which he also studies elliptic functions (Jacobi 1827). Although Abel (1827) had discussed the general theory of transformation and the properties of elliptic functions, and his paper had been published several months before Jacobi sent his paper to the journal, Jacobi (1827) did not publicly refer to the work of Abel. Therefore, Abel wrote a second paper and then a third one with special emphasis on the theory of transformations (Abel 1828b, 1828c). In 1828, he published a paper (Abel 1828d) in which he demonstrates his addition theorem for hyperelliptic integrals by applying the ideas from his Paris memoir (Abel 1841). Subsequently, he wrote another and very long paper (Abel 1829a) in which he presented his addition theorem, the elliptic functions, and the theory of transformations in a way that differed from his earlier work. Due to a combination of unfortunate circumstances (Stubhaug 2000), the Paris memoir was not published before 1841, 12 years after Abel's early death from tuberculosis. In the last paper Abel wrote before he died (Abel 1829b), on 6 April 1829, he gave a very compact proof of the addition theorem in its most general form (presented in Sect. 4.3), upon which his Paris memoir is based. It consists of only two pages, the first containing the statement of the theorem and the second containing the proof.

The French mathematician Emile Picard (1856–1941) wrote the following about Abel's theorem at the end of the nineteenth century: "*Le théorème parait tout à fait élémentaire, et il n'y a peut-etre pas, dans l 'histoire de la Science, de proposition aussi importante obtenue á l 'aide de considérations aussi simples*" ("The theorem appears utterly elementary, and perhaps there has never been in the history of science a proposition so important which can be reached by such simple considerations.") The Norwegian mathematician Atle Selberg (1917–2007) wrote in 2002: "*Det har alltid stått for meg som den rene magi. Hverken Gauss eller Riemann, eller noen annen, har noe som riktig kan måle seg meddette.*" ("For me this has always appeared as pure magic. Neither Gauss nor Riemann nor anyone else have anything that really measures up to this.")

After Abel's death, Jacobi's book on elliptic integrals and functions (Jacobi 1829) was published. It became a key reference for mathematicians working on the theory of elliptic integrals and functions in the following years. However, it was later criticized for making insufficient reference to Abel's work.

After Abel had published some of his groundbreaking articles, it became known that Gauss had also been working on the theory of elliptic integrals and functions and that as early as in 1798 he had achieved some of the same results as Abel (Sørensen 2004). However, Gauss never published his results and thus the mathematical community had no knowledge of his work before the publication of Abel's articles.

Whereas Abel's theory solves the problem of defining and analyzing the properties of elliptic functions (and more generally abelian functions) with elementary means, it does not immediately extend to the complex field, such as in the case where the polynomial $p(x)$ in Theorems 1 and 2 is negative, has complex roots or has

complex coefficients. Still there is no essential difference between the functions which correspond to real and to complex values of the coefficients and constants. It became the fate of Karl Theodor Wilhelm Weierstrass (1815–1897) to remedy this deficiency and provide a rigorous foundation of Abel's theory, outlined in Weierstrass (1856). Unfortunately, the theory then loses its elementary character.

6 Conclusion

To learn about ideas and approaches in mathematics is a highly demanding task for the nonspecialist. Often the background knowledge necessary of an understanding beyond a fragmentary and superficial level is formidable. However, as regard the development of the theory of elliptic integrals and functions some 200 years ago, it is possible to understand key results, including proofs, solely with background in elementary calculus, as demonstrated in this chapter. As noted above, Abel's approach was fundamentally different from earlier contributions, and, as has been mentioned by many mathematicians in the past, it is astonishing that such important results can be achieved by such simple means. Abel's approach is so powerful that it extends to the case hyperelliptic integrals of any degree and more generally to Abelian integrals and functions. Abel's work in this field inspired a great number of mathematicians in the years that followed and eventually led to Riemann and Weierstrass developing the theory of algebraic functions and algebraic curves further.

Abstract

In a number of works, we have suggested that whereas the ordered field **R** of real numbers should merely be regarded as constituting an *arithmetic continuum (modulo the Archimedean axiom)*, the ordered field **No** of *surreal numbers* may be regarded as a sort of *absolute arithmetic continuum (modulo NBG)*. In the present chapter, as part of a more general exposition of the absolute arithmetic

continuum, we will outline some of the properties of the system of surreal numbers that we believe lend credence to this mathematico-philosophical thesis. We will also provide an overview of **No**'s rich structure as a *simplicity-hierarchical (*or *s-hierarchical) ordered field* that recursively emerges from the interplay between its structure as an ordered field and its structure as a *lexicographically ordered full binary tree*. Finally, we will draw attention to how properties of the system of surreal numbers considered as an s-hierarchical ordered algebraic structure can be appealed to in conjunction with classical relations between ordered algebraic and geometric systems to help resolve, for the surreal case, one of the purported difficulties that lies at the heart of attempts to bridge the gap between the domains of number and of geometrical magnitude. In particular, we will explain how it is possible that despite the fact that every surreal number, considered as a member of an s-hierarchical ordered field, differs from every other in characteristic individual properties, the *absolute (Euclidean) geometrical continuum*, which is modeled by the Cartesian space over the ordered field **No** of surreal numbers, appears as an amorphous pulp of points that display little individuality.

Keywords

Absolute Arithmetic Continuum · Absolute Geometric Continua · Surreal Numbers · Non-Archimedean Continua · Non-Archimedean ordered algebraic systems

1 Introduction

Since the discovery that a diagonal of a square is incommensurable with its sides, the question of the possibility of bridging the gap between the domains of discreteness and of continuity, or between arithmetic and geometry, has been of fundamental concern to mathematicians, logicians, and philosophers alike. Indeed, as Abraham Fraenkel, Yehoshua Bar-Hillel, and Azriel Levy aptly observed:

> Bridging the gap between these two heterogeneous domains is not only the central but also the oldest problem in the foundations of mathematics and in the related philosophical fields. (1973, p. 212)

Moreover, as they go on to say:

> To understand the nature of the problem one should stress the fundamental difference between the *discrete, qualitative, individual* nature of *number* in the "combinatorial" domain of counting (arithmetic) and the *continuous, quantitative, homogeneous* nature of the points of *space* (or of time) in the "analytical" domain of *measuring* (geometry). Every integer differs from every other in characteristic individual properties comparable to the differences between human beings, while the continuum appears as an amorphous pulp of points which display little individuality. (1973, p. 212)

Cantor and Dedekind believed they had bridged the gap with the creation of their arithmetico-set theoretic continuum **R** of real numbers, and for more than a century now it has been one of the central tenets of standard mathematical philosophy that indeed they had. In accordance with this view, the geometric linear continuum is taken to be isomorphic with the *arithmetic continuum*, the axioms of geometry being so selected to ensure this would be the case. Given the Archimedean nature of **R** once this mathematico-philosophical thesis is adopted, we have the classic result of standard mathematical philosophy that infinitesimals are superfluous to the analysis of the structure of a continuous straight line.

During the past few decades, however, we have suggested that (Ehrlich 1987, 1989b, 1992, 1994, p. xxviii; 2002a, 2005, p. 508; 2010, 2012, 2021) whereas the Cantor-Dedekind theory succeeds in bridging the gap between the domains of arithmetic and of classical Euclidean geometry, it only reveals a glimpse of a far richer theory of continua that not only allows for infinitesimals, but also leads to a vast generalization of portions of Cantor's theory of the infinite, a generalization that also provides a setting for Abraham Robinson's nonstandard approach to analysis (1961, 1966) as well as for the important and all too often overlooked non-Cantorian theories of the infinite (and infinitesimal) pioneered by Giuseppe Veronese (1891, 1894), Tullio Levi-Civita (1892–3, 1898), David Hilbert (1899), and Hans Hahn (1907; also see Ehrlich 1995) in connection with their work on non-Archimedean ordered algebraic and geometric systems, and by Paul du Bois-Reymond (e.g., 1870–1871, 1875, 1877, 1882), Otto Stolz (1883, 1885), Felix Hausdorff (1907, 1909), and G. H. Hardy (1910, 1912) in connection with their work on the rates of growth of real functions, theories which have come to play fundamental roles in important segments of contemporary non-Archimedean mathematics. Central to the theory is J. H. Conway's ordered field of *surreal numbers* (1976), a system of numbers containing the reals and the ordinals as well as a great many less familiar numbers including $-\omega$, $\omega/2$, $1/\omega$, $\sqrt{\omega}$, e^{ω}, $\log\omega$, and $\sin(1/\omega)$ to name only a few, where ω is the least infinite ordinal. Indeed, this particular number system, which Conway calls **No**, is so remarkably inclusive that, subject to the proviso that numbers – construed here as members of ordered fields – be individually definable in terms of sets of von Neumann-Bernays-Gödel set theory with Global Choice (NBG), it may be said to contain "All Numbers Great and Small" (Conway 1976, p. 3).

In addition to its inclusive structure as an ordered field, **No** has a rich algebraico-tree-theoretic structure which was brought to the fore by Ehrlich (1994, 2001, 2002a, b) and further explored in (van den Dries and Ehrlich 2001; Ehrlich 2011, 2012; Ehrlich and Kaplan 2018, 2021; Fornasiero 2006, 2016; also see Berarducci and Mantova 2018; Kuhlmann and Matusinski 2015). This *simplicity-hierarchical* (or *s-hierarchical*) *structure* depends upon **No**'s structure as a *lexicographically ordered full binary tree* and arises from the fact that the sums and products of any two members of the tree are the simplest possible elements of the tree consistent with **No**'s recursively defined structure as an ordered group and an ordered field, respectively, it being understood that x is *simpler than* y (written $x <_s y$) just in case x is a predecessor of y in the tree.

Among the striking *s*-hierarchical features of **No** is that every surreal number can be assigned a canonical "proper name" that is a reflection of its characteristic *s*-hierarchical properties. These *Conway names* or *normal forms* are expressed as formal sums of the form

$$\sum_{\alpha<\beta} r_\alpha \omega^{y_\alpha},$$

where β is an ordinal, $(y_\alpha)_{\alpha<\beta}$ is a strictly decreasing sequence of surreals, and $(r_\alpha)_{\alpha<\beta}$ is a sequence of nonzero real numbers, the Conway name of an ordinal being just its Cantor normal form.

Figure 1 offers a glimpse of some of the early stages of the recursive unfolding of the members of the s-hierarchical ordered field of surreal numbers in terms of their Conway names, where ω is the least infinite ordinal as well as *the simplest positive infinite number*, $-\omega$ is the additive inverse of ω as well as *the simplest negative infinite number*, $1/\omega$ is the multiplicative inverse of ω as well as *the simplest positive infinitesimal number*, and so on. A complete recursive unfolding of the surreals in terms of their Conway names is given in (Ehrlich 2011).

In a number of works (*op. cit.*), we have suggested that whereas the ordered field of real numbers should merely be regarded as constituting an arithmetic continuum modulo the Archimedean axiom (see Sect. 11), the ordered field of surreal numbers may be regarded as a sort of *absolute arithmetic continuum* (modulo NBG). In the present chapter, as part of a more general exposition of the purported absolute arithmetic continuum and its s-hierarchical counterpart, we will outline some of

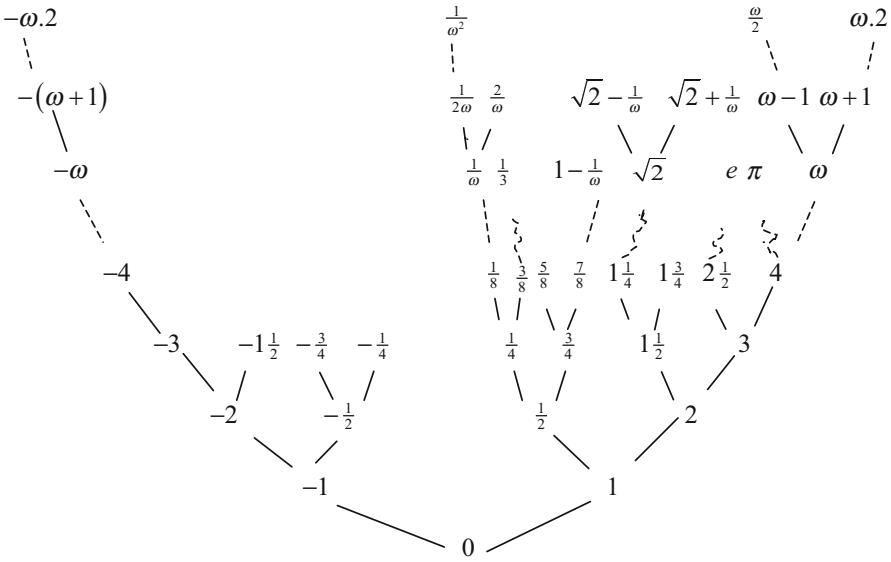

Fig. 1 Some of the early stages of the recursive unfolding of **No**

the properties of the system of surreal numbers that we believe lend credence to this mathematico-philosophical thesis. In doing so, we hope to provide a gateway to some of the leading ideas of the theory. Following the above, we will draw attention to how properties of the system of surreal numbers considered as an s-hierarchical ordered algebraic structure can be appealed to in conjunction with classical relations between ordered algebraic and geometric systems to help resolve, for the surreal case, one of the purported difficulties that lies at the heart of attempts to bridge the gap between the domains of number and of geometrical magnitude. That is, inspired by the challenge implicit in the remarks of Fraenkel, Bar-Hillel, and Levy that don the title page of our text, we will attempt to explain how it is possible that despite the fact that every surreal number differs from every other in characteristic individual properties comparable to the differences between human beings, *the absolute (Euclidean) geometrical continuum*, which is modeled by the *Cartesian space over the ordered field of surreal numbers*, appears as an amorphous pulp of points which display little individuality. Among the results that are central to our resolution is *despite the fact that* **No** *considered as an s-hierarchical ordered algebraic structure admits only the identity automorphism, the Cartesian space over the ordered field of surreal numbers admits a vast array of nontrivial automorphisms in which any given point may be associated with any other given point.* While our discussion will be restricted to plane Euclidean geometry, our analysis generalizes (with suitable modifications) to n-dimensional Euclidean, hyperbolic, and elliptic geometry for all $n \geq 2$ (Ehrlich 1987).

Throughout the chapter, the underlying set theory is assumed to be NBG, where a sentence in the language of sets is true if and only if it is true in ZFC and where all proper classes (i.e., classes that are not sets) are in bijective correspondence with the class of all ordinals (e.g., Mendelson 2010). Since in the language of sets, the sets of NBG have precisely the same properties as the sets of ZFC, the above assertion that **No** may be regarded as containing all numbers great and small that are individually definable in terms of the sets of NBG may be understood as asserting that **No** may be regarded as containing all numbers great and small that are individually definable in terms of sets of standard set theory.

2 The Surreal Number Tree: A Prelude

In Conway's development of the theory of surreal numbers, the system of surreal numbers has the structure of an ordered field, the field operations like the surreal numbers themselves being defined by transfinite recursion. Conway shows that the recursively defined ordered class of surreal numbers can be given the structure of a lexicographically ordered full binary tree, but this structure plays a limited role in his treatment. What does play a more significant role in Conway's development is a *birthday* function that maps each surreal number to the level of recursion at which it is created (along with a related though weaker notion of simplicity that is applicable to Conway's more general theory of games). The birthday of a surreal number in

Conway's treatment corresponds to the tree-rank of a surreal number in the author's development of surreal numbers presented below.

As in several of the classical constructions of real numbers, surreal numbers for Conway are formally construed as equivalence classes. In accordance with Conway's construction, each surreal number is in fact an equivalence class consisting of an entire proper class of equivalent representations, which makes it impossible to collect the proper class of all surreal numbers thus construed into a legal class of NBG. If one wishes, one can carry out Conway's construction in the equiconsistent set theory of Ackermann (Ehrlich 1994, p. 246; 2006, p. 9). In NBG, on the other hand, the numbers must be "cut down to size"; this can be done most easily by identifying each number with a canonical representative of each of Conway's equivalence classes, or by identifying each number with a canonical subset of each class. For the purpose of formalization, Conway (1976, p. 65) proposes the latter approach, making use of the set-theoretic rank function. By contrast, we have introduced two alternative constructions that employ canonical representatives: one based on cuts due to Cuesta Dutari (1954) that generalize the familiar cuts of Dedekind (Ehrlich 1988; Alling and Ehrlich 1986, 1987), and the other being a generalization of the von Neumann ordinal construction (Ehrlich 1994, 2002a, b, 2012). In each case, the surreal numbers can be defined recursively or by means of an explicit definition (Ehrlich 1994, p. 242; also see Appendix I). One can also introduce the system of surreal numbers using *sign-expansions* (see below) of surreal numbers. However, this technically simpler approach, which was introduced by Conway (1976, p. 65), and made popular by Gonshor (1986), divorces the theory of surreal numbers from Conway's more general theory of games, and it presupposes the existence of the ordinals, something neither Conway's construction nor the generalization of the von Neumann construction do. In the present discussion, following a review of some of the basic definitions from the theory of lexicographically ordered binary trees, we will introduce the surreal numbers recursively via the the above-mentioned generalization of the von Neumann ordinal construction.

3 Lexicographically Ordered Binary Trees: Preliminary Definitions

A *tree* $\langle A,<_A\rangle$ is a partially ordered class such that for each $x \in A$, the class $\{y \in A : y <_A x\}$ of *predecessors* of x, written $\mathrm{pr}_A(x)$, is a set well ordered by $<_A$. A maximal subclass of A well ordered by $<_A$ is called a *branch* of the tree. Given any two distinct elements x and y of A, precisely one of the following is the case: Either x is a predecessor of y (i.e., $x <_A y$), y is a predecessor of x (i.e., $y <_A x$), or neither $x <_A y$ nor $y <_A x$. In the latter case, x is said to be *incomparable* with y. Thus, for distinct elements x and y of A, x is incomparable with y if and only if x and y lie on different branches of the tree. An *initial subtree* of $\langle A,<_A\rangle$ is a subclass A' of A with the order inherited from $<_A$ such that for each $x \in A'$, the set of predecessors of x in A' coincides with the set of predecessors of x in A. The *tree-rank* of $x \in A$, written

$\rho_A(x)$, is the ordinal corresponding to the well-ordered set of predecessors of x; the α *th level* of A is the set of all members of the tree having tree-rank α; and a *root* of A is a member of the zeroth level. If $x, y \in A$, then y is said to be an *immediate successor* of x if $x <_A y$ and $\rho_A(y) = \rho_A(x) + 1$, and if $(x_\alpha)_{\alpha<\beta}$ is a *chain* in A (i.e., a subclass of A well ordered by $<_A$), then y is said to be *an immediate successor of the chain* if $x_\alpha <_A y$ for all $\alpha < \beta$ and $\rho_A(y)$ is the least ordinal greater than the tree-ranks of the members of the chain. The *length of a chain* $(x_\alpha)_{\alpha<\beta}$ in A is the ordinal β. A tree $\langle A, <_A\rangle$ is said to be *binary* if each member of A has at most two immediate successors and every chain in A of limit length (including the empty chain) has at most one immediate successor. If every member of A has two immediate successors and every chain in A of limit length has an immediate successor, then the binary tree $\langle A, <_A\rangle$ is said to be *full*. Since a full binary tree has a level for each ordinal, the universe of a full binary tree is a proper class.

Using the Axiom of Global Choice (or simply the Axiom of Choice if A is a set), a tree may be shown to be binary if and only if it is isomorphic to an initial subtree of the *canonical full binary tree* $\langle B, <_B\rangle$, where B is the class of all sequences of +s and -s indexed over some ordinal and $x <_B y$ signifies that x is a proper initial subsequence of y (e.g., Drake 1974, p. 216).

By an ordered tree $\langle A, <, <_A\rangle$, we mean a tree $\langle A, <_A\rangle$ whose universe is totally ordered by $<$. Thus, an ordered tree $\langle A, <, <_A\rangle$ has two orderings: a partial ordering $<_A$ in virtue of which $\langle A, <_A\rangle$ is a tree and a total ordering $<$ in virtue of which $\langle A, <\rangle$ is an ordered class. As is well known, $\langle B, <_B\rangle$ can be totally ordered lexicographically in accordance with the definition: $(x_\alpha)_{\alpha<\mu} <_{lex(B)} (y_\alpha)_{\alpha<\sigma}$ if and only if $x_\beta = y_\beta$ for all $\beta <$ some δ, but $x_\delta < y_\delta$, it being understood that $-<$ *undefined* $<+$. The resulting structure $\langle B, <_{lex(B)}, <_B\rangle$ is called the *lexicographically ordered canonical full binary tree*.

Figures 2, 3, and 4 exhibit levels 0–3 of $\langle B, <_{lex(B)}, <_B\rangle$, the level of the tree being indicated in Fig. 2 on the right. In Fig. 3, the members of the tree that are connected to a given member by strictly descending sequences of dots are the predecessors of the given member. And in Fig. 4, the ordering of the positions of the projected sequences on the line indicates the total ordering of the members of levels 0–3 in accordance with the lexicographical ordering.

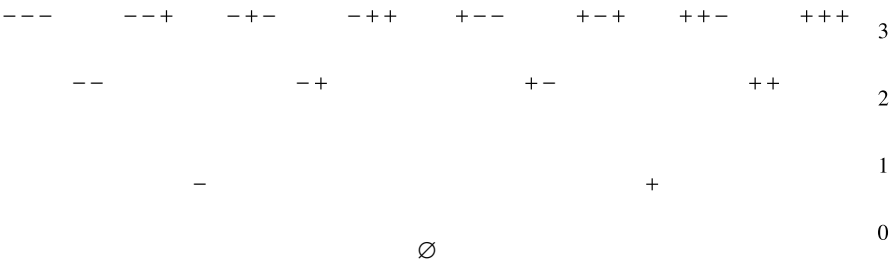

Fig. 2 Levels 0–3 of $\langle B, <_{lex(B)}, <_B\rangle$

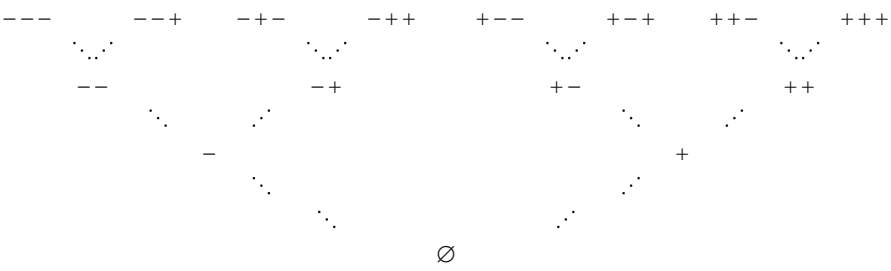

Fig. 3 The tree structure of levels 0–3 of $\langle B, <_{lex(B)}, <_B \rangle$

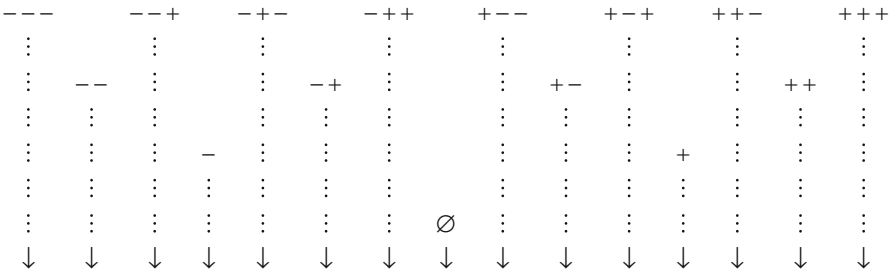

Fig. 4 The total ordering of levels 0–3 of $\langle B, <_{lex(B)}, <_B \rangle$

In a subsequent section, we will explore the relation between the ordered surreal number tree and $\langle B, <_{lex(B)}, <_B \rangle$. For the time being, we turn our attention to the ordered surreal number tree itself.

4 The Construction of the Ordered Surreal Number Tree $\langle$No, <, $<_s\rangle$

Von Neumann defines an ordinal as a transitive set that is well ordered by the membership relation. As a result, for von Neumann, an ordinal emerges as the set of all of its predecessors in the long though rather trivial binary tree $\langle Ord, \in \rangle$ of all ordinals. So, for example, 0 is identified with Ø, 1 is identified with $\{\emptyset\} = \{0\}$, 2 is identified with $\{\emptyset, \{\emptyset\}\} = \{0, 1\}$, and so on. In the following generalization of the von Neumann ordinal construction, each surreal number x emerges as an ordered pair (L_x, R_x) of sets of surreal numbers that are predecessors of x. Although L_x and R_x are defined independently of the total ordering that is imposed on the surreal number tree, they ultimately coincide with the sets of all predecessors of x that are less than x and greater than x, respectively. $\langle Ord, \in \rangle$ is not usually described as a binary tree since its familiar structure as a well-ordered class is indistinguishable from its structure as a tree. In the theory of surreal numbers, however, one must distinguish

between its binary tree structure, on the one hand, and its structure as a totally ordered class, on the other. The particular approach we will employ requires one to have a surreal number (L, R) at hand before it can be recusively identified as a surreal number. To ensure the availability of the requisite class of set-theoretical entities, we follow Conway in first recursively defining the class of *games*.

4.1 Construction of Games

If L and R are any two sets of games, then there is a game (L, R). All games are constructed in this way.

It is not difficult to see that this construction leads to an entire proper class of games beginning with the game $(\emptyset, \emptyset)$, where $\emptyset$ is the empty set (of games). The closure condition "All games are constructed in this way" simply ensures that nothing is a game that does not arise in the specified way. To recursively extract the surreal numbers from the class of games, we make use of the following terminology from (Ehrlich 2002a, b).

4.2 Preliminary Definitions

A game x is said to be *simpler than* a game $y = (L_y, R_y)$, written $x <_s y$, if $x \in L_y$ or $x \in R_y$; a chain of games (i.e., a class of games totally ordered by $<_s$) is said to be *ancestral* if it is closed under the simpler than relation, i.e., x is a member of the chain whenever y is a member of the chain and $x <_s y$; and by an *orderly partition* L, R of an ancestral chain C of games we mean an ordered pair (L, R) of disjoint subsets of C whose union is C and for which $L \supseteq L_x$ and $R_x \subseteq R$ for each element $x = (L_x, R_x)$ of the chain.

The members of the class **No** of surreal numbers are now identified by means of the following simple construction in which the clause "there is a surreal number (L, R)" signifies that the game (L, R) is a surreal number.

4.3 Construction of Surreal Numbers

If (L, R) is an orderly partition of an ancestral chain of surreal numbers, then (L, R) is a surreal number. All surreal numbers are constructed in this way.

At this point (employing much the same argument from (Ehrlich 1994, pp. 242–144)), it is not difficult to show that $\langle \mathbf{No}, <_s \rangle$ is a full binary tree where the definition of the simpler than relation for surreal numbers is inherited from the definition for games. For this purpose, however, one needs the ordinals. If one wishes, one could avail oneself of the von Neumann ordinals, which are already at hand. On the other hand, if one wants to rely solely on the ordinals developed within the theory of surreal numbers, one must first identify "our" ordinals.

4.4 Isolation of the Ordinals

A surreal number $x = (L_x, R_x)$ will be said to be an ordinal if $R_x = \emptyset$. By *On*, we mean the class of ordinals so defined. For all ordinals x and y, x will be said to be less than y, written $x <_{On} y$, if $L_x \subset L_y$.

In accordance with the above definition, $(\emptyset, \emptyset)$ is an ordinal, $(\{(\emptyset, \emptyset)\}, \emptyset)$ is an ordinal, $(\{(\emptyset, \emptyset), (\{(\emptyset, \emptyset)\}, \emptyset)\}, \emptyset)$ is an ordinal, and so on. In fact, the just-cited ordinals are eventually identified with the finite ordinals $0 = (\emptyset, \emptyset)$, $1 = (\{0\}, \emptyset)$, and $2 = (\{0, 1\}, \emptyset)$, respectively.

That the ordered class $\langle On, <_{On} \rangle$ of ordinals has all of the requisite properties possessed by any of the more familiar constructs so-called follows from

Propostion 1 *There is a one-to-one order preserving correspondence between the ordered class* $\langle On, <_{On} \rangle$ *and the ordered class* $\langle Ord, \in \rangle$ *of von Neumann ordinals.*

Using the ordered class of ordinals so defined, the structure of the surreal numbers that emerge vis-à-vis the above construction may be characterized as follows.

Theorem 1 (Ehrlich 1994) $(\emptyset, \emptyset)$ *is a surreal number; if* $x = (L_x, R_x)$ *is a surreal number, then* $(L_x, \{x\} \cup R_x)$ *and* $(L_x \cup \{x\}, R_x)$ *are surreal numbers; moreover, if* $(x_\alpha)_{\alpha < \beta}$ *is a chain of surreal numbers (ordered by* $<_s$*) of infinite limit length, then* $\left(\cup_{\alpha<\beta} L_{x_\alpha}, \cup_{\alpha<\beta} R_{x_\alpha}\right)$ *is a surreal number. Nothing is a surreal number except in virtue of the above.*

The reader will note that $(L_x, \{x\} \cup R_x)$ and $(L_x \cup \{x\}, R_x)$ are the immediate successors in $\langle \mathbf{No}, <_s \rangle$ of the surreal number x, and that $\left(\cup_{\alpha<\beta} L_{x_\alpha}, \cup_{\alpha<\beta} R_{x_\alpha}\right)$ is the immediate successor in $\langle \mathbf{No}, <_s \rangle$ of the chain $(x_\alpha)_{\alpha < \beta}$ of surreal numbers indexed over the infinite limit ordinal β. In fact, as it turns out, $(L_x, \{x\} \cup R_x)$ is the immediate successor of x less than x, $(L_x \cup \{x\}, R_x)$ is the immediate successor of x greater than x, and $\left(\cup_{\alpha<\beta} L_{x_\alpha}, \cup_{\alpha<\beta} R_{x_\alpha}\right)$ is always greater than the members of $\cup_{\alpha<\beta} L_{x_\alpha}$ and less than the members of $\cup_{\alpha<\beta} R_{x_\alpha}$. To lend precision to these ideas and to ideas regarding **No** considered as a totally ordered class more generally, we require the following definition.

4.5 The Rule of Order

For all surreal numbers $x = (L_x, R_x)$ and $y = (L_y, R_y)$, $x < y$ if and only if $x \in L_y$ or $y \in R_x$ or $R_x \cap L_y \neq \emptyset$.

The three cases that comprise the rule of order correspond to the three mutually exclusive and collectively exhaustive relations that two surreal numbers x and y may bear to one another when x is less than y; namely, x is simpler than y, y is simpler than x, and x is incomparable with y, respectively. Using this in conjunction with Theorem 1, one may prove

Corollary 1 (Ehrlich 1994) *For each surreal number x,*

$$x = \left(L_{s(x)}, R_{s(x)}\right),$$

where

$L_{s(x)} = \{a \in \mathbf{No} : a <_s x \text{ and } a < x\}$ and $R_{s(x)} = \{a \in \mathbf{No} : a <_s x \text{ and } x < a\}$.

Moreover, by appealing to Corollary 1 together with the definition of **No**'s ordinals and the definition of the corresponding ordering thereof, we also have

Corollary 2 (Ehrlich 1994) **No***'s ordinals are the members of the rightmost branch of* $\langle \mathbf{No}, <, <_s \rangle$*, the ordinal* α *being the member of tree-rank* α*. As such, for all ordinals* α *and* β*,* $\alpha <_{On} \beta$ *if and only if* $\alpha <_s \beta$ *if and only if* $\alpha < \beta$*. Moreover, if* α *is an ordinal, then*

$$\alpha = (L_{s(\alpha)}, \emptyset).$$

Remark The above construction of the surreals makes no use of the ordinals. Like Conway, we believe this is befitting a construction of "all numbers great and small." It is worth noting, however, that if one permits the use of the von Neumann ordinals in the construction, one can introduce $\langle \mathbf{No}, <, <_s \rangle$ more simply employing the following definition along with $<_s$ and $<$ as defined above.

Definition (Ehrlich 2010, p. 248) $(\emptyset, \emptyset)$ is a surreal number; if $x = (L_x, R_x)$ is a surreal number, then $(L_x, \{x\} \cup R_x)$ and $(L_x \cup \{x\}, R_x)$ are surreal numbers; moreover, if $(x_\alpha)_{\alpha<\beta}$ is a sequence of surreal numbers of infinite limit length β in which $x_\mu \in L_{x_\nu} \cup R_{x_\nu}$ whenever $\mu < \nu < \beta$, then $\left(\cup_{\alpha<\beta} L_{x_\alpha}, \cup_{\alpha<\beta} R_{x_\alpha}\right)$ is a surreal number. Nothing is a surreal number except in virtue of the above.

5 The Structure of the Ordered Surreal Number Tree $\langle \mathbf{No}, <, <_s \rangle$

For each surreal number x, there is a unique enumeration $(x_\alpha)_{\alpha<\rho_{\mathbf{No}}(x)}$ of the predecessors of x well ordered by the simpler than relation. Following (Ehrlich 1994), we refer to this enumeration as the *genealogy* of x. By the *sign-expansion* of x, we mean the sequence $(g_\alpha(x))_{\alpha<\rho_{\mathbf{No}}(x)}$ defined by the condition: for all $\alpha < \rho_{\mathbf{No}}(x)$,

$$g_\alpha(x) = \begin{cases} +, & \text{if } x_\alpha \in L_{s(x)} \\ -, & \text{if } x_\alpha \in R_{s(x),} \end{cases}$$

where x_α is the α *th* term in the genealogy of x (i.e., the predecessor of x having tree-rank α). This definition of the sign-expansion of a surreal number differs

considerably from Conway's (1976, pp. 29–30) which is defined using the ordered additive structure of **No**.

It is not difficult to show that every surreal number has a sign-expansion; distinct surreal numbers have distinct sign-expansions; and every sequence of elements of $\{+, -\}$ of length $\beta \in On$ is the sign-expansion of some surreal number (Ehrlich 1994, Theorem 1.4). Moreover, and more importantly, however, is

Theorem 2 (Ehrlich 1994) $\langle \mathbf{No}, <, <_s \rangle$ and $\langle B, <_{lex(B)}, <_B \rangle$ *are isomorphic as ordered trees, the map that sends each surreal number to its sign-expansion being the unique such isomorphism*.

While $\langle B, <_{lex(B)}, <_B \rangle$ sheds important light on the structure of $\langle \mathbf{No}, <, <_s \rangle$, in the general theory of surreal numbers it is advantageous to have available a representation independent characterization of those ordered trees that are isomorphic to initial ordered subtrees of $\langle B, <_{lex(B)}, <_B \rangle$ and, hence, of $\langle \mathbf{No}, <, <_s \rangle$. There are two particularly useful such characterizations that will be appealed to in the subsequent discussion, the first of which we take as the standard definition.

Definition 1 (Ehrlich 2001) *A lexicographically ordered binary tree is an ordered binary tree in which distinct members are incomparable if and only if they have a common predecessor lying between them*.

A subclass I of an ordered class $\langle A, < \rangle$ is said to be *convex* if every member of A that lies between two members of I is likewise a member of I. The familiar intervals of an ordered class $\langle A, < \rangle$ of the forms $\{x \in A : a \leq x \leq b\}$, $\{x \in A : a < x < b\}$, $\{x \in A : a \leq x < b\}$, and $\{x \in A : a < x \leq b\}$ are all convex subclasses. Besides these, however, there may be convex subclasses of $\langle A, < \rangle$ without a greatest lower bound a or without a least upper bound b. The ordered set of rational numbers of course contains many such convex subclasses, and non-Archimedean ordered fields invariably contain many such convex subclasses as well.

The idea of a convex subclass of an ordered class plays a leading role in the formulation of the second of the two representation independent characterizations of a lexicographically ordered binary tree alluded to above. Also important in this regard are the following notational and terminological conventions that will be employed throughout the remainder of the chapter.

If L and R are subclasses of an ordered class $\langle A, < \rangle$ (where L or R may be empty), then "$L < R$" signifies that every member of L precedes every member of R. In addition, if x and y are members of an ordered tree $\langle A, <, <_s \rangle$, then (as in the case of surreal numbers) $x <_s y$ will be read *x is simpler than y*; moreover, an element x of a nonempty subclass I of A will be said to be "the simplest member" of I if $x <_s y$ for all $y \in I - \{x\}$. Finally, mimicking the stipulations introduced in Corollary 1, by "$L_{s(x)}$" we mean $\{a \in A : a <_s x \text{ and } a < x\}$ and by "$R_{s(x)}$" we mean $\{a \in A : a <_s x \text{ and } x < a\}$.

The second of our representation independent characterizations of a lexicographically ordered binary tree is given by

Theorem 3 (Ehrlich 2001: Theorems 1 and 2) *$\langle A, <, <_s\rangle$ is a lexicographically ordered binary tree if and only if $\langle A, <, <_s\rangle$ is an ordered tree in which every nonempty convex subclass contains a simplest member, and for all $x, y \in A$, $x <_s y$ if and only if $L_{s(x)} < \{y\} < R_{s(x)}$ and $x \neq y$.*

Now suppose L and R are subsets of a lexicographically ordered binary tree $\langle A, <, <_s\rangle$ where $L < R$. It follows from the just-stated theorem that the convex subclass of A consisting of all the members of A lying between L and R is either empty or contains a simplest member. If a simplest such member always exists, $\langle A, <, <_s\rangle$ will be said to be *complete*. As the following theorem makes clear, the concept of a complete lexicographically ordered binary tree and the concept of a full lexicographically ordered binary tree provide us with complementary perspectives on the nature of **No**.

Theorem 4 (Ehrlich 1994, 2001) *A lexicographically ordered binary tree is complete if and only if it is full and if and only if it is isomorphic to $\langle \mathbf{No}, <, <_s\rangle$.*

An automorphism is an isomorphism of a structure $\langle A, \ldots\rangle$ onto itself. Roughly speaking, if f is an automorphism of $\langle A, \ldots\rangle$ in which $f(x) \neq x$ for some $x \in A$, then $f(x)$ and x can play exactly the same roles as one another in isomorphic structures having the common universe A. As is evident from (Ehrlich 1989a, Sect. 2), $\langle \mathbf{No}, <\rangle$ has a vast array of automorphisms. However, as the following result makes clear, all but one fail to take into account from whence the numbers come.

Theorem 5 (Ehrlich 1994) *The identity map is the sole automorphism of $\langle \mathbf{No}, <\rangle$ that preserves predecessors. That is, an automorphism f of $\langle \mathbf{No}, <\rangle$ satisfies the condition $\mathrm{pr}_{\mathbf{No}}(f(x)) = \mathrm{pr}_{\mathbf{No}}(x) = L_{s(x)} \cup R_{s(x)}$ for all $x \in \mathbf{No}$ if and only if $f(x) = x$ for all $x \in \mathbf{No}$.*

The identity map is likewise the only automorphism of $\langle \mathbf{No}, <\rangle$ that preserves tree-rank. Moreover, the following consequence of Theorem 5 provides still another way of characterizing this map.

Corollary 3 (Ehrlich 1994) *$\langle \mathbf{No}, <, <_s\rangle$ has no automorphism other than the identity automorphism.*

6 Ordered Fields with Simplicity Hierarchies

Let $\langle A, <, <_s\rangle$ be a lexicographically ordered binary tree. If x is the simplest member of A lying between two subsets L and R of A where $L < R$, then we will denote x by "$\{L|\ R\}^A$" or simply by "$\{L|\ R\}$," when no ambiguity will arise. Moreover, applying

Conway's conventions (Conway 1976, p. 4) to our definition of "$\{L \mid R\}$," if $x = \{L \mid R\}$ we write "x^L" for a typical member of L and "x^R" for a typical member of R; for x itself, we write "$\{x^L \mid x^R\}$"; and $x = \{a, b, c, \ldots | d, e, f, \ldots\}$ means that $x = \{L \mid R\}$ where $a, b, c, \ldots$ are typical members of L and $d, e, f, \ldots$ are typical members of R.

The following consequence of Theorem 3 is central to the subsequent development.

Proposition 2 *If $\langle A, <, <_s\rangle$ is a lexicographically ordered binary tree and $x \in A$, then there are (possibly empty) subsets L and R of A such that $L < R$ and for which $x = \{L \mid R\}$; in particular, x is the simplest member of A lying between its predecessors on the left and its predecessors on the right, that is, $x = \{L_{s(x)} \mid R_{s(x)}\}$.*

In the following definition, x^L, x^R, y^L, and y^R are understood to be typical members of arbitrary sets L_x, R_x, L_y, and R_y, respectively, for which $x = \{L_x \mid R_x\}$ and $y = \{L_y \mid R_y\}$.

Definition 2 (Ehrlich 2001) *$\langle A, +, \cdot, <, <_s, 0, 1\rangle$ is said to be an s-hierarchical ordered field if (i) $\langle A, +, \cdot, <, 0, 1\rangle$ is an ordered field; (ii) $\langle A, <, <_s\rangle$ is a lexicographically ordered binary tree; and (iii) for all $x, y \in A$,*

$$x + y = \left\{x^L + y, x + y^L | x^R + y, x + y^R\right\}$$

and

$$xy = \{x^L y + xy^L - x^L y^L, x^R y + xy^R - x^R y^R \mid x^L y + xy^R - x^L y^R, x^R y + xy^L - x^R y^L\}.$$

The reader will note that in virtue of the conventions introduced at the beginning of this section, the s-hierarchical constraint on sums in the above definition asserts that $x + y = \{L_{x+y} \mid R_{x+y}\}$ where L_{x+y} is the set consisting of all sums of the form $x^L + y$ where $x^L \in L_x$ as well as all sums of the form $x + y^L$ where $y^L \in L_y$, and R_{x+y} is the set consisting of all sums of the form $x^R + y$ where $x^R \in R_x$ as well as all sums of the form $x + y^R$ where $y^R \in R_y$. The s-hierarchical constraint on products is analogously understood.

Using the s-hierarchical constraints on sums and products, respectively, it is a simple matter to show that $0 = \{\emptyset \mid \emptyset\} = \{|\}$ is the simplest element of, as well as the unique root in, an s-hierarchical ordered field A, and that $1 = \{\{\{\emptyset \mid \emptyset\}\} \mid \emptyset\} = \{0|\}$ is the simplest positive element of A (Ehrlich 2001). Moreover, it is a consequence of the following result that except for the signs of elements, the portion of the tree less than 0 is a mirror image of the portion of the tree greater than 0.

Proposition 3 (Ehrlich 2001) For each element x of an s-hierarchical ordered field

$$-x = \{-x^R | -x^L\}.$$

Like the just-stated algebraico-tree-theoretic condition governing additive inverses, the algebraico-tree-theoretic constraints placed on sums and products of elements of an s-hierarchical ordered field are apt to appear rather cryptic to readers unfamiliar with the theory of surreal numbers. We will decipher their significance shortly. Before doing so, however, we note that a good deal of their motivation arises from the following straightforward tree-theoretic variation of a remarkable result due to Conway (1976).

Theorem 6 (Ehrlich 2001) $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$ *is an s-hierarchical ordered field when* $+$, $-$, *and* $\cdot$ *are defined by recursion as follows where* x^L, x^R, y^L, *and* y^R *are understood to range over the members of* $L_{s(x)}$, $R_{s(x)}$, $L_{s(y)}$, *and* $R_{s(y)}$, *respectively.*

Definition of $x + y$.

$$x + y = \{x^L + y, x + y^L | x^R + y, x + y^R\}.$$

Definition of $-x$.

$$-x = \{-x^R | -x^L\}.$$

Definition of xy.

$$xy = \{x^L y + xy^L - x^L y^L, x^R y + xy^R - x^R y^R \mid x^L y + xy^R - x^L y^R, x^R y + xy^L - x^R y^L\}.$$

As our remarks preceding the statement of Theorem 6 suggest, the constraints on sums and products found in Definition 2 are tree-theoretic adaptations of the recursive definitions of $+$ and $\cdot$ employed by Conway in his construction of the ordered field of surreal numbers (1976, p. 5). Appealing to ideas alluded to in the Introduction, the import of these constraints may be encapsulated thus.

Let $x, y \in A$. Since $x = \{x^L \mid x^R\}$ and $y = \{y^L \mid y^R\}$, it follows that for all x^L, x^R, y^L, and y^R:

$$(*) \qquad x^L < x < x^R \text{ and } y^L < y < y^R.$$

Furthermore, combining $(*)$ with the fact that A is an ordered field (and, hence, an ordered additive group), it follows that $x^L + y < x + y < x^R + y$ and $x + y^L < x + y < x + y^R$, and, hence, that

$$(**) \qquad \{x^L + y, x + y^L\} < \{x + y\} < \{x^R + y, x + y^R\}.$$

Therefore, since $x + y$ must lie between the two sets of members of A specified in $(**)$, clause (iii) of Definition 2 requires that $x + y$ be *the simplest member of A lying between those sets*.

Similarly, since, by clause (i) of Definition 2, A is an ordered field, it follows from $(*)$ that each of the differences $x - x^L, x^R - x, y - y^L, y^R - y$ is positive and, hence, so is each of the products $(x - x^L)(y - y^L)$, $(x^R - x)(y^R - y)$, $(x - x^L)(y^R - y)$, and $(x^R - x)(y - y^L)$. But by applying this together with routine high school algebra of ordered fields to each of these products, one obtains

$$(***) \qquad \begin{aligned} &\left\{x^L y + xy^L - x^L y^L, x^R y + xy^R - x^R y^R\right\} < \\ &\qquad < \{xy\} < \left\{x^L y + xy^R - x^L y^R, x^R y + xy^L - x^R y^L\right\}. \end{aligned}$$

Therefore, since xy must lie between the two sets of members of A specified in $(***)$, clause (iii) of Definition 2 requires that xy be *the simplest member of A lying between those sets*.

Given an ordered field $\langle A, +, \cdot, <, 0, 1\rangle$, it is possible to define a lexicographically ordered binary tree structure on its ordered class $\langle A, <\rangle$ of elements in infinitely many ways. That is, there are infinitely many distinct predecessor relations $<_A$ that can be defined on the members of A in accordance with which $\langle A, <, <_A\rangle$ is a lexicographically ordered binary tree. In the case of $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$, in particular, a lexicographically ordered binary tree structure can be imposed on its ordered class of elements in as many ways as there are ordinals. Moreover, while the constraints on sums and products dictated by $(**)$ and $(***)$, respectively, will be satisfied in any of the resulting systems, one is largely free to assign the sum and product of any two members of the system to any position in the tree one pleases. If the resulting structure is to be an s-hierarchical ordered field, however, this is not the case. Indeed, requiring that the sums and products of members of A be the simplest possible elements of the tree consistent with $(**)$ and $(***)$ is tantamount to requiring that sums and products of members of A have the lowest possible tree rank consistent with those constraints. In the case of an s-hierarchical ordered field like **No**, whose sums and products are defined by recursion, this implies that the sums and products of elements get defined just as soon as there is sufficient previously defined ordered algebraico-tree-theoretic information to do so. As we mentioned in the Introduction and the subsequent sections of the chapter will show, this has profound implications for the s-hierarchical ordered field of surreal numbers.

7 S-Hierarchical Mappings and S-Hierarchical Morphisms

There is a uniquely defined image of each rational number r in every ordered field. Moreover, if A is an ordered subfield of the ordered field $\mathbf{R}_{alg}$ of *real algebraic numbers* – i.e., the ordered subfield of $\mathbf{R}$ whose members are solutions to polynomial equations with integer coefficients – and r is an irrational member of A, such as $\sqrt{2}$, then every ordered field containing an isomorphic copy of A will have a uniquely

defined image of r as well. However, there are no other members of ordered fields for which this is true without qualification. Of course, every member r of an ordered subfield of the reals has a unique image in the ordered field of real numbers, and, as such, within the confines of an ordered subfield of real numbers one can speak unambiguously of the real number r whether it be a rational number, a real algebraic number that is not rational, or a transcendental number, i.e., an irrational number, such as π or e, that is not a real algebraic number. However, if A is an Archimedean ordered field containing a *transcendental number r*, then *no non-Archimedean ordered field containing an isomorphic copy of A will have a uniquely defined image of r.* That is, there will always be isomorphisms f and g from A into the non-Archimedean ordered field in question for which $f(r) \neq g(r)$. In fact, *if A is an arbitrary ordered field, whose universe is a set, and r a member of A that is not one of A's real algebraic numbers, there is an entire proper class of isomorphisms of A into* **No** *for which no two of them send r to the same surreal number!* Happily, however, as the remainder of this and the subsequent section will show, not only does the absence of uniquely defined images fail to arise for members of s-hierarchical ordered fields under suitably defined morphisms, but every such element has a uniquely defined image in $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$. In saying as much, we are alluding to the fact that the type of isomorphisms appropriate for s-hierarchical ordered fields are more stringent than those appropriate for ordered fields without s-hierarchical structures. It is to these *s-hierarchical morphisms*, as we call them, to which we now turn.

Definition 3 (Ehrlich 2001) *A mapping $f: A \to A'$ between two lexicographically ordered binary trees $\langle A, <, <_A\rangle$ and $\langle A', <', <_{A'}\rangle$ is said to be an s-hierarchical mapping if for all $x \in A$, $f(x) = \{ f(L) \mid f(R)\}^{A'}$ whenever $x = \{L \mid R\}^A$. If, in addition, A and A' are s-hierarchical ordered fields and the mapping is also an embedding of ordered fields, it is said to be an s-hierarchical embedding or an s-hierarchical isomorphism.*

It is not difficult to show that a mapping $f: A \to A'$ between two lexicographically ordered binary trees $\langle A, <, <_A\rangle$ and $\langle A', <', <_{A'}\rangle$ is s-hierarchical if and only if the mapping preserves order, the predecessor relation, and tree-rank (Ehrlich 2001, Lemma 1): that is, for all $x, y \in A$: (i) $f(x) <' f(y)$ whenever $x < y$; (ii) $f(x) <_{A'} f(y)$ whenever $x <_A y$; and (iii) $\rho_A(x) = \rho_{A'}(f(x))$. This in conjunction with the structure of s-hierarchical ordered fields underlies the following result that brings to the fore just how distinguished s-hierarchical mappings of s-hierarchical ordered fields really are.

Theorem 7 (Ehrlich 2001: Lemma 2, Theorem 5) *Every s-hierarchical mapping between s-hierarchical ordered fields is an s-hierarchical embedding; moreover, if $f: A \to S$ and $g: A \to S$ are s-hierarchical mappings, then $f = g$ and $f(A)$ is an initial subtree of S. There is an s-hierarchical mapping of every s-hierarchical ordered field into $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$.*

In virtue of Corollary 3, it is clear that the sole automorphism of $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$ is the identity automorphism. However, in virtue of Theorem 7, we have more.

Corollary 4 *The identity automorphism is the sole s-hierarchical embedding of an s-hierarchical ordered field into itself. Accordingly, if* $\langle A, +, \cdot, <, <_s, 0, 1\rangle$ *is an s-hierarchical ordered field, then the identity automorphism is the sole embedding of* $\langle A, +, \cdot, <, 0, 1\rangle$ *into itself that preserves* $<_s$.

In particular:

Corollary 5 *The identity automorphism is the sole s-hierarchical embedding of* $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$ *into itself. Thus, the identity automorphism is the sole embedding of* $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$ *into itself that preserves* $<_s$.

Structures whose automorphism groups consist solely of the identity automorphism are said to be *rigid*. If the identity automorphism is the sole embedding of a structure into itself (i.e., is the sole endomorphism of a structure), the structure is said to be *strongly rigid*. While strongly rigid structures are rigid, rigid structures need not be strongly rigid. For example, whereas the ordered set **N** of natural numbers is rigid, it is not strongly rigid since it is isomorphic to the ordered set $\mathbf{N} - \{0\}$ of natural numbers greater than 0. However, in accordance with Corollary 4, s-hierarchical ordered fields are strongly rigid, and in this regard they behave like **R** and the ordered ring **Z** of integers. We do not know whether it is the rigidity of **Z**, the strong rigidity of **Z**, or something else entirely that Fraenkel, Bar-Hillel, and Levy had in mind when they maintained (see Introduction) that "[e]very integer differs from every other in characteristic individual properties comparable to the differences between human beings." However, while the rigidity of **Z** certainly suffices to underwrite their contention, it does not provide the full story. The strong rigidity of **Z** ensures that neither a permutation of the members of **Z** nor the members of a proper substructure of **Z** could exhibit all the properties of all the members of **Z** expressed in the language $L = \{+, \cdot, <, 0, 1\}$ of ordered rings, whereas the rigidity of **Z** only ensures the former. In sharp contrast with **Z**, the ordered field of surreal numbers has a vast array of endomorphisms that are not automorphisms as well as a vast array of automorphisms other than the identity automorphism. It is only when the s-hierarchical nature of **No** is taken into account that its strong rigidity emerges.

A subfield A of an s-hierarchical ordered field S is said to be an *initial subfield* if the universe of A is an initial subtree of S.

Proposition 4 (**Ehrlich 2001**) *An initial subfield of an s-hierarchical ordered field is itself an s-hierarchical ordered field; furthermore, an ordered field admits a*

relational expansion to an s-hierarchical ordered field if and only if it is isomorphic as an ordered field to an initial subfield of an s-hierarchical ordered field.

In a number of subsequent sections, the closely related notions of s-hierarchical embedding and initial subfield play important roles in shedding further light on **No**'s structure as an s-hierarchical ordered field. We begin with **No**'s s-hierarchical ordered subfield of real numbers.

8 The S-Hierarchical Ordered Field of Real Numbers

Thus far, the only s-hierarchical ordered fields whose existence we have discussed are complete s-hierarchical ordered fields. However, there is a vast array of s-hierarchical ordered fields that fall short of completeness, the full spectrum of which was characterized by Ehrlich (2001, §4). It is a consequence of Theorem 7 and Proposition 4 that revealing the spectrum of s-hierarchical ordered fields reduces to revealing the spectrum of initial subfields of **No**. While we will make no attempt in this chapter to spell out the entire spectrum, in this and a subsequent section we will draw attention to components of the spectrum that are of particular importance from the standpoints of the classical, elementary (i.e., first-order), and absolute theories of continua. In this section, we introduce the s-hierarchical ordered field of real numbers, a structure that, as we shall later see, plays a critical role in assigning canonical appellations to arbitrary surreal numbers.

Definition 4 Let **D** be the set of all surreal numbers having finite tree-rank, and further let

$$\mathbf{R} = \mathbf{D} \cup \{\{X \mid Y\} : (X, Y) \text{ is a Dedekind gap in } \mathbf{D}\},$$

where, as the reader will recall, a Dedekind gap (X, Y) *in* **D** is a partition of **D** into two nonempty subsets X and Y such that $X < Y$, X has no greatest member, and Y has no least member.

The following result is essentially due to Conway (1976, pp. 23–25).

Proposition 5 **R** *(with* $+, -, \cdot$ *and* $<$ *defined à la* **No***) is isomorphic to the ordered field of reals defined in any of the more familiar ways,* **D** *being* **No***'s ring of dyadic rationals (*i.e.*, rationals of the form* $m/2^n$ *where* m *and* n *are integers);* $n = \{0, \ldots, n-1|\}$ *for each positive integer* n, $-n = \{|-(n-1), \ldots, 0\}$ *for each positive integer* n, $0 = \{|\}$, *and the remainder of the dyadics are the arithmetic means of their left and right predecessors of greatest tree-rank;* e.g., $\frac{1}{2} = \{0|1\}$.

Being an ordered field, **No** contains exactly one subring of integers, one subring of dyadic rationals, and one subfield of rationals. On the other hand, as we alluded to

above, **No** contains an entire proper class of distinct isomorphic copies of the ordered field of reals. What distinguishes **R** from the rest is captured by the first part of

Theorem 8 (**Ehrlich 2001**) **R** *is the unique isomorphic copy of the ordered field of reals that is an initial subfield of* **No**. *In fact, every Archimedean ordered field is isomorphic to exactly one initial subfield of* **No**, *the latter being an initial subfield of* **R**.

The first part of Theorem 8 being its requisite justification, henceforth we shall refer to **R** as the ordered field of real numbers. In accordance with this convention, **R** is the set of all surreal numbers whose sign-expansions have length $\leq \omega$ that end neither in an infinite sequence of $-$ s nor in an infinite sequence of $+$ s. The real numbers whose sign-expansions have length $< \omega$ are the dyadic rationals, and the remaining rational numbers are the members of **R** having sign-expansions that end with finite sequences of signs, containing at least one $+$ and at least one $-$, that recurs ω times. For instance, $\frac{1}{3}$ is the surreal number having the sign-expansion the begins with $+-$ and is followed by the sequence $-+$ repeated ω times. For a simple rule, due to Elwyn Berlekamp, for obtaining the value of a real number from its sign-expansion, see (Conway 1976, p. 31).

9 Every Surreal Number Has its Own Proper Name

As we mentioned in the Introduction, each surreal number can be assigned a canonical proper name that is a reflection of its characteristic individual properties. In order to define these *Conway names*, or *normal forms* as Conway (1976, p. 33) calls them, we require a number of definitions beginning with the following classical ones from the theory of ordered algebraic systems applied to **No**.

Two elements a and b of **No** are said to be *Archimedean equivalent*, written $a \approx b$, if there are positive integers m and n such that $m|a| > |b|$ and $n|b| > |a|$; if $a \approx b$ and $|a| < |b|$, then we write $|a| \ll |b|$ and a is said to be *infinitesimal (in absolute value) relative to* b and b is said to be *infinite (in absolute value) relative to* a; the class of all members of **No** that are Archimedean equivalent to some member of **No** is said to constitute an *Archimedean class* of **No**. 0, which is infinitesimal (in absolute value) relative to every other surreal number, is the sole surreal number that is not a member of an Archimedean class.

Following Conway (1976, p. 31), an element of **No** is said to be a *leader* if it is the simplest member of the class of positive elements of an Archimedean class of **No**. Since the class of positive elements of an Archimedean class of **No** is a convex subclass of **No**, the concept of a leader is well defined. Henceforth, by Lead(**No**) we mean the class of all leaders of **No**.

One of the salient features of Lead(**No**) is given by the following result, where $<_{\mathbf{No}}|\text{Lead}(\mathbf{No})$ and $<_s|\text{Lead}(\mathbf{No})$ denote the restrictions to Lead(**No**) of the order and simpler than relations in **No**.

Theorem 9 (**Ehrlich 2001**) $\langle \text{Lead}(\mathbf{No}), <_{\mathbf{No}} | \text{Lead}(\mathbf{No}), <_s | \text{Lead}(\mathbf{No}) \rangle$ is a lexicographically ordered full binary tree, and, as such, the unique s-hierarchical mapping from Lead(**No**) to **No** (henceforth, $\Phi_{\mathbf{No}}$) is a bijection.

The following recursive definition, which is a variation on an idea due to Conway (1976, p. 31), provides a unique appellation for each leader in **No**. In effect, it assigns the appellation "ω^0" to 1, which is the simplest leader in **No**, the appellation "ω^{-1}" to the simplest leader in **No** less than ω^0, the appellation "ω^1" to the simplest leader in **No** greater than ω^0, and so on.

Definition 5 *For each* $y \in \mathbf{No}$, $\omega^y = \left\{0, n\omega^{L_{S(y)}} | \frac{1}{2^n}\omega^{R_{S(y)}}\right\}^{\mathbf{No}}$, *where n is understood to range over all positive integers and* $\omega^{L_{S(y)}}$ *and* $\omega^{R_{S(y)}}$ *are understood to range over the members of* $\{\omega^x : x \in L_{s(y)}\}$ *and* $\{\omega^x : x \in R_{s(y)}\}$, *respectively.*

Justification for the contention that Definition 5 provides a unique appellation to each leader in **No** accrues from

Theorem 10 (**Ehrlich 2001**) $\omega^y = \Phi_{\mathbf{No}}{}^{-1}(y)$, *for each* $y \in \mathbf{No}$.

Using a classical argument, one may show that if $x \in \mathbf{No} - \{0\}$, there is a unique $r \in \mathbf{R} - \{0\}$, a unique $y \in \mathbf{No}$, and a unique $a \in \mathbf{No}$ such that $x = r\omega^y + a$ where a is infinitesimal (in absolute value) relative to ω^y. To put this somewhat differently, if $x \in \mathbf{No} - \{0\}$, there is a unique $r \in \mathbf{R} - \{0\}$ and a unique $y \in \mathbf{No}$ for which $|x - r\omega^y| \ll \omega^y$. This elementary observation plays pivotal roles in both the formulation and proof of the following s-hierarchical recasting of an argument sketched by Conway (1976, pp. 32–33).

Theorem 11 (**Ehrlich 2001**) *For each* $x \in \mathbf{No} - \{0\}$, *there is a unique descending chain* I^x_α, $\alpha < \beta \in On$, *of convex subclasses of* **No** *whose intersection contains x as its simplest member, and whose components are defined by recursion as follows:* I^x_α *is the subclass of all members of* **No** *of the form* $s_\alpha + r_\alpha\omega^{y_\alpha} + a_\alpha$, *where*

(i) $s_\alpha = 0$, if $\alpha = 0$, and s_α is the simplest member of $\cap_{\gamma<\alpha} I^x_\gamma$, otherwise.
(ii) $r_\alpha\omega^{y_\alpha}$– henceforth called the α-term of x– is the unique member of **No** for which $r_\alpha \in \mathbf{R} - \{0\}$, $y_\alpha \in \mathbf{No}$ and $|x - (s_\alpha + r_\alpha\omega^{y_\alpha})| \ll \omega^{y_\alpha}$.
(iii) $|a_\alpha| \ll \omega^{y_\alpha}$.

Since the intersection of a chain of convex subclasses is itself a convex subclass, it follows from Theorem 11 that, for each $x \in \mathbf{No} - \{0\}$ there is a unique convex subclass of **No** containing x as its simplest member consisting of all and only those surreal numbers whose α-term is $r_\alpha\omega^{y_\alpha}$ for all $\alpha <$ some ordinal β that depends on x. With this as its underlying justification, the completion of the assignment of appellations to surreal numbers begun with Definition 5 is carried out via

Definiton 6 We will refer to the formal expression

$$\sum_{\alpha<\beta}\omega^{y_\alpha}.r_\alpha$$

as the Conway name of a surreal number x, treat the Conway name of x as a proper name of x, and, accordingly, write "$x = \sum_{\alpha<\beta}\omega^{y_\alpha}.r_\alpha$" if and only if either $x = 0$ and $\beta = 0$ or x is the simplest surreal number whose α-term is $r_\alpha\omega^{y_\alpha}$ for all $\alpha < \beta$. (Moreover, we will delete the summation sign or insert sum signs between successive terms when it is convenient to do so, as well as write $\omega^0.r = r$, $\omega^y.-r = -\omega^y.r$, $\omega^1.1 = \omega$, $\omega.\frac{1}{2} = \frac{\omega}{2}$, $\omega^{-y} = \frac{1}{\omega^y}$, and so on, in accordance with standard practice.)

As is well known, in virtue of a celebrated theorem due to Cantor (1897) and Hessenberg (1906), every ordinal has a unique *Cantor normal form*, i.e., a unique representation of the form

$$\sum_{\alpha<n}^{c}\omega^{\cdot_c y_\alpha}.{}_c a_\alpha$$

where $\{y_\alpha : \alpha < n\}$ is a (possibly empty) finite descending sequence of ordinals, $\{a_\alpha : \alpha < n\}$ is a sequence of nonzero finite ordinals, and the "c" affixed to the various operations indicates that the operations are the familiar Cantorian operations on ordinals. The following result shows, among other things, that Conway names of surreal numbers generalize the Cantor normal forms of ordinals.

Theorem 12 (Conway 1976; Ehrlich 2001) *Every surreal number has a Conway name; distinct surreal numbers have distinct Conway names; moreover, the formal expression*

$$\sum_{\alpha<\beta}\omega^{y_\alpha}.r_\alpha$$

is the Conway name of some surreal number if and only if $\{y_\alpha : \alpha < \beta \in On\}$ is a (possibly empty) descending sequence of members of **No** *and $\{r_\alpha : \alpha < \beta\}$ is a sequence of nonzero real numbers, the Conway name of an ordinal being its Cantor normal form.*

Conway names provide highly perspicuous representations of surreal numbers. $\omega - \pi$ is indeed the surreal number obtained by subtracting π from ω, $\frac{\omega}{2}$ is ω divided by 2, $\frac{1}{\omega}$ is the multiplicative inverse of ω as well as the cube root of $\frac{1}{\omega^3}$, $\omega^\omega + \omega.2 + 1$ and $\sqrt{2}$ are the ordinal and real number, respectively, so named, and so on. Even Conway names indexed over all $\alpha <$ some infinite limit ordinal β encode significant

algebraico-tree-theoretic information about the surreal numbers they denote (e.g., Ehrlich 2001, Theorem 15 (iii)).

Besides providing perspicuous representations, Conway names make surreal numbers more tractable from an algebraic point of view. Indeed, when surreal numbers are denoted by their respective Conway names, the basic field operations can be performed on them analogously to the familiar operations on polynomials as can the familiar ordering of elements by first-differences, the identification of multiplicative inverses, and the extraction of n-th roots. In the case of addition and multiplication, in particular, the operations are the familiar polynomial operations where terms having a common exponent are added by the rule

$$\omega^x.a +_H \omega^x.b = \omega^x.(a+b)$$

where $a + b$ is the ordinary sum of real numbers, and the product of an arbitrary pair of terms is given by

$$\omega^x.a \cdot_H \omega^y.b = \omega^{x +_H y}.ab$$

where ab is the ordinary product of real numbers and $x +_H y$ is the aforementioned sum. So, for example, given two surreal numbers $\omega - \frac{1}{2}$ and $1 + \frac{1}{\omega}$, their sum is given by $\omega + \frac{1}{2} + \frac{1}{\omega}$ and their product by $\omega - \frac{1}{2} + \frac{1}{\omega.2}$. Moreover, $1 + \frac{1}{\omega} < \omega - \frac{1}{2}$ since at the first corresponding term in which $\omega^1.0 + \omega^0.1 + \omega^{-1}.1$ and $\omega^1.1 + \omega^0.-\frac{1}{2} + \omega^{-1}.0$ differ (i.e., $\omega^1.0$ and $\omega^1.1$) $0 < 1$.

Underwriting the preceding observations regarding the representational and algebraic virtues of Conway names is the following result where the operations $+_H$ and $\cdot_H$ are defined on, and the relation $<_H$ is defined between, surreal numbers denoted by their respective Conway names (supplemented with "dummy" terms with zeros for coefficients to permit a uniform representation of all surreal numbers).

Theorem 13 (Conway 1976; Ehrlich 2001) $\langle \mathbf{No}, +_H, \cdot_H, <_H, <_s, 0, 1\rangle = \langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$, *when* $+_H$, $\cdot_H$, *and* $<_H$ *are defined as follows:*

$$\sum_{y \in \mathbf{No}} \omega^y.a_y +_H \sum_{y \in \mathbf{No}} \omega^y.b_y = \sum_{y \in \mathbf{No}} \omega^y.(a_y + b_y),$$

$$\sum_{y \in \mathbf{No}} \omega^y.a_y \cdot_H \sum_{y \in \mathbf{No}} \omega^y.b_y = \sum_{y \in \mathbf{No}} \omega^y.\left[\sum_{\mu +_H \nu = y} a_\mu b_\nu\right],$$

$$\sum_{y \in \mathbf{No}} \omega^y.a_y <_H \sum_{y \in \mathbf{No}} \omega^y.b_y, \text{ if } a_y = b_y \text{ for all } y > \text{some } x \in \mathbf{No} \text{ and } a_x < b_x.$$

When restricted to ordinals, $+_H$ and $\cdot_H$ are not the familiar noncommutative sums and products of Cantor, but rather the so-called *natural sums* and *natural products* of

ordinals due to Hessenberg (1906) and Hausdorff (1927), respectively, and $<_H$ is the standard ordering of ordinals (written in *Cantor normal form*) by first-differences (e.g., Ehrlich 2006, pp. 24–25). The subscript "*H*" affixed to the symbols denoting the field operations and the ordering relation, however, is not a tribute to Hessenberg and Hausdorff. After all, Cantor normal forms of ordinals are always indexed over finite ordinals. Rather, the subscripts are in honor of Hans Hahn (1907), whose corresponding field operations and ordering relation defined on transfinite power series are the *loci classici* for the types of operations and ordering relation defined in Theorem 13. In fact, Theorems 12 and 13 essentially show that **No**, considered as an ordered field, is isomorphic to the *On*-restricted Hahn field $\mathbf{R}((\mathbf{No}))_{On}$ of formal power series with coefficients in the ordered field **R** and exponents in **No** considered as an ordered additive group (Alling 1987; Ehrlich 1988, 2001).

10 The Ordered Field of Surreal Numbers

Following Emil Artin and Otto Schreier (1926), an ordered field *A* may be said to be *real-closed* if it admits no extension to a more inclusive ordered field that results from supplementing *A* with solutions to polynomial equations with coefficients in *A*. Intuitively speaking, real-closed ordered fields are precisely those ordered fields having no "holes" that can be filled by algebraic means alone. The ordered field of real numbers is the paradigmatic real-closed ordered field; indeed, it was the desire to capture the algebraic theory of the reals that motivated the development of Artin and Schreier's theory (Sinaceur 1994). Among a number of important properties of **R** they showed are satisfied by real-closed ordered fields more generally is the *intermediate value theorem for polynomials of a single variable*. In fact, as soon became clear, for an ordered field *A*, the satisfaction of the intermediate value theorem for polynomials of a single variable over *A* is equivalent to *A* being real-closed (e.g., Tarski 1939; Warner 1965, pp. 492–493). Accordingly, the idea of a real-closed ordered field is equivalent for the case of polynomials of a single variable to satisfying what has traditionally been regarded as one of the quintessential properties of a continuous function – the formalization of the intuitive idea that a continuous curve connecting points on the opposite sides of a straight line intersects the given line. Tarski (1948) also shed important model-theoretic light on Artin and Schreier's algebraic conception by showing that real-closed ordered fields are precisely the ordered fields that are first-order indistinguishable from the ordered field of reals. For this reason, they are sometimes called *elementary arithmetic continua*.

Like **R**, **No** is real-closed (Conway 1976). However, since there is a multitude of real-closed ordered fields, it is natural to inquire if, like **R**, it is possible to distinguish **No** (to within isomorphism) from the remaining real-closed ordered fields by appealing solely to its order. As we shall now see, the following definition, which

embodies the order-theoretic content of the above-mentioned idea of a complete lexicographically ordered binary tree, enables one to do just that.

Definition 7 (Ehrlich 1988) An ordered class $\langle A, < \rangle$ is said to be an *absolute linear continuum* if for all subsets L and R of A where $L < R$ there is a $y \in A$ such that $L < \{y\} < R$.

In (Ehrlich 1988, 1992, 1994) and a number of other early works, we refer to absolute linear continua as η_{On}*-orderings* because they extend to proper classes Hausdorff's (1907, 1909) idea of an η_α*-ordering of power* $\aleph_\alpha$, i.e., an ordered set A of power $\aleph_\alpha$ such that for all subsets L and R of A where $L < R$ and $|L|, |R| < \aleph_\alpha$ there is a member of A lying strictly between those of L and those of R. In a number of earlier works (Ehrlich 1987, p. 243; 1992, p. 172; 1994, p. xxvii), we also described the property expressed in the definition of an absolute linear continuum as a condition of absolute density. However, we subsequently came to believe it is more appropriate and more revealing to split the condition into two conditions in the following fashion, where one of the conditions, which is a more restricted sense of absolute density, is now called "absolute density."

An absolute linear continuum $\langle A, < \rangle$ is both *absolutely dense* in the sense that for each pair of *nonempty* subsets L and R of A where $L < R$, there is a $y \in A$ such that $L < \{y\} < R$, and *absolutely extensive* in the sense that given any subset L of A there are $a, b \in A$ such that $\{a\} < L < \{b\}$. In fact, since in the definition of an absolute linear continuum L or R may be empty, one can readily show that an ordered class is an absolute linear continuum if and only if it has both of the just-stated properties. Thus, since every element of an ordered class must either lie between two of its nonempty subclasses or lie to the right or to the left of some (possibly empty) subclass, absolute linear continua are ordered classes having *no order-theoretic limitations that are definable in terms of sets of standard set theory.*

In the first installment of his *Contributions to the Founding of the Theory of Transfinite Numbers*, Cantor (1895, Sect. 11) provided an order-theoretic characterization of the classical linear continuum. The following is the analog for absolute linear continua of Cantor's result.

Theorem 14 (Ehrlich 1988) $\langle \mathbf{No}, < \rangle$ *is (up to isomorphism) the unique absolute linear continuum.*

Unlike the ordered field of reals, however, the ordered field of surreal numbers is not distinguished (up to isomorphism) from other ordered fields by its structure as an ordered class. Indeed, there are infinitely many pairwise nonisomorphic ordered fields that are absolute linear continua. In fact, since every α-saturated ordered field is an η_α-ordering, to obtain such an ordered field one need only form the union of a continuous chain A_α ($\alpha < On$) of ordered fields where A_0 is not real-closed and $A_{\alpha+1}$ is an $\alpha + 1$-saturated elementary extension of A_α for each α (e.g., Chang and Keisler 1990, ch. 5). Happily, however, what one can prove is:

Theorem 15 (Ehrlich 1988, Lemma 2) $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$ *is (up to isomorphism) the unique real-closed ordered field that is an absolute linear continuum.*

In virtue of Theorem 15, **No** is not only devoid of set-theoretically defined order-theoretic limitations, but also it is devoid of algebraic limitations; moreover, to within isomorphism, it is the unique ordered field that is devoid of both types of limitations. That is, **No** not only exhibits *all possible algebraic and set-theoretically defined order-theoretic gradations consistent with its structure as an ordered field*, it is to within isomorphism the unique structure that does. It is ultimately this together with a number of closely related results that underlies our contention that **No** may be naturally regarded as an absolute arithmetic continuum (modulo NBG).

Whereas every absolute linear continuum is absolutely dense, there is a vast array of absolutely dense ordered classes that are not absolute linear continua. Simple examples are the semiopen and nondegenerate closed intervals of absolute continua. While these ordered classes are absolutely dense, they are not absolutely extensive. More distinguished examples are the convex proper subrings of **No** (Ehrlich and Kaplan 2018, Theorem 7.2 and pp. 15–16). On the other hand, there is no absolutely dense ordered field that is not an absolute linear continuum. To demonstrate this, we make use of the following definitions which are straightforward extensions for ordered classes of definitions for ordered sets due to Hausdorff (1914, ch VI; also see Harzheim 2005, pp. 77–79).

A subclass Y of an ordered class X is said to be *cofinal* (*coinitial*) with X if for each $x \in X$ there is a $y \in Y$ such that $y \geq x$ ($y \leq x$). Moreover, an ordered class X is said to have *cofinal character* α (*coinitial character* α) if α is the least ordinal $\leq On$ such that there is a cofinal (coinitial) subclass of X that is isomorphic with α (α^*), where α^* is the inverse of α. In addition, if x is a member of an ordered class X, then x is said to have *character* (α, β) if $\{y \in X : y < x\}$ has cofinal character α and $\{y \in X : y > x\}$ has coinitial character β.

Lemma 1 *An ordered field is an absolute linear continuum if and only if it is absolutely dense.*

Proof Let A be an absolutely dense ordered field. By results of Roman Sikorski (1948, pp. 74–75: (ii), (iii), (v)), which readily extend from sets to classes, if x is a member of an ordered field A, then x has character (α, α), where α is both the cofinal and coinital character of A. Accordingly, to prove the nontrivial portion of the lemma, it suffices to show that the coinital character of the additive identity 0_A of A is On. For this purpose, suppose the coinital character of 0_A is $<On$. Then there is a cointial subset B of $A^+ = \{x \in A : x > 0_A\}$. And so, by absolute density, there is an $x \in A$ such that $\{0_A\} < \{x\} < B$, and hence since B is a cointial subset of A^+, $\{0_A\} < \{x\} < A^+$, which is impossible.

Accordingly, in light of Theorem 15 and Lemma 1, we have:

Theorem 16 $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$ *is (up to isomorphism) the unique absolutely dense real-closed ordered field.*

11 Arithmetic Continua: Archimedean and Absolute

An ordered field A is said to be *Archimedean* if whenever a and b are positive members of A where $a < b$, there is a positive integer n such that $na > b$; if A is not Archimedean, it is said to be *non-Archimedean*. Since every ordered field A contains a unique isomorphic copy $\mathbf{Q}_A$ of the ordered field of rational numbers, an element a of A may be said to be infinitesimal if $|a|$ is less than every positive member of $\mathbf{Q}_A$ and it may be said to be infinite if $|a|$ is greater than every positive member of $\mathbf{Q}_A$. An ordered field is Archimedean if and only if it contains neither infinite nor nonzero infinitesimal elements. Non-Archimedean ordered fields, by contrast, contain infinite as well as nonzero infinitesimal elements, the latter being the multiplicative inverses of the former. The zero of the field is the sole infinitesimal member of an Archimedean ordered field.

Before concluding our discussion of $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$, we wish to shed a bit more light on its inclusiveness as an ordered field, its relation to the classical *Archimedean arithmetic continuum* $\langle \mathbf{R}, +, \cdot, <, 0, 1\rangle$, and its amorphousness as a system of numbers great and small.

To begin with, every categorical characterization of the ordered field of surreal numbers expresses in one way or another just how rich in types of numbers great and small **No** really is. Unlike the ones offered in Theorems 15 and 16, the two provided in Theorem 17 below are of a model-theoretic nature. The first is based upon

Definition 8 (**Ehrlich 1987, 1988**) An ordered field A is said to be universally extending if for each ordered subfield B of A of power $<On$ and each ordered field A' extending B, there is an isomorphism $f: A' \rightarrow A$ that is an extension of the identity map on B.

Intuitively speaking, A is a universally extending ordered field if every possible way of enriching the ordered field-theoretic gradations of an ordered subfield B of A that is consistent with NBG is already (isomorphically) realized as an extension of B in A, if the universe of B is a set. The reader will notice that insofar as every ordered field is an extension of the ordered field of rationals, every universally extending ordered field contains an isomorphic copy of every ordered field. There is, however, a plethora of ordered fields that are inclusive in this sense but are not universally extending. However, as we shall shortly see, the following definition provides the means to distinguish between the universally extending ordered fields and those that are "merely" universal.

Definition 9 (**Ehrlich 1987, 1988**) *An ordered field A is said to be homogeneous-universal if it is universal – every ordered field can be embedded in A, and it is homogeneous – every isomorphism between ordered subfields B and B′ of A of power <On can be extended to an automorphism of A.*

Since an automorphism of A is an isomorphism of A onto itself, the homogeneity condition essentially ensures that any pair of ordered subfields of A whose universes

are sets that are structurally indistinguishable have structurally indistinguishable surroundings as well. As a result, any role that can be played in A by a given ordered subfield whose universe is a set can be played equally well by any of its other isomorphic counterparts in A.

Mimicking the corresponding definitions for ordered fields, an Archimedean ordered field A is said to be *homogeneous-universal* if every Archimedean ordered field can be embedded in A and every isomorphism between ordered subfields of A can be extended to an automorphism of A; and an Archimedean ordered field A is said to be *universally extending* if for each ordered subfield B of A and each Archimedean ordered field A' extending B, there is an isomorphism $f : A' \to A$ that is an extension of the identity map on B. The reader will notice that in the above two definitions implicit use is made of the fact that every subfield of an Archimedean ordered field is itself an Archimedean ordered field whose universe is a set.

The following theorem helps to bring to the fore the intimate relation between the classical arithmetic continuum and the purported absolute arithmetic continuum considered as inclusive ordered fields.

Theorem 17 (**Ehrlich 1987, 1989a, 1992**) *(I) The following sets of axioms constitute (categorical) axiomatizations of* $\langle \mathbf{R}, +, \cdot, <, 0, 1 \rangle$*; (II) by deleting the Archimedean axiom from the following axiomatizations, one obtains categorical axiomatizations of* $\langle \mathbf{No}, +, \cdot, <, 0, 1 \rangle$.

Axioms for ordered fields.

Archimedean axiom.

Axiom of (arithmetic) homogeneous-universality,

or, alternatively,

Axiom of (arithmetic) universal extensibility,

whereby the axiom of arithmetic homogeneous-universality (universal extensibility), we mean the assertion: The collection of numbers together with the corresponding relations defined on it constitutes a homogeneous-universal (universally extending) model of the above stated axioms.

Intuitively speaking, Theorem 17 asserts that whereas $\langle \mathbf{R}, +, \cdot, <, 0, 1 \rangle$ is (up to isomorphism) the unique ordered field containing all possible types of numbers great and small modulo the Archimedean axiom, $\langle \mathbf{No}, +, \cdot, <, 0, 1 \rangle$ is (up to isomorphism) the unique ordered field containing all possible types of numbers great and small modulo NBG. We believe the axioms of arithmetic homogeneous-universality and universal extensibility may be naturally regarded as *continuity axioms* since in the context of the above axiomatizations they are equivalent to any of the more familiar continuity conditions including those due to Cantor (1872), Dedekind (1872), and Hilbert (1900, 1971). An analogous remark likewise applies to their geometric counterparts expressed in Theorem 22 below.

We hasten to emphasize, however, that the import of the homogeneity portion of the first continuity condition differs substantially from the Archimedean case to the non-Archimedean case. This is a consequence of the fact that whereas $\langle \mathbf{R}, +, \cdot, <, 0, 1 \rangle$ contains exactly one isomorphic copy of each Archimedean ordered field,

$\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$ contains a plethora of isomorphic copies of most ordered fields whose universes are sets. To be more precise, if A is an ordered field whose universe is a set and A is not isomorphic to a subfield of $\mathbf{R}_{alg}$, then $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$ contains a proper class of pairwise distinct isomorphic copies of A. Thus, whereas the homogeneity condition holds vacuously in $\langle \mathbf{R}, +, \cdot, <, 0, 1\rangle$ (since every isomorphism between subfields of **R** extends solely to the identity automorphism of **R**), it points to a genuine amorphousness in $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$ that applies not only to the members of **No** outside of $\mathbf{R}_{alg}$ but also to a vast array of subfields of **No** as well.

In the following section, we will see that as striking as the relation between the Archimedean and absolute arithmetic continua is, the relation between the *s-hierarchical Archimedean arithmetic continuum* and the *s-hierarchical absolute arithmetic continua* is more striking still.

12 S-Hierarchical Arithmetic Continua: Archimedean and Absolute

As we alluded to above, an ordered field is Archimedean if and only if it is isomorphic to a subfield of **R**. That is, **R** is up to isomorphism the unique universal Archimedean ordered field. **R** is also (up to isomorphism) the unique *nonextensible* Archimedean ordered field, the condition of maximality or of nonextensibility being Hilbert's (1900, 1971, p. 45) classical continuity condition. Analogs of these results, however, fail to hold for **No** considered as an ordered field (Ehrlich 2001, Proposition 3). On the other hand, as Theorems 6, 7, and 8 show, analogous results do in fact hold for the s-hierarchical counterparts of $\langle \mathbf{R}, +, \cdot, <, 0, 1\rangle$ and $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$. This being the case, the latter results may be encapsulated as follows, where if A is an s-hierarchical Archimedean ordered field (resp. s-hierarchical ordered field), then A is said to be *universal* if every s-hierarchical Archimedean ordered field (resp. s-hierarchical ordered field) is isomorphic to an initial subfield of A, and A is said to be *maximal* (or *nonextensible*) if there is no s-hierarchical Archimedean ordered field (resp. s-hierarchical ordered field) that properly contains A as an initial subfield.

Theorem 18 (Ehrlich 2001) *(I) The following sets of axioms constitute (categorical) axiomatizations of* $\langle \mathbf{R}, +, \cdot, <, <_s, 0, 1\rangle$*; (II) by deleting the Archimedean axiom from the following axiomatizations, one obtains categorical axiomatizations of* $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$.

Axioms for s-hierarchical ordered fields.

Archimedean axiom.

Axiom of s-hierarchical universality,

or, alternatively,

Axiom s-hierarchical maximality,

whereby the axiom of s-hierarchical universality (axiom of s-hierarchical maximality), we mean the assertion: The collection of numbers together with the

corresponding relations defined on it constitutes a universal (maximal) model of the above-stated axioms.

Unlike Archimedean ordered fields, not every ordered field is isomorphic to an initial subfield of **No**. On the other hand, every ordered field has a theoretically distinguished extension to an ordered field that is. More specifically, by a classical result of Artin and Schreier (1926), every ordered field A has (up to isomorphism) a unique *real-closure*, i.e., a smallest real-closed ordered field containing A. If A is itself real-closed, then A is its own real-closure, otherwise the real-closure of A is a (cardinality preserving) proper extension of A. Accordingly, while the following result does not expose the full range of initial subfields of **No**, it shows that the spectrum of initial subfields of **No** encompasses a class that is as theoretically significant as it is robust.

Theorem 19 (**Ehrlich 2001**) *Every real-closed ordered field (*i.e.*, elementary arithmetic continuum) is isomorphic to an initial subfield of* **No**.

Since the initial subfields of **No** emerge by recursion from the empty set of surreal numbers, Theorem 19 tells us that every real-closed ordered field, beginning with $\mathbf{R}_{alg}$ and terminating with **No**, unfolds by recursion as the surreal numbers themselves unfold. While some of these elementary continua, including $\mathbf{R}_{alg}$, **R**, and **No**, recursively unfold in precisely one way, there are initial real-closed subfields of **No** that are isomorphic as ordered fields though not isomorphic as s-hierarchical ordered fields.

For the full spectrum of ordered fields that are isomorphic to initial subfields of **No**, see (Ehrlich 2001, Theorem 18; 2012, Theorem 14; Ehrlich and Kaplan 2021, Theorem 8.1).

As we have already seen, $\langle \mathbf{No}, +, \cdot, <, 0, 1\rangle$ is up to isomorphism the unique absolutely dense real-closed ordered field. This result does not take into account the s-hierarchical nature of **No**. We draw this section to a close by observing that when this aspect of **No** is taken into account the elementary arithmetic nature of **No** can be omitted from the characterization.

Theorem 20 $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$ *is up to isomorphism the unique absolutely dense s-hierarchical ordered field.*

Proof In virtue of Theorems 6 and 16, $\langle \mathbf{No}, +, \cdot, <, <_s, 0, 1\rangle$ is an absolutely dense s-hierarchical ordered field. For the converse, first observe that by Lemma 1 an absolutely dense s-hierarchical ordered field is an absolute linear continuum. Furthermore, by Theorem 4 and the definition of a complete lexicographically ordered binary tree, a lexicographically ordered binary tree is an absolute linear continuum if and only if it is complete if and only if it is isomorphic to $\langle \mathbf{No}, <, <_s\rangle$. Accordingly, to complete the proof, it suffices to note that in virtue of Theorem 7: (i) The only s-hierarchical mapping of $\langle \mathbf{No}, <, <_s\rangle$, and, hence, an isomorphic copy thereof, into

$\langle \mathbf{No}, <, <_s \rangle$ is a surjection, and (ii) the s-hierarchical mapping is an embedding of ordered fields.

13 Euclidean Geometric Continua: Archimedean and Absolute

Whereas Theorem 17 may be regarded as providing comparative categorial characterizations of **R** and **No** considered as arithmetic continua, Theorem 18 may be regarded as providing comparative categorial characterizations of **R** and **No** considered as s-hierarchical arithmetic continua. In this section, we provide the Euclidean analog of Theorem 17.

The relation between **No** and Euclidean geometry can be fleshed out using any of the standard Euclidean geometrical frameworks. For our purpose here, however, Tarski's system $\mathcal{P}$ (Tarski 1959; Schwabhäuser et al. 1983) provides an especially convenient formulation.

In Tarski's system $\mathcal{P}$, which is formulated in the first-order predicate calculus with "=" treated as logical identity, only points are treated as individuals and the only nonlogical predicates employed in the axioms are a ternary predicate B (where "$Bxyz$" is read *y lies between x and z* – the case when y coincides with x or z not being excluded) and a quarternary predicate $\equiv$ (where "$xy \equiv zu$" is read *x is as distant from y as z is from u*). Over the years, Tarski's system of axioms for $\mathcal{P}$ has undergone substantial evolution (Tarski and Givant 1999), culminating in a set of ten axioms (e.g., Schwabhäuser et al. 1983; Ehrlich 1997, p. 61) that are collectively equivalent to Hilbert's classical axioms of order, incidence, congruence, and parallelism (1899, 1971). That is, Tarski's system of axioms for $\mathcal{P}$, henceforth A_1–A_{10}, is equivalent to Hilbert's system of axioms for Euclidean geometry save Hilbert's continuity axioms – the axioms that limit the models of Hilbert's other axioms to isomorphic copies of classical Cartesian geometry over **R**. In place of the latter axioms, Tarski supplements A_1–A_{10} with an *elementary continuity scheme*, henceforth A_{11}, that restricts the models of A_1–A_{10} to those that are elementary equivalent to classical Cartesian geometry over **R**. The resulting system of geometry based on A_1–A_{11}, henceforth $\mathcal{E}$, is referred to as *complete elementary Euclidean geometry* in virtue of the completeness of $\mathcal{E}$.

To simplify readability, the strings of universal quantifiers that precede A_1–A_{11} are deleted below.

A_1. *Reflexivity axiom for equidistance.*

$$ab \equiv ba.$$

A_2. *Transitivity axiom for equidistance.*

$$ab \equiv pq \wedge ab \equiv rs \rightarrow pq \equiv rs.$$

A_3. *Identity axiom for equidistance.*

$$ab \equiv cc \rightarrow a = b.$$

A_4. *Axiom of segment construction.*

$$\exists x(Bqax \wedge ax \equiv bc).$$

A_5. *Five-segment axiom.*

$$a \neq b \wedge Babc \wedge Ba'b'c' \wedge ab \equiv a'b' \wedge bc \equiv b'c' \wedge ad \equiv a'd' \wedge bd \equiv b'd' \rightarrow cd \equiv c'd'.$$

A_6. *Identity axiom for betweenness.*

$$Baba \rightarrow a = b.$$

A_7. *Pasch's axiom.*

$$Bapc \wedge Bbqc \rightarrow \exists x(Bpxb \wedge Bqxa).$$

A_8. *Lower dimension axiom.*

$$\exists a \exists b \exists c(\neg Babc \wedge \neg Bbca \wedge \neg Bcab).$$

A_9. *Upper dimension axiom.*

$$p \neq q \wedge ap \equiv aq \wedge bp \equiv bq \wedge cp \equiv cq \rightarrow Babc \vee Bbca \vee Bcab.$$

A_{10}. *Euclid's parallel axiom.*

$$Badt \wedge Bbdc \wedge a \neq d \rightarrow \exists x \exists y(Babx \wedge Bacy \wedge Bxty).$$

A_{11}. *Elementary continuity schema.* All sentences in the language $\equiv$, B of the form:

$$\exists a \forall x \forall y(\phi(x) \wedge \psi(y) \rightarrow Baxy) \rightarrow \exists b \forall x \forall y(\phi(x) \wedge \psi(y) \rightarrow Bxby),$$

where φ and ψ are first order formulas in which the variables a, b, y do not occur in φ and the variables a, b, x do not occur in ψ.

Unlike $A_1 - A_{10}$, A_{11} is entirely modern in conception; roughly speaking, it is the infinite set of assertions obtained from the following formulation of the Dedekind continuity condition due to Tarski that results by replacing the explicit references to arbitrary sets of points X and Y with implicit references to those sets which are definable in the language $\equiv$, B by first order means.

Dedekind Continuity Axiom

$$\forall X \forall Y(\exists a \forall x \forall y(x \in X \wedge y \in Y \rightarrow Baxy) \rightarrow \exists b \forall x \forall y(x \in X \wedge y \in Y \rightarrow Bxby)).$$

The version of the Archimedean axiom appropriate for $\mathcal{E}$ is given by the following assertion from (Ehrlich 1997):

Archimedean Axiom.

Whenever Ba_0a_1c, *there is a finite set of points* $a_0, \ldots, a_n$ *such that* $a_0a_1 \equiv a_ia_{i+1}$ *and* $Ba_{i-1}a_ia_{i+1}$ *for all* $1 \leq i < n$ *and* Ba_1ca_n.

The conception that bridges the gap between the domains of number and Euclidean magnitude is the classical notion of a Cartesian space over an ordered field. In the most recent version of Tarski's framework (Schwabhäuser et al. 1983), this familiar concept assumes the following simple form.

A *Cartesian space* $C_2(F)$ *over an ordered field* $\langle F, +, \cdot, \leq \rangle$ is a structure $\langle A_F, B_F, \equiv_F \rangle$ where the relations B_F and $\equiv_F$ are defined on $A_F = \{(x_1, x_2) : x_1, x_2 \in F\}$ by the stipulations:

$$B_F\, xyz \text{ if and only if there is a } \lambda \in F \text{ for which}$$

$$0 \leq \lambda \leq 1 \text{ and } y_\alpha - x_\alpha = \lambda(z_\alpha - x_\alpha) \text{ for } \alpha = 1, 2;$$

$$xy \equiv_F uv \text{ if and only if } \sum_{\alpha=1}^{2} (x_\alpha - y_\alpha)^2 = \sum_{\alpha=1}^{2} (u_\alpha - v_\alpha)^2.$$

The relation between Cartesian spaces and models of $\mathcal{E}$ is given by the following classical result due to Tarski (1948, 1959).

Representation Theorem. M is a model of $\mathcal{E}$ if and only if M is isomorphic to $C_2(F)$ for some real-closed ordered field F.

To prove the representation theorem, Tarski first shows that a Cartesian space over a real-closed ordered field is elementary equivalent to $C_2(\mathbf{R})$, which is known to be a model of $\mathcal{E}$. And his proof of the converse essentially consists of two components, the first of which is an appeal to what may be called *the fundamental lemma of elementary Cartesian geometry*: If o and e are distinct points in a model $M = \langle A, B, \equiv \rangle$ of $\mathcal{P}$ and l is the line in M through o and e, then by letting o and e serve as the zero and unit, respectively, and by appealing to the Euclidean theory of proportions which can be derived from $\mathcal{P}$, one can define (in terms of the relations B and $\equiv$) operations $+_l$ and $\cdot_l$ on, and a relation $\leq_l$ between, any two points of l so that the resulting structure $F^l_{oe}(M) = \langle l, +_l, \cdot_l, \leq_l, o, e \rangle_M$ is an ordered field (that is, to within isomorphism, independent of the choices of l, o, and $e \neq o$). Employing $F^l_{oe}(M)$ together with lines l and l' and point e', where l and l' are perpendicular and have the point o in common and e' is the point on l' such that $oe \equiv oe'$, one introduces a system of Cartesian coordinates and determines the distance between pairs of points in accordance with the Pythagorean Theorem, and shows more generally: There is an isomorphism – henceforth *the coordinatization mapping* – from M onto $C_2\left(F^l_{oe}(M)\right)$. To complete the proof, it is shown that since the elementary continuity scheme holds in

M, $F^l_{oe}(M)$ is real-closed (Tarski 1959, pp. 21–22; Schwabhäuser et al. 1983, pp. 144–145). Without the elementary continuity scheme, one can only show that $F^l_{oe}(M)$ is a *Pythagorean ordered field*, i.e., an ordered field in which $\sqrt{a^2+b^2}$ is in the field whenever a, b are in the field.

The ordered field $F^l_{oe}(M)$, or any isomorphic copy thereof, may be said to be the *characteristic field* of M. Since every ordered field has (up to isomorphism) a unique real-closure, if M is a model of $\mathcal{P}$ then there is (up to isomorphism) a least model M' of $\mathcal{E}$ containing M, which may be said to be the $\mathcal{E}$-*closure* of M; moreover, the characteristic field of M' is a real-closure of the characteristic field of M. In particular, if $C_2\left(F^l_{oe}(M)\right)$ is a model of $\mathcal{P}$, there is (up to isomorphism) a unique $\mathcal{E}$-closure $C_2\left(F^{l'}_{oe}(M')\right)$ of $C_2\left(F^l_{oe}(M)\right)$ where $F^{l'}_{oe}(M')$ is a real closure of $F^l_{oe}(M)$, insofar as the two points o and e determine l' as well as l, since $l \subseteq l'$.

Since **No** is (up to isomorphism) the unique real-closed ordered field that is an absolute linear continuum, it is evident from the above and Lemma 1 that if M is a model of $\mathcal{E}$, then to ensure that its characteristic field is isomorphic to **No** it suffices to ensure that its characteristic field is itself an absolute linear continuum. This may be accomplished by supplementing the axioms for $\mathcal{E}$ with the following variation of Tarski's version of the Dedekind continuity axiom in which X and Y are understood to range over sets.

A_{12}. *Absolute Continuity Axiom* (Ehrlich 1987).

$$\forall X \forall Y[\exists a \forall x \forall y(x \in X \wedge y \in Y \rightarrow Baxy \wedge x \neq y) \rightarrow$$
$$\exists b \forall x \forall y(x \in X \wedge y \in Y \rightarrow Bxby \wedge b \neq x \wedge b \neq y)].$$

Indeed, using A_{12} in conjunction with A_1–A_{11} and Tarski's aforementioned representation theorem, one may prove the following result which the author stated without proof in (Ehrlich 1987).

Theorem 21 *A model M of $\mathcal{E}$ satisfies the absolutely continuity axiom if and only if M is isomorphic to C_2(**No**).*

Proof Let M be a model of $\mathcal{E}$, l be a line in M with distinct points o and e, and $F^l_{oe}(M)$ be the characteristic field of M. Further suppose X and Y are nonempty subsets of l for which $X < Y$, and let X' be a cofinal subset of X having a least member, say p. Such an X' plainly exists and $\{p\} \leq X' \leq Y'$, which implies $\exists a \forall x \forall y(x \in X' \wedge y \in Y \rightarrow Baxy \wedge x \neq y)$. Now suppose M satisfies A_{12}. Then $\exists b\, \forall x\, \forall y(x \in X' \wedge y \in Y \rightarrow Bxby \wedge b \neq x \wedge b \neq y)$. But then $X' < \{p'\} < Y$ for some $p' \in l$, which implies $X < \{p'\} < Y$ since X' is cofinal with X. This implies l is absolutely dense with respect to $<$, and, hence by Theorem 16, $F^l_{oe}(M)$ is isomorphic to **No**, which implies M is isomorphic to C_2(**No**). For the converse, suppose M is isomorphic to C_2(**No**), which implies l is an absolute linear continuum with respect to $<$. Then l is absolutely extensive with respect to $<$, which implies $\{p'\} < X < Y$ for some $p' \in l$ and, hence, $\exists a\, \forall x\, \forall y(x \in X \wedge y \in Y \rightarrow Baxy \wedge x \neq y)$. But this combined with absolute

density implies $\exists b\, \forall x\, \forall y(x \in X \wedge y \in Y \rightarrow Bxby \wedge b \neq x \wedge b \neq y)$ and, hence, the absolutely continuity axiom.

The following result, which was announced in (Ehrlich 1987) in anticipation of (Ehrlich 1989a, 1992), is the above-mentioned Euclidean analog of Theorem 17, where the Euclidean analogs of the concepts of a homogeneous-universal ordered field (resp. Archimedean ordered field) and of a universally extending ordered field (resp. Archimedean ordered field) are defined in the expected manners.

Theorem 22 *(I) The following sets of axioms constitute (categorical) axiomatizations of* $C_2(\mathbf{R})$*; (II) by deleting the Archimedean axiom from the following axiomatizations, one obtains categorical axiomatizations of* $C_2(\mathbf{No})$.

Axioms for complete elementary Euclidean geometry ($\mathcal{E}$*).*

Archimedean axiom.

Axiom of (geometric) homogeneous-universality,

or, alternatively,

Axiom of (geometric) universal extensibility,

whereby the axiom of geometric homogeneous-universality (geometric universal extensibility), we mean the assertion: The collection of points together with the corresponding relations defined on it constitutes a homogeneous-universal (universally extending) model of the above-stated axioms.

Proof (*Archimedean case*). Let M be an Archimedean model of $\mathcal{E}$, o and e be distinct points on a line l of M, and $F^l_{oe}(M)$ be the characteristic field of M generated by the choice of o and e. Since M is Archimedean, so is $F^l_{oe}(M)$, and hence there is a unique isomorphism f of $F^l_{oe}(M)$ onto a subfield of $\mathbf{R}$, say, A. But then f induces an isomorphism g of M onto $C_2(A) \subseteq C_2(\mathbf{R})$, which suffices to show $C_2(\mathbf{R})$ is a universal Archimedean model of $\mathcal{E}$. Now suppose M and M' are models of $\mathcal{E}$ such that $M, M' \subseteq C_2(\mathbf{R})$ and let f be an isomorphism from M onto M'. Further let l and l' be lines in M and M', respectively, where l' is the image of g, g being the restriction of f to l. Moreover, let $l_{\mathbf{R}}$ and $l'_{\mathbf{R}}$ be the lines in $C_2(\mathbf{R})$ that respectively extend l and l', let o and e be distinct points on l, and let o' and e' be the images of o and e under g. Then g is an isomorphism from $F^l_{oe}(M)$ onto $F^{l'}_{o'e'}(M')$, and there is a unique g' extending g that is an isomorphism from $F^{l_{\mathbf{R}}}_{oe}(M)$ onto $F^{l'_{\mathbf{R}}}_{o'e'}(M)$, the uniqueness following from the Archimedean nature of the structures. But g' induces an automorphism f' of $C_2(\mathbf{R})$ that is an extension of f, which establishes $C_2(\mathbf{R})$ is homogeneous. To complete the Archimedean portion of the proof, it suffices to observe: If a theory T has a homogeneous-universal model whose universe is a set, then A is a homogeneous-universal model of T if and only if A is a universally extending model of T, and any two universal models of T are isomorphic (Ehrlich 1992, p. 170: (iv)).

(*Absolute case*). By results of the author (Ehrlich 1989a; also see 1992, p. 171: (v)): If T is an $\forall\exists$-theory with an infinite model that satisfies the joint embedding and

amalgamation properties for models whose universes are sets, then T has up to isomorphism a unique homogeneous-universal model; moreover, a model of T is homogeneous-universal if and only if it is universally extending. Accordingly, since $\mathcal{E}$ is an $\forall\exists$-theory (Tarski 1948, 1959) with infinite model $C_2(\mathbf{No})$, to complete the proof it suffices to show that $C_2(\mathbf{No})$ has the following two properties:

Universality for set-models: *For any set-model M of $\mathcal{E}$ (in the language B, $\equiv$), there is an embedding $f : M \to C_2(\mathbf{No})$.*

Amalgamation for set-models: *For any set-models of A, M, and M' of $\mathcal{E}$ in the language B, $\equiv$ and embeddings $f : A \to M$ and $f' : A \to M'$, there are embeddings $g : M \to C_2(\mathbf{No})$ and $g' : M' \to C_2(\mathbf{No})$ such that $gf = g'f'$.*

The proof essentially shows that universality and amalgamation, which hold for **No** with respect to real-closed fields and ordered fields more generally (Ehrlich 1989a, 1992), transfer to $C_2(\mathbf{No})$.

(*Universality*). Let M be a set-model of $\mathcal{E}$, l be a line in M, and o, e be distinct points on l. To prove universality for set-models, it suffices to note that since **No** is a universal ordered field there is an embedding of $f : F^l_{oe}(M) \to \mathbf{No}$ which induces a canonical coordinatization mapping $g : C_2\left(F^l_{oe}(M)\right) \to C_2(\mathbf{No})$.

(*Amalgamation*). Let A, M, M', f, f' be as specified above, let a, b be distinct points in A, and let $F_{ab}(A)$ be the characteristic field of A. Further, let $F^l_{oe}(M)$ and $F^{l'}_{o'e'}(M')$ be characteristic fields of M and M' where o and e are the images under f of a and b and o' and e' are the images under f' of a and b, and let k and k' be the restrictions of f to $F_{ab}(A)$ and f' to $F_{ab}(A)$, respectively. Notice that since isomorphisms of models of $\mathcal{P}$ preserve collinearity, $k(F_{ab}(A)) \subseteq F^l_{oe}(M)$ and $k'(F_{ab}(A)) \subseteq F^{l'}_{o'e'}(M')$. Moreover, since **No** has the analogous amalgamation property for real-closed ordered fields, there are ordered field embeddings $h : F^l_{oe}(M) \to \mathbf{No}$ and $h' : F^{l'}_{o'e'}(M) \to \mathbf{No}$ such that $hk = h'k'$, and these in turn induce canonical coordinatization mappings $g : M \to C_2\left(F^l_{oe}(M)\right) \subset C_2(\mathbf{No})$ and $g' : M' \to C_2\left(F^{l'}_{o'e'}(M')\right) \subset C_2(\mathbf{No})$ of models of $\mathcal{E}$ such that $gf = g'f'$.

Corollary 6 *Same as Theorem 22 except that the axioms for $\mathcal{E}$ are replaced with the axioms for $\mathcal{P}$.*

Proof This follows immediately from Theorem 22, the fact that every model of $\mathcal{P}$ has (up to isomorphism) a unique $\mathcal{E}$-closure and a result due to the author (1989a, Sect. 2; 1992, p. 171: (vi)).

14 Bridging the Gap between the Domains of Discreteness and of Continuity

For each Archimedean model of $\mathcal{E}$, there is an infinite array of pairwise distinct embeddings of it in $C_2(\mathbf{R})$. More strikingly still, for each model of $\mathcal{E}$ whose universe is a set, there is an entire proper class of pairwise distinct embeddings of it in $C_2(\mathbf{No})$.

In virtue of these observations and the homogeneity of $C_2(\mathbf{R})$ and $C_2(\mathbf{No})$, the highly amorphous nature of these geometric continua is can be made apparent. However, there are familiar geometrical considerations that lead to much the same conclusion regarding the points in models of $\mathcal{P}$ more generally. For example, it is well known that every *Euclidean rigid motion* (products of translations, rotations, and reflections) of a model of classical Euclidean geometry is an automorphism of the model (e.g., Greenberg 2008, ch. 9; Venema 2006, ch. 12) and that this theorem of classical geometry carries over to arbitrary models of $\mathcal{P}$ (Hartshorne 2000, pp. 148–158; Schwabhäuser et al. 1983, p. 36). The Euclidean rigid motions or *isometries* of a model $\langle A, B, \equiv\rangle$ of $\mathcal{P}$ coincide with the one-to-one onto mappings $f : A \to A$ that satisfy the condition: $ab \equiv f(a)f(b)$ for all $a, b \in A$; that is, they are precisely the distance preserving surjections of the plane (e.g., Hartshorne 2000, p. 155: problem 17.2). On the basis of this, it is easy to see that every such model has at least as many distinct nontrivial automorphisms as there are points of the space.

Some indication of the vast range of the isometries of a model $\langle A, B, \equiv\rangle$ of $\mathcal{P}$ is given by the following well-known result (e.g., Hartshorne 2000, p. 149):

(i) For any pair of points $a, a' \in A$, there is an isometry f such that $f(a) = a'$.
(ii) For any three points $o, a, a' \in A$, there is an isometry f such that $f(o) = o$ and f maps the ray $\overrightarrow{oa}$ onto the ray $\overrightarrow{oa'}$.
(iii) For any line l of A, there is an isometry f such that $f(a) = a$ for all $a \in l$ and f interchanges the points on the two sides of l.

As the qualifying phrase "some indication" suggests, the isometries referred to in (i)-(iii) above do not exhaust the isometries of $\langle A, B, \equiv\rangle$, nor for that matter do the isometries exhaust the automorphisms of $\langle A, B, \equiv\rangle$. A more general class of automorphisms of $\langle A, B, \equiv\rangle$ is the *similarities*, that is, the one-to-one onto mappings $f : A \to A$ that satisfy the condition: $f(a)f(b) \equiv kab$ for all $a, b \in A$ where k is a positive element of the characteristic field of $\langle A, B, \equiv\rangle$. These automorphisms are called "similarities" because they map every triangle of a plane onto a similar triangle. In the case of an Archimedean model of $\mathcal{P}$, the similarities coincide with the automorphisms of the model (Greenberg 2008, p. 409). If the Archimedean condition fails, however, this need not be the case (Greenberg 2008, p. 472: problem 69). Nevertheless, on the basis of (i)-(iii) alone, it is evident that, unlike the ordered field of real numbers, the s-hierarchical ordered field of surreal numbers, and the s-hierarchical real-closed subfields of the surreals more generally, models of $\mathcal{P}$ are highly amorphous indeed. Whereas the former structures are rigid, the latter admit vast arrays of nontrivial automorphisms.

Despite this critical disparity, the idea of a Cartesian space over an ordered field provides the requisite vehicle for bridging the gap between the domains of arithmetic and geometry. Indeed, much as the Cartesian space over the ordered field of real numbers succeeds in bridging the gap between the domains of number and of classical Euclidean geometry, the Cartesian space over the ordered field of surreal numbers bridges the gap between the domains of number and of absolutely

continuous elementary Euclidean geometry. Underlying this success is the fact that the analytic representations afforded by these structures are intrinsically amorphous, and rightfully so, even though the ordered field of reals and the s-hierarchical ordered field of surreals are not. It is this unsung feature of the classical scaffolding that we believe is central to the resolution of the age-old problem recounted by Fraenkel, Bar-Hillel, and Levy in the opening passages of our text. Moreover, this resolution applies more generally to the relation between the elementary arithmetic continua considered as rigid s-hierarchical structures and their amorphous (non-s-hierarchical) geometrical counterparts.

15 Postscript

Since the embrace of the Cantor-Dedekind thesis that the ordered field **R** of real numbers should be identified as the "arithmetic continuum," we have been accustom to regarding the arithmetic continuum as a strongly rigid system of numbers. By contrast, the ordered field of surreal numbers, which is arguably **R**'s most natural non-Archimedean counterpart, does not share this property. Indeed, like $C_2(\mathbf{No})$, **No** is remarkably rich in nontrivial automorphisms and nontrivial endomorphisms more generally. It is worth emphasizing, however, that **No**'s lack of rigidity, let alone strong rigidity, is not uncommon among non-Archimedean real-closed ordered fields. In fact, at present, there appears to be no known rigid non-Archimedean real-closed ordered field whose existence is provable in ZFC (Enayat 2018), and, to the best of our knowledge, the question of their existence in NBG for class-structures more generally is open as well. It was the apparent absence of examples that led Saltzman to ask if there exists such structures, and, while not settling the matter for ZFC or NBG, Saharon Shelah has shown that the existence of such structures is provable in ZFC supplemented with "suitable set theoretic hypotheses" (1983, p. 183). Nevertheless, even if Saltzman's query was found to have a positive answer in ZFC or NBG, the rigid non-Archimedean real-closed ordered fields that would evidence this would not include the real-closed fields that are central to present-day non-Archimedean mathematics, including those that have emerged in the theory of Hahn fields, nonstandard analysis, the theories of ordered exponential and differential fields, and the theory of surreal numbers. It is only suitable non-trivial relational expansions of the latter structures that could exhibit the strong rigidity that is characteristic of their Archimedean counterparts. On the basis of such considerations as simplicity, elegance, and the power of the results that can be derived therefrom, we believe it is the s-hierarchical nature (or natures) that the just-said elementary arithmetic continua inherit from their recursive unfolding in the s-hierarchical absolute arithmetic continuum of surreal numbers that is the natural candidate for this requisite additional structure, where and when it is desired.

Acknowledgments This chapter is an updated, revised, and expanded version of a portion of a paper entitled The Absolute Arithmetic Continuum that was written for the unconsummated proceedings of the conference *The Continuum in Mathematics and Philosophy*, The Carlsberg Academy, Copenhagen, Denmark, November 25–27, 2004.

Abstract

In the history of mathematical practice, geometry serves as an important focal point through which numerous changes in practice and associated (mathematical) worldviews can be studied. For instance, eighteenth century Kantian views on the synthetic a priori nature of geometry obfuscate practices of the likes of Menelaus of Alexandria who lived 16 centuries before him and are rarely mentioned. One could argue that Kant's philosophy on the nature of space (and geometry) was relational to human perception and cognition, as opposed to specific mathematical discoveries per se. Tracing a curated selection of advances in Euclidean and non-Euclidean geometry is useful to understand the mathematical practices of the ancient Greeks, and the remarkable contributions of Arab mathematicians leading to post-Renaissance advances that ushered in the modern era with the work of Grothendieck, and Busemann in the "return to Euclid."

1 Introduction

In Kant's (1781) *Critique of Pure Reason*, there are several references to Euclidean geometry as a means to support some of the arguments made by the philosopher. For Kant, geometry was a science which determined the properties of space a priori. It did not, like arithmetic, draw its concepts from the general concept of magnitude in general, but rather it was concerned with a concept of space as a magnitude given a priori, built on pure intuitions of space and time. Kant used Euclidean geometry as an example to illustrate the nature of synthetic a priori knowledge, which he argued was necessary and universally true but not derived from experience. To him, geometry provided a perfect example of such knowledge because it was a science that dealt with properties of space, and the necessary truths of geometry could be known through reason alone, without having to rely on empirical observation. Geometry based on intuitions of space and time and the pure concepts that were derived from them were called pure concepts of understanding. These concepts, such as those of point, line, and plane, were not derived from experience but were innate in human cognition. Thus, geometry served as a powerful example of how our a priori concepts and categories shape our understanding of the world and contribute to our knowledge of it. By using geometry to support his claims about pure reason, Kant attempted to show that certain types of knowledge were not derived from experience but were instead based on innate structures of the mind. In this way, he sought to demonstrate that the human mind had a capacity for knowledge that was independent of experience. Categories that structured our experience of the world and allowed us to make sense of space and time were consistent with the axioms and principles of Euclidean geometry. These concepts were thus necessary and universally true for all human beings, regardless of their particular experiences.

Another philosopher who used similar concepts was Gottfried Wilhelm Leibniz albeit in a completely different context. Leibniz's concept of "necessary truths" was similar to Kant's concept of synthetic a priori knowledge in that both involved knowledge that was not derived from experience but was instead based on inherent structures of the mind. Poincaré (1905) used the distinction between analytic and synthetic propositions in his philosophy of mathematics to argue that mathematical concepts and principles were grounded in intuition and experience, while also possessing a necessary and universal character. Note that Poincaré does not separate intuition and experience like Kant did. For him, mathematical concepts and principles were not simply derived from logic and definitions, as in the case of analytic propositions. Rather, he argued that mathematical knowledge is grounded in intuition and experience, and that this knowledge is both synthetic and a priori. It is synthetic because it involves the combination of simple ideas to form more complex ones, and it is a priori because it is independent of experience. Conceivably, Poincaré's view of mathematical knowledge as synthetic a priori was influenced by Kant's ideas about synthetic judgments. However, Poincaré also introduced new elements to this account, such as the role of intuition and the idea that mathematical concepts and principles are constructed through a process of mental synthesis. Poincaré in his book *Science and Hypothesis* (*La Science et l'Hypothèse*), first published in French in 1902, discussed

the nature of mathematical knowledge and its relationship to empirical science. He argued that mathematical concepts and principles are not derived from sensory experience but are instead conditions for the possibility of experience. Poincaré developed his own original ideas about the role of intuition, convention, and creativity in the formation of mathematical concepts and theories. His specific criticisms of Kant's philosophy are primarily directed at Kant's concept of space and his theory of knowledge. Poincaré argued that Kant's notion of space as purely intuitive was problematic because it relied on an implicit assumption of Euclidean geometry. Non-Euclidean geometries posed a challenge to Kant's account of space, and that there was no way to justify the choice of one geometry over another as the correct a priori structure of space. The geometrical axioms were therefore neither purely and intuitively synthetic nor experimental facts.

Poincaré discussed the implications of non-Euclidean geometry for the axiomatic method in mathematics. The axiomatic method that involves starting with a set of basic axioms and deducing further statements from them was not the only way to develop a mathematical theory. The development of non-Euclidean geometry challenged the idea that mathematics is based on absolute truths that are independent of human experience. Non-Euclidean geometries showed that different systems of geometry could be developed, depending on the assumptions or axioms that were used. The choice of axioms was not a matter of absolute truth but rather a matter of convention or convenience. Therefore, although the axiomatic method was a powerful tool for organizing and systematizing mathematical knowledge, it was not the only way to develop mathematical theories. Other methods, such as the use of analogies or the use of physical intuition, could also play a role in the development of mathematical ideas.

The axiomatic method has limitations, particularly in areas of mathematics where the axioms were not well-understood or where there were no obvious starting points for the development of a theory. In such cases, he suggested other methods, such as the use of conjectures or the use of experimental data, might be more appropriate.

> *If geometry were an experimental science, it would not be an exact science. it would be subject to continual revision ... the geometrical axioms are therefore neither synthetic* a priori *intuitions nor experimental facts. They are conventions. Our choice among all possible conventions is guided by experimental facts; but it remains free, and is only limited by the necessity of avoiding every contradiction, and thus it is that postulates may remain rigorously true even when the experimental laws which have determined their adoption are only approximate. In other words the axioms of geometry (I do not speak of those of arithmetic) are only definitions in disguise. What then are we to think of the question: Is Euclidean geometry true? It has no meaning. We might as well ask if the metric system is true and if the old weights and measures are false; if Cartesian coordinates are true and polar coordinates are false. One geometry cannot be more true than another; it can only be more convenient.* (Poincaré 1905, pp.58–59)

In this section of the handbook, several chapters address the history and context of geometry. Bardi's chapter on *Cultures of Mathematical Practice in Alexandria* focuses on the mathematical practices in ancient Alexandria, particularly the work of Claudius Ptolemy and his commentators. Bardi discusses the historical context of the

development of mathematical practices in Alexandria, including the influence of Greek and Egyptian cultures, and the significance of the Library of Alexandria as a center of intellectual activity. Bardi examines Ptolemy's mathematical works, including the Almagest and its contributions to the development of mathematical practices. The chapter then shifts to an analysis of Ptolemy's commentators, who were scholars that elaborated on and criticized Ptolemy's mathematical works. Bardi examines the works of several commentators, including Theon of Smyrna and Pappus of Alexandria, and discusses their contributions to the development of mathematical practices in Alexandria. One gets an overview of the mathematical practices in Alexandria during the second to fourth centuries CE, with a focus on the work of Claudius Ptolemy and his commentators. It highlights the historical and cultural context of the development of mathematical practices in Alexandria and the significance of Ptolemy's contributions to the field. In another chapter, Bardi discusses how Copernicus used axiomatics to establish the foundations of his heliocentric model of the solar system. Bardi notes that Copernicus was influenced by the axiomatic approach to mathematical reasoning developed by Euclid in the Elements, but that Copernicus departed from Euclid's approach in some significant ways, applying axioms to astronomy and cosmology rather than geometry and making assumptions about the physical world and the movements of celestial bodies. Bardi argues that Copernicus' use of axiomatics was a major contribution to the development of modern astronomy and cosmology.

An earlier departure from a strictly Euclidean view is explained by Papadopoulos, in his chapter on *Menelaus' Spherics.* Several misconceptions about Menelaus are clarified such as the misleading notion that this work pertains to astronomy. Such exaggerations led some scholars to believe that the Spherics was written specifically for astronomical purposes. Papdopoulos writes that the origin of this misinterpretation can be traced back to Bjørnbo and Heath, who erroneously declared that a significant part of the Spherics is dedicated to astronomy. These two scholars were likely influenced by the idea that the only "sphere of interest" (pun intended) to the Greeks was the celestial sphere, a view that mathematicians like him who have delved into original sources, find implausible. The sphere and its intersections by planes (playing the role of straight lines) are a natural object of study, just as the cone with its intersection by planes is the subject of Apollonius' Conics, or the ordinary plane with its straight lines is the subject of Euclidean geometry. Furthermore, Heath's claim that Book III of Menelaus' Spherics belongs to "trigonometry" is incorrect, as spherical trigonometry (as the study of the relations between sides and angles of a triangle) was not developed until centuries later (by the Arabs). The only use of a theorem from Menelaus' Spherics, in ancient times, was made by Ptolemy in his Almagest. The theorem was used by Ptolemy in his computations and in establishing his astronomical tables. In conversations with Papadopoulos, he mentions that Menelaus' work was translated in English only as recently as 2017 from Arabic manuscripts. Before that his name was known in the mathematical community (which excludes historians or linguists) only for a theorem in projective geometry, which carries his name, because it was used by ancient authors, including Chasles and others who worked on projective geometry, and who referred to this theorem as "Menelaus' Theorem." Incidentally, this is the result that Ptolemy used in

the Almagest. Conceivably, because of the importance of this "Theorem of Menelaus" in projective geometry, every mathematician thought that this is what he did and that is all.

The fact that the only result of Menelaus that people knew was used in astronomy contributed to the belief that Menelaus' Spherics was written for its use in astronomy. Papadopoulos' chapter reveals the vital contributions of Arab mathematicians in preserving and propagating the Spherics, its profoundness, and the difficulty of the theorems. But this knowledge did not reach the modern period. Euler, Lagrange, and Lambert, who are the three main figures of eighteenth century spherical geometry, never mention Menelaus; they were not aware of his existence. Two of the three founders of non-Euclidean geometry, Gauss and Lobachevsky, were also strongly involved in spherical geometry, but they never mention Menelaus, and they were not aware of the Spherics. Non-Euclidean geometry at the beginning of the twentieth century was already a dead subject, that is, it was not a research field; it was used in mathematical research only for some work on automorphic functions, but people there were essentially using works of Klein and Poincaré. The real introduction of non-Euclidean geometry in mathematical research started in the 1970, with W. P. Thurston, and became capital. Thurston started with both spherical and hyperbolic geometry. His first notes contain a chapter on both. It turned out that spherical 3-manifolds are very easily classified, and the hyperbolic (Lobachevsky) were the interesting ones. Research on the big problems of low-dimensional topology (like the Poincaré conjecture) started using geometry in an essential way, and hyperbolic geometry became at the forefront of research.

Brückler and Stilinovic in *From Friezes to Quasicrystals* provide a detailed history of (Euclidean) symmetry groups. They begin with earliest possible appearances and make numerous connections with art, culminating in the geometric classifications by nineteenth century crystallographers, and the related work in the theory of groups in the second half of the nineteenth century. Their chapter also provides twentieth century generalizations to symmetry groups in higher dimensions and mention that this extended to non-Euclidean spaces and applications in theoretical physics. Another notable shift in mathematical practice found in the nineteenth century is explored by Pedeferri in *Visual Representations of Euclidean Geometry: Diagrammatic Reasoning in Oliver Byrne's Work*. Pedeferri highlights several Euclidean propositions in Byrne's visual representations and the diagrammatic reasoning, which presented Euclid's Elements in a visually striking format. Pedeferri examines how Byrne's color-coded diagrams effectively convey geometric concepts and aids the reader in understanding the arguments of mathematical reasoning. Byrne's work provides an alternative means of understanding the first six books of Euclid's Elements and the significance of visual representations in mathematical practice.

Morales' chapter titled *The Notion of Space in Grothendieck* explains how he aimed to unite arithmetic and geometry into a single entity called "space-number." This notion suggests a connection between the physical aspects of space and Grothendieck's mathematical endeavors. The essay explores the evolution of Grothendieck's ideas on space, starting with his foundational work in algebraic geometry, introducing schemes and toposes as generalizations of spaces. It then

delves into topics such as tame topology and the formulation of a geometry of forms. Grothendieck's perspective places form at the core of geometry, viewing it as the branch of mathematics that studies the aspects of the universe related to form. The chapter concludes by proposing that further exploration of the space-number concept could enhance our understanding of Grothendieck's notion of space, and it presents this as a future project. Poenauru (2016) wrote that Grothendieck's vision of algebraic geometry progresses from schemes to toposes and then to motives. Schemes provide an efficient way to encode both systems of equations and their solutions, going beyond the set of points to include irreducible subvarieties. Toposes, a generalization of Riemann's multivalued functions, replace the lattice of open sets with étale sets, leading to étale cohomology and sheaves. Grothendieck's ultimate dream, motives, encompass various cohomology theories, breaking morphisms among algebraic varieties and performing other intricate tasks. This field has seen significant contributions from Voevodsky, Kontsevitch, Connes, Marcolli, and others, extending into quantum field theory and theoretical physics (Poenaru 2016). Grothendieck's unique style of mathematics involves starting with the correct level of abstraction and generality, solving problems from the top down.

The twentieth century in mathematics has seen the birth and the spectacular development of several geometric fields: algebraic topology, geometric topology, differential topology, algebraic geometry, singularity theory, and there are others. There is, however, one domain, which has advanced slowly and continuously rather than by producing spectacular results. This is the domain called "metric geometry." It is today an essential domain of the geometric landscape. Even if there are predecessors – Karl Menger (1902–1985) is among those who come to mind – the main founders of this field are two: Alexandre Danilovitch Alexandrov (1912–1999), in the Soviet Union, and Herbert Busemann (1905–1994), who was German but who practically had his career in the United States. Alexandrov founded a school of metric geometry that had an important impact. His students included Alexei Pogorelov, Victor Zalgaller, and Grigorii Perelman, and his work influenced Yuri and Dmitri Burago, Sergei Ivanov, Misha Gromov, and many others. In a tribute to Alexandrov, Semen Samsonovich Kutateladze wrote that Alexandrov used to work under the slogan: "Return to Euclid," and that he used to say that "the pathos of contemporary mathematics is the return to Ancient Greece." Busemann worked also in the same spirit, a return to Euclid, but in relative isolation. It is this important aspect of twentieth century mathematics that Papadopoulos presents in the "return to Euclid," highlighting the spirit under which Busemann used to choose the problems he worked on.

Alexandria in Egypt · Almagest · Astronomical tables · Commentaries · Handy Tables · Pappus · Ptolemy · Tables · Theon of Alexandria

1 Introduction

The mathematical astronomy of Claudius Ptolemy originated in Alexandria in Egypt under Roman rule in the second century CE and held for more than a millennium, even beyond the Copernican theories of the sixteenth century (Boll 1894; Toomer 1975; Taub 1993; Feke 2018; Juste et al. 2020). To trace the origins of such mathematical creativity calls for an examination of Ptolemy's philosophy of mathematical practice, the ancient commentators of Ptolemaic works, and the historical context of Alexandria in Egypt, a multicultural city which became a cradle of cultures of mathematical practices and flourished into the Ptolemaic system and its several related outputs (e.g., astronomical tables) between the second and the fourth centuries CE.

Alexandria was founded in 331 by Alexander the Great during his campaign in Africa and the Middle East. Due to its favorable strategic position, being located at the crossroads of Asia, Africa, and Europe, Alexander established the capital of his empire in Alexandria. The city would soon benefit from cross-cultural encounters, making it a prominent cosmopolitan center. Historical documents account for Alexandria's population as composed of native Egyptians, Greeks, Jews, Persians, Ethiopians, Syrians, Romans, and Arabs (Fraser 1972; Netz 2020, 257–305). The credit for making Alexandria an intellectual hub of the Hellenistic world goes to Ptolemy the First (305–283 BCE), the general who took over control of Egypt upon Alexander's death. Inspired by the model of famous Greek intellectual circles such as those formed around Pythagoras, Plato, and Aristotle, Ptolemy decided that Alexandria should become the center of Greek culture in this new world.

Ptolemy's patronage for the arts and sciences took shape in the *Museion* (museum), a sacred place devoted to the Muses, daughters of Zeus and Mnemosyne, the personifications of memory, and their protector Apollo. Adjacent to the Museum, Ptolemy constructed a library, which was intended not only to house and preserve important works but also to be open to the general public. This famous library contained a huge number of volumes for the time and was meant to contain all human knowledge in one place (Blum 1991, 95–123). Ptolemy invited scholars from all over the world to Alexandria and supported them with scholarship grants. Consequently, all manner of scholars gathered at this Museion, which was akin to a society of fellows or an institute of advanced studies: mathematicians, poets,

philosophers, philologists, astronomers, geographers, physicians, historians, and artists. How such exceptional circumstances came about remains a matter of historiographical discussion: two factors seem to have deeply influenced the character of the culture which grew out of the mixture of peoples and scholars and the broadened physical horizons. First, the Alexandrians' commercial interests brought geographical and navigational problems to the fore and directed attention to materials, methods of production, and the improvement of skills. Second, because commerce was carried out by free people who were not segregated socially from the scholars, the latter became aware of and involved in the problems facing the people at large. As a result, scholars were induced to unite their flourishing theoretical studies with concrete, practical, scientific, and engineering investigations. Technical fields were pursued and extended, training schools were established, and sciences were fostered and cultivated. Later, the wars between Alexander's successors saw the success of the Roman power, with Egypt becoming a Roman province in 30 BCE.

Alexandria under Roman rule was the environment in which Claudius Ptolemy worked and formed the background in which his mathematical creativity could thrive and spread. The science of that time, usually described as "Hellenistic," benefitted from encounters with several traditions that merged and mingled thanks to the cultural institutions in Alexandria, namely, the Museion and the Library (Neugebauer 1957, 145–190). The literary culture of Alexandria became so rich and elaborate that texts would reflect connections between arts and sciences; mathematics played alongside poetry in new ways (Netz 2009). The accumulated mass of data in literature and science became so vast that early systems of bibliography and cataloguing had to be invented, and the art of philology could thrive (Blum 1991). In astronomy, scholars could draw on knowledge stemming from the Egyptian, Greek, and Babylonian traditions. Besides providing a huge volume of records of observational data for astronomers, the Greek and the Babylonian traditions had conceived theoretical frameworks which were influential for Ptolemy and his generation: the Greeks conceived the cosmos geometrically, while the Babylonians dealt with celestial phenomena arithmetically (Neugebauer 1957, 97–144). Ptolemy's mathematical astronomy would produce new knowledge by combining the two traditions (Neugebauer 1957, 191–207; Goldstein 2007).

Ptolemy's mathematical practice will be explored under three lenses: (a) an examination of the mathematical prose of Ptolemy's *Almagest* alongside the corresponding passages in its Alexandrian commentaries; (b) the social, material, and semantic layers of Ptolemy's mathematics; and (c) the conception of true philosophy in Ptolemy's theory of knowledge.

2 Claudius Ptolemy and His Time: A Brief Overview of His Life and Works

Claudius Ptolemy lived in Alexandria in the second century (ca. 100–ca. 170), a period which historiography usually describes with the term *pax romana* (Roman peace). The time was characterized by bilingualism (Greek and Latin) and saw four

renowned Roman emperors in power: Trajan (ruled 98–117), Adrian (ruled 117–38), Antoninus Pius (ruled 138–61), and Marcus Aurelius (ruled 161–80) (Goldsworthy 2016). People with access to education were usually studying toward a full command of Greek and Latin because the spheres of influence between the two idioms had been shaped through cultural-historical processes, so that eventually Greek became the language of science and philosophy, Latin the language of law, administration, and trade. Any Roman of the second century who was intellectually ambitious had to learn Greek; this was achieved chiefly with the help of Greek tutors or through years of study in Athens, Alexandria, or any other city in the eastern provinces (Brown 1971; Cribiore 2001; Watts 2012).

Ptolemy wrote his works in Greek, and they are the only source we have about his life, apart from later indirect sources. For instance, the tenth-century Byzantine lexicon *Suda* mentions Ptolemy as an Alexandrian philosopher. This may sound surprising to a modern readership, but astronomy and mathematics have been considered part of philosophy for centuries, and this was a common framework in Hellenism and the Middle Ages (Taub 1993; Feke 2018; Jones 2020). Without pretending to map all the semantic possibilities of *philosophy* in Antiquity and the Middle Ages, it is worth noting that Ptolemy himself provides a philosophical statement in *Almagest* Book 1 in which he claims that mathematics is the highest form of philosophy, thus it provides the highest form of knowledge (see below).

Ptolemy's polymathy is indeed well reflected in his scholarly outputs. To mention some of his works, on the sciences of the heavens he authored the *Almagest* or *Mathematical Syntaxis* (Toomer 1984), the *Handy Tables* (Tihon and Mercier 2011), the *Tetrabiblos* (Robbins 1940), and the *Planetary Hypotheses* (Goldstein 1967; Hamm 2011). On other sciences, the *Geography* (Berggren and Jones 2000), *Optics* (Mark Smith 1996), the *Harmonics* (Swerdlow 2004), and also a philosophical work, the *Criterion*, alongside further, lesser explored works (Toomer 1975; Jones 2020).

The *Almagest* is Ptolemy's most successful work and is essential to understanding his mathematical practice (Toomer 1984; Goldstein 2007; Pedersen 2011). In the text, it is evident how Ptolemy was benefitting from Babylonian, Egyptian, and Greek astronomical traditions to generate a new mathematical system to be applied to astronomy: in sum, Babylonian sexagesimal system and astronomical parameters alongside observational records, Egyptian arrangement of calendar and division of day, and Greek geometrical devices to account for celestial motions.

The opus consists of 13 books. The first two are introductory, explaining astronomical assumptions and mathematical methods. Ptolemy proves the sphericity of the Earth and postulates the sphericity of the heavens and their revolution around the Earth immobile in the center. He discusses and redetermines the obliquity of the ecliptic by using trigonometry and relying on previous astronomers (or philosophers), Hipparchus and Menelaus of Alexandria. Every distance on the sphere is an angular one; the measurement of angles is replaced by the consideration of the chords subtending the corresponding arcs. The circle is divided into 360 parts and the diameter into 120 parts. Ptolemy used sexagesimal numbers: each of the

60 parts of the radius was divided into 60 small parts, and these again were divided into 60 smaller ones. A table of chords (sides of regular polygons) was computed for every half degree, each chord being expressed in parts of the radius, minutes, and seconds. The table of chords is followed by a geometrical argument leading to the calculation of the relations of arcs of the equator, ecliptic, horizon, and meridian. The same kind of discussion is continued in Book 2 with reference to the length of the longest day at a given latitude. Book 3 deals with the length of the year and the theory of the Sun, with the exposition of the models of eccentrics and epicycles, both probably already developed by the Greek astronomer Apollonius of Perga around the second century BCE. Book 3: length of the month and theory of the Moon. Book 4: construction of the astrolabe; theory of the Moon continued; diameters of the Sun, Moon, Earth's shadow, distance of the Sun, dimensions of the Sun, Moon, and Earth. Book 6: solar and lunar eclipses. Books 7–8: catalogue of the Stars (Graßhoff 1990); precession of the equinoxes; the Milky Way; and the construction of a celestial globe. Books 9–13: planetary motions. Book 9: order of the planets according to their distances from the Earth and periods of revolution; Mercury. Book 10: Venus; Book 11: Jupiter and Saturn; Book 12: stationary points and retrogressions; Book 13: motions of planets in latitude, inclinations, and magnitudes of their orbits.

The goal of the *Almagest* was to educate its readers to reach a contemplative status of the laws governing the heavens and thus become god-like, in the Platonic sense. Not accidentally, the collection of Greek poems from Late Antiquity known under the title *Palatine Anthology* provides an epigram ascribed to Ptolemy, in which the possibility of reaching divine realms in Platonic terms through the study of astronomy and detachment of the self from the earth is put into verse (Page 1981, 112).

Among the outcomes of the *Almagest* is to provide, to use a current word, the "know-how" to construct astronomical tables. A full command of the "know-how" of the astronomical tables enables the drawing of schematic maps of the heavens for the present, the past, and the future. Ptolemy himself produced such a set of tables, the *Handy Tables*, which is a structured set of astronomical tables that he composed after completing the *Almagest*, largely adapting them from the tables embedded in that treatise (Tihon and Mercier 2011). An astronomical table is an arrangement of numbers (plus other graphic signs), which stand for the values assumed by a quantity as a function of values of an argument. The tables can be considered a quantitative representation of the geometric model, in a tabular format. Practically, on the one hand, a table is approachable to people uninterested in the mathematical theory; on the other hand, it is also deemed the aim of tabular astronomy, for Ptolemy and his peers regard table-making as a good astronomical practice: these two aspects will prove crucial for the outcomes of Ptolemy's mathematical practice. While a table never appears on its own in the *Almagest*, but rather as a constitutive element of a mathematical argument that shows how the table is derived from the geometric model (Sidoli 2014), by contrast, the *Handy Tables* are tables on their own. The goal of Ptolemy's tables, in both *Almagest* and *Handy Tables*, is to show that apparently irregular motions are actually based on the periodic motions of circles.

Ptolemy's tables superseded other formats of astronomical knowledge, such as the tables of Babylonian tradition, which had been produced according to arithmetic models (Jones 1997a, b, 1998, 2000).

The tables acquired immense importance in antiquity and in the medieval traditions of the Western and Eastern Mediterranean and the Middle East: kings, caliphs, and emperors alike granted funding to have the best and most accurate astronomical tables (Kennedy 1956; King et al. 2001; Chabás and Goldstein 2012).

3 Ptolemy's Legacy in Alexandria: Pappus and Theon

The fourth-century Alexandrian mathematicians Pappus (Cuomo 2000) and Theon (Toomer 1976) are essential point of reference when exploring Ptolemy's mathematical practice. Between 300 and 350 CE, Pappus authored several works, the most famous being the *Synagoge* or *Collection* of mathematical problems (Jones 1986); his *Commentary on the Almagest* survives in fragments (Rome 1931–1945).

Theon was active in the second half of the fourth century. Remembered as the last attested member of the Museion, he was either a contemporary of Pappus or belonging to the generation immediately following him. He co-authored or accomplished the *Commentary on the Almagest* initiated by Pappus and he also published two commentaries on the *Handy Tables*, which are known as *The Great Commentary on the Handy Tables* (Mogenet and Tihon 1985; Tihon 1991; Tihon 1999) and *The Little Commentary on the Handy Tables* (Tihon 1978). The former is extensive, spanning five books: it explains not only how to use the tables but also the reasons behind the operations to be carried out and the theory behind the tables' construction and, accordingly, provides geometrical proofs. By contrast, *The Little Commentary* is just a collection of instructions: each chapter provides procedures on how to use the tables. Due to its practice-oriented nature, it would soon become the model for all subsequent generations of authors writing handbooks on how to use astronomical tables, from Late Antiquity till Early Modernity, in Christian, Jewish, and Islamicate contexts.

Pappus's and Theon's commentaries were chiefly meant to explain the difficult content of the *Almagest* to students and provide them with the basic knowledge to access its theorems (Jones 1999). It turned out that their practice of commenting on Ptolemy generated a new kind of mathematical practice, which, though conservative in nature, granted the tools to further develop Ptolemy's mathematics to subsequent generations – similar to what happened to other commentaries on Greek mathematics, the "deuteronomic texts," as Netz (1998) dubs them.

4 Ptolemy's Philosophy of Mathematical Practice: Astronomy, Astrology, and Astronomical Tables

As anticipated, according to Ptolemy's theory of knowledge, the highest form of philosophy is mathematics. More precisely, he attaches to this conception not just a mere theoretical dimension but a practical one too, intending the two sides to be mutually beneficial: all this is evident in the first passage of the *Almagest*:

> The true philosophers, Syrus, were, I think, quite right to distinguish the theoretical part of philosophy from the practical. For even if practical philosophy, before it is practical, turns out to be theoretical, nevertheless one can see that there is a great difference between the two: in the first place, it is possible for many people to possess some of the moral virtues even without being taught, whereas it is impossible to achieve theoretical understanding of the universe without instruction; furthermore, one derives most benefit in the first case [practical philosophy] from continuous practice in actual affairs, but in the other [theoretical philosophy] from making progress in the theory. Hence we thought it fitting to guide our actions (under the impulse of our actual ideas [of what is to be done]) in such a way as never to forget, even in ordinary affairs, to strive for a noble and disciplined disposition, but to devote most of our time to intellectual matters, in order to teach theories, which are so many and beautiful, and especially those to which the epithet 'mathematical' is particularly applied. (Toomer 1984, 35)

Furthermore, the notion of mathematics as the highest form of philosophy in Ptolemy is related to the knowledge and practice of astrology. Astrology, in Ptolemy's theory of knowledge, is the "physical" branch of the sciences of the stars, and the most influential systematization of knowledge labelable as "astrology" was redacted by Ptolemy himself in his *Tetrabiblos* (Robbins 1940). To understand astrology through the eyes of Ptolemy and the Alexandrian scholars, let us read his introduction to the *Tetrabiblos*:

> OF the means of prediction through astronomy, o Syrus, two are the most important and valid. One, which is first both in order and in effectiveness, is that whereby we apprehend the aspects of the movements of sun, moon, and stars in relation to each other and to the earth, as they occur from time to time; the second is that in which by means of the *physical* character of these aspects themselves we investigate the changes which they bring about in that which they surround. The first of these, which has its own science, desirable in itself even though it does not attain the result given by its combination with the second, has been expounded to you as best we could in its own treatise *by the method of geometrical proofs*. We shall now give an account of the second and less self-sufficient method in a properly philosophical way, so that one whose aim is the truth might never compare its perceptions with the sureness of the first, unvarying science, for he ascribes to it the weakness and unpredictability of material qualities found in individual things, nor yet refrain from such investigation as is within the bounds of possibility, when it is so evident that most events of a general nature draw their causes from the enveloping heavens. But since everything that is hard to attain is easily assailed by the generality of men, and in the case of the two before-mentioned disciplines the allegations against the first could be made only by the blind, while there are specious grounds for those leveled at the second—for its difficulty in parts has made them think it completely incomprehensible, or the difficulty of escaping what is known has disparaged even its object as useless—we shall try to examine briefly the measure of both the possibility and the usefulness of such prognostication before offering detailed instruction on the subject. (Translation Robbins 1940, 2–4; slightly reworked, my emphasis)

In sum, the mathematical branch of the science of the stars with a higher degree of certainty is the one whose certainty is granted by geometrical proofs, while there is a less self-sufficient method, which lies at the foundations of the physical branch of astronomy, that is, astrology, which hinges upon the certainty of the former branch. Astrology is knowable on the grounds of the regular occurrence of the same effects of the Sun and the Moon and of other regular occurrences observed by farmers and sailors. To these observational records, in order to be scientific, one needs to add an

accurate knowledge of the movements of the heavenly bodies. In other words, one needs to study the mathematics contained in the *Almagest*, which, in fact, as said, was meant to teach readers the mathematics needed to reach a contemplative status of the laws governing the heavens and thus become god-like, in the Platonic sense. Those who can reach the contemplative status are, by implication, able to construct astronomical tables as taught by the *Almagest*. As noted above, having a full command of the "know-how" of the astronomical tables allows one to have schematic maps (horoscopes) of the heavens for the present, the past, and the future (North 1986). They can be interpreted properly after studying the *Tetrabiblos*. On all these grounds, the true philosopher, according to Ptolemy, must learn both *Almagest* and *Tetrabiblos*, and that is the way to reach the full contemplation, the highest form of knowledge granted by the study of mathematics.

5 Ptolemy's Mathematical Practice in the Alexandrian Context: Texts, Languages, and Genres

An analysis of Ptolemy's mathematical practice can be undertaken via several approaches. For instance, (a) by recomputing the mathematical procedures and tables provided in Ptolemy's works (e.g., Van Brummelen 1993 recomputed Ptolemy's tables) or (b) by examining the *Almagest* and the corresponding passages in Alexandrian commentaries, paying attention to the language authors employed and the literary contexts in which they were working (they did not have to write "papers," their canonical genres were different). The latter has never been done in these terms so far. A case study in this concern is offered here.

Within such an approach, Ptolemaic texts must be understood in the cultural context of the production of knowledge in which Ptolemy, Pappus, and Theon were living, that is, the Museion and the Library of Alexandria, which embody and symbolize the institutionalization of the culture of mathematical practice that Ptolemy and his successors had developed. The products that have survived from that age are the texts, which act as both goals and tools for further development of the knowledge which in Alexandria was acquired, catalogued, and systematized (Renn 2020, 302–303, 308–309). In the case of astronomy, the knowledge stemming from Egyptian, Babylonian, and Greek astronomy could be systematized and used to generate the Ptolemaic system. On this account, the focus will be on the mathematical prose of Ptolemy, Pappus, and Theon.

The working questions are as follows: (1) What is the nexus between the *Almagest* and the commentaries of Pappus and Theon of Alexandria, why are the commentaries needed? (2) Are the commentaries didactic books, or how should they be conceived? (3) What is the role of the tables in Ptolemaic treatises? (4) What changes between Ptolemy and his commentators can be explained by historical circumstances, and how?

To study the Greek mathematical prose is to study a language that is basically composed of words, numbers, and diagrams. Due to historical grounds, it lacks the

level of radical formalization of contemporary mathematics, but its powerful linguistic resources were the basis for the development of Western mathematics, and its hypothetico-deductive structure shaped a solid cognitive substratum that pervaded Western mathematics till Modernity, as set out in *The Shaping of Deduction in Greek Mathematics: A Study in Cognitive History* (Netz 1999). A study of Ptolemy's mathematical discourse in terms of the function of individual units provided a classification of types of mathematical prose: theorem, problem, analysis, computation, table, and description (Sidoli 2004). A seminal study on the Greek language of Euclid has detected three different stylistic codes: the demonstrative code, the procedural code, and the algorithmic code (Acerbi 2021). The three studies mentioned in this paragraph have offered insightful interpretative tools to the present examination of Ptolemy's mathematical practice.

The present case study focuses on one of the most renowned and influential topics in the history of astronomy, namely, the assumption that celestial bodies are subjected to regular and circular motion, according to Aristotle's physical assumptions for the superlunar world. This assumption finds one of its most renowned textual witnesses in *Almagest* Book 3, in which the theory of the Sun is set out. Hinging upon the Aristotelian assumption, Ptolemy provides an epicyclic and eccentric hypothesis in order to account geometrically for the apparent variations in the motions of the Sun.

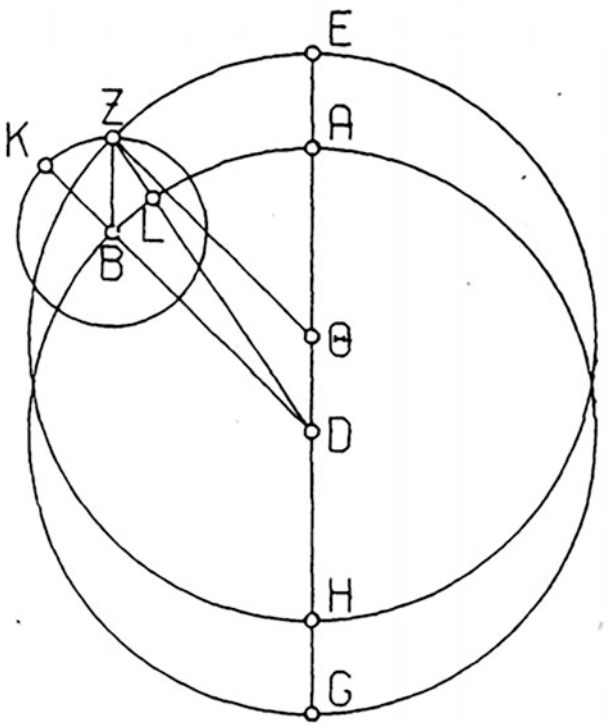
This subject, furthermore, was chosen because it is one of the most prominent in the history of astronomy. On the one hand, the assumption of regular circular motion was one of the issues for which several medieval astronomers criticized Ptolemy. On the other hand, the very same assumption was the basis for Copernicus's hypothesis of heliocentrism.

The equivalence of the eccentric and the epicyclic models is expounded, *inter alia*, in *Almagest* Book 3:

> Our next task is to demonstrate the apparent anomaly of the sun. But first we must make the general point that the rearward displacements of the planets with respect to the heavens are, in every case, just like the motion of the universe in advance, by nature uniform and circular. That is to say, if we imagine the bodies or their circles being carried around by straight lines, in absolutely every case the straight line in question describes equal angles at the centre of its revolution in equal times. The apparent irregularity [anomaly] in their motions is the result of the position and order of those circles in the sphere of each by means of which they carry out their movements, and in reality there is in essence nothing alien to their eternal nature in the 'disorder' which the phenomena are supposed to exhibit. The reason for the appearance of irregularity can be explained by two hypotheses, which are the most basic and simple. When their motion is viewed with respect to a circle imagined to be in the plane of the ecliptic, the centre of which coincides with the centre of the universe (thus its centre can be considered to coincide with our point of view), then we can suppose, either that the uniform motion of each [body] takes place on a circle which is not concentric with the universe, or that they have such a concentric circle, but their uniform motion takes place, not actually on that circle, but on another circle, which is carried by the first circle, and [hence] is known as the 'epicycle'. It will be shown that either of these hypotheses will enable [the planets] to appear, to our eyes, to traverse unequal arcs of the ecliptic (which is concentric to the universe) in equal times. (Translation Toomer 1984, 141)

This is followed by an exposition of the eccentric and the epicyclic hypotheses and their equivalence with reference to the motions of the Sun. Theorems, proofs, and diagrams are the basic elements of the prose. Theorems and proofs are written in a Greek that follows the canonic language of Greek geometry as found in Euclid's *Elements* (the demonstrative code, following Acerbi 2021).

The following diagram graphically resumes the equivalence of the two hypotheses. Imagine that we are on Earth, center of the universe, on point D, center of the circle ADG. We will end up finding the Sun at point Z on a certain time from a certain latitude either if we assume that it moves along the circle EΘH, with center Θ, *eccentric* from D, or if we take the Sun along the small circle (*epicycle*) whose center is B, which moves along the circle ADG.



(from Toomer 1984, 149)

Both hypotheses are structured according to a common scheme shared by practitioners of Greek geometry, initially developed by Euclidean scholars and later fixed into writing by Proclus (fifth century) in his *Commentary on the First Book of Euclid's Elements* (Morrow 1970). It reads as follows:

> Every problem and every theorem that is furnished with all its parts should contain the following elements: an *enunciation*, an *exposition*, a *determination*, a *construction*, a *proof*, and a *conclusion*. Of these the enunciation states what is given and what is being sought from

> it, for a perfect enunciation consists of both these parts. The *exposition* takes separately what is given and prepares it in advance for use in the investigation. The *determination* takes separately the thing that is sought and makes clear precisely what it is. The *construction* adds what is lacking in the given for finding what is sought. The *proof* draws the proposed inference by reasoning scientifically from the propositions that have been admitted. The *conclusion* reverts to the enunciation, confirming what has been proved. So many are the parts of a problem or a theorem. The most essential ones, and those which are always present, are enunciation, proof, and conclusion; for it is alike necessary to know in advance what is being sought, to prove it by middle terms, and to collect what has been proved. It is impossible that any of these three should be lacking; the other parts are often brought in but are often left out when they serve no need. (Translation Morrow 1970, 159, slightly revised; my emphasis)

Throughout the *Almagest*, Ptolemy takes Euclidean geometry for granted, and this seems to generate misunderstandings in the canonical style of Greek mathematics, especially if the reader is not trained in Euclidean geometry. Pappus and Theon intervene and provide the hidden knowledge in their commentaries (Jones 1999).

The corresponding passages of *Almagest* Book 3, in Pappus's and Theon's *Commentary on the Almagest* (Rome 1931–1945: III, 845 ff.) feature the demonstrative code and the procedural one. But, most importantly, their commentary is a paraphrase and summary of the subjects. The common elements of sentences are constituted by expressions like: "here he [meaning Ptolemy] says" + "direct quotations from the text of the Almagest." Moreover, Pappus and Theon provide passages from Euclid or other canonical works in circumstances which Ptolemy did not explain.

It is evident that the focus is on the tables, and certain keywords – such as *kanonographia* (writing tables) and *kanonopoiia* (constructing tables) – are emphasized (Rome 1931–1945: III, 891). The computations of the tables of the Sun feature the procedural code (Rome 1931–1945: III, 907 ff.), but also computations in the second person of the imperative mood to describe an operation, in a paratactic syntax (the algorithmic code, following Acerbi 2021), and these computations are aimed at summing up the operations expounded in the preceding part by applying them to a computation sample, according to the values on which tables are structured, that is, the cycle of years, months, days, hours, and latitude of Alexandria (e.g., Rome 1931–1945: III, 911).

Notably, the next chapter of the commentary (Rome 1931–1945: III, 912 ff.) is devoted to the correspondences between the computations in the *Almagest* and the *Handy Tables*. This shows that such computations were not just copied from the *Almagest* but reworked by Ptolemy himself.

Theon's *Great Commentary on the Handy Tables* treats the theory of the Sun (Mogenet and Tihon 1985, 103) by exposing how to derive the regular motions of the Sun to build tables and teaches how to read the tables. Proofs are combined with procedures. By contrast, the *Little Commentary on the Handy Tables* just provides procedures on how to use the *Handy Tables*, that is, how to work out the operations and which table to choose for a given problem, which column, which line. In the latter work, there is absolutely no requirement of understanding the theory underlying the tables.

To sum up:

1. There is a shift from complexity of syntax and morphology to a simplification (e.g., the same computations in different codes).
2. The notion of epicycle and eccentrics are progressively lost.
3. The diagram is unnecessary, thus absent, in the tables and in the commentary thereon.
4. According to Sidoli's units, while Ptolemy's *Almagest* and Pappus's and Theon's commentary thereon contain units 1 to 6 (see above), the focus on the tables leads to a deployment of just 5 (the tables) and 6 (description) in the *Handy Tables*. At the same time, there is a loss of theorems and problems but an increase in (3) analysis (of tables) and (4) computation (within the system of the tables) on the commentaries on tables.
5. The texts reflect the orientation to the practice that astronomy underwent after Ptolemy's *Almagest*:
   a. greater attention placed on the tables and how to use them (*kanonopoiia* and *kanonographia*);
   b. prevalence of the procedural code;
6. Process of systematization: in commenting on the *Almagest*, Pappus and Theon not only follow Ptolemy's division into chapters but also enumerate theorems to allow readers to orientate into the theory;
7. Commentators were likely operating when they perceived the prose as incomplete. The commentaries to the *Almagest* are therefore not to be understood as mere didactic tools or simplified versions of the work they are commenting on, but as proper, self-standing works (Chemla and Most 2022), which allowed the preservation and continuation of mathematical practice ("deuteronomic texts," as Netz (1998) puts it).

6 Socio-historical and Material Aspects of Ptolemy's Mathematical Practice

The case study offered above shows a shift of focus from the construction of tables toward the use of tables. At the same time, a huge change occurs at the epistemological level, after the second century, as an outcome of what practitioners of Ptolemaic mathematics were experiencing. The proofs that one was supposed to master to become a true philosopher were perceived as being too difficult. Therefore, practitioners chose to focus on the use of tables and to omit theorems and proofs. To be sure, the ideals of Ptolemy's philosophy of mathematical practice were betrayed, already in the Alexandrian context. Pappus and Theon provide evidence of the difficulty of the subject and the problems encountered by students in Alexandria. The social history of astronomy in the fourth century in Alexandria is recounted in Theon's *Commentary on the Almagest*, Book 1:

> What has been left without a commentary seems difficult. As for those people about whom Ptolemy, at the beginning of the work [i.e. the *Almagest*], says are willing to prove the whole topic geometrically, *they end up managing most of the topics in handy tables through simple methods*. On the contrary, we have not only put our best efforts into going through each topic through geometrical proofs as far as possible, but have also left nothing at all of difficult teaching, and we are not among those people who hold this opinion on the subject. (My translation; Rome 1931–1945: III, 318, lines 8–14, my emphasis)

Furthermore, Theon's *Little Commentary on the Handy Tables*:

> My Epiphanius, we have accurately provided a more rational method for the computation of the stars in the Handy Tables in another treatise in five books. However, because *the majority of those who followed our classes in order to learn the subject not only are unable to follow sufficiently the multiplications and divisions of the numbers*, *but also are completely ignorant of geometrical proofs*, we have done our best to systematically comment on them [the tables] by providing plain methods so that the exposition of the subject would be clearer to them [i.e. those who do not understand geometry]. (My translation; Tihon 1978, 199, lines 1–10; my emphasis)

Not surprisingly, students, forthcoming practitioners of Ptolemaic astronomy, recurred easily to tables and learned how to use them, without having any interest in the geometrical proofs underlying their construction. The Hellenistic world after the second century saw the emergence of the practice of tables without being taught in geometrical proofs become pervasive in scholarly realms. Such a practice was commonly perceived as "astronomy" and "science" in the population who had access to education. This conception of mathematical practice in astronomical sciences obviously became the most successful and spread in the subsequent centuries in several cultural contexts (Bardi 2021).

This social aspect of mathematical practice would attract criticism from all generations of scholars after Ptolemy. For instance, Ptolemaic works reached the Arabic world through translations from Syriac and Middle Persian. The elements one finds in Ptolemy and his commentators in terms of theory, practice, and differences in the nature of the two branches of the science of the stars were transmitted almost unvaried. For example, in ninth-century Baghdad, Abū Maʿšar composed *The Great Introduction to Astrology*, where he claims that true mathematicians/philosophers must have a full command of the *Almagest* and not just be able to use the astrological part and that, moreover, they must be able to construct tables and not just learn how to use them (Burnett 2002). Another later and emblematic example, in a European context this time, is Regiomontanus (Johannes Müller) in the fifteenth century, in his lecture at the University of Padua, where he lamented that the scholars of his time claimed to be astrologers just because they knew how to use the tables without having mastered the mathematics behind them (Byrne 2006; Rutkin 2019, 369–373; Omodeo 2021).

The shift from proofs to procedures as well as the increased attention being paid to the practical dimension of tables are also reflected in a semantic shift in the Greek word to designate the table, *canon*, a shift attested to in commentaries on the tables.

Passages which define the concept of astronomical table show that, while for Pappus and Theon the word *canon* means both the object and the knowledge contained in the table, in the first commentary modeled on Theon's, the word *canon* means just the object, not the mathematical knowledge provided by and systematized into the table. More precisely, in the fourth century, Theon of Alexandria wrote:

> we call "table" the whole knowledge of this kind of work, which is arranged into the table, even if it happens to occupy more than one page; [we call] "line" what is labeled with this name in the current fashion; [we call] "column" what is placed in vertical, which happens to have only degrees or only sixties – we call them again both "column." (My translation; Tihon 1978, 201, lines 4–9)

In the seventh century, the Byzantine scholar Stephen of Alexandria, rephrasing Theon's definition, built a new *Commentary on the Handy Tables*:

> we call "table" this kind of work, even if it happens to occupy more than one page; [we call] "line" what is labeled with this name in the current fashion, that is read from the left to the right; [we read] "column" what is read from above to the bottom. (My translation; Lempire 2016, p. 84, lines 15–18)

The semantic shift occurs in parallel with a material-historical factor, which is understandable when the historical role assumed by tables is seen in the light of the transmission process of Ptolemaic works between the second and fourth centuries. Briefly, the history of Ptolemy's mathematical practice took shape alongside one of the most prominent changes in the transmission of knowledge, namely, the shift from scroll to codex (Cavallo 1975; Roberts and Skeat 1983). This transition was not direct, similar to what one experiences nowadays in the transition from the physical book to the digital format. Initially, the *Almagest* was thought to be displayed in scrolls, but Theon redacted his commentaries with the codex in mind. In fact, in his commentary on the tables, Theon claims that tables might be contained by several pages, and scrolls do not have pages. This transition from scroll to codex is also reflected in the change in the format of the tables in the *Handy Tables* compared to that of the *Almagest*, which goes from 45 to 30 lines in each table, as well as in the change in the numbers of year cycles, from 18 to 25 (Acerbi 2020, 597). Ptolemy's commentators adapted Ptolemaic mathematical content to the new material support, thus irreversibly influencing the minds of new practitioners of Ptolemaic astronomy.

7 Conclusion

The historical and philosophical features of Ptolemy's mathematical practice are the outcome of exceptionally favorable historical, cultural, and material circumstances, which emerged in Alexandria in Egypt under Roman rule from the second to the fourth centuries CE, and thanks to patrons of arts and sciences and institutions which preserved culture, such as the Museion and the Library. In this context, astronomical knowledge stemming from Babylonian, Egyptian, and Greek traditions could be

preserved and employed to develop a new mathematical astronomy, whose major products are to be found in Ptolemy's *Almagest*, the *Handy Tables*, and Pappus's and Theon's commentaries thereon.

The astronomical tables became the main object of the culture of mathematical practice which took the *Almagest* as its main reference. In fact, all the examined texts refer to the tables in one way or another, but the way in which they referred to tables changed significantly. On this account, examinations of mathematical practice should consider the *Almagest* and the *Commentaries* as a *corpus* of texts as well as a collective effort of Alexandrian mathematicians to produce and use the best set of tables in their institutional and scholarly contexts.

To be sure, Ptolemy's tabular format has been successful over the tradition of tables in Alexandria. Non-Ptolemaic tables are generally not based on the principle of regular circular motion and are aimed at tracking apparent motions of celestial bodies, while the novelty of Ptolemy consists in providing tables which correspond to the mathematical principles of the geometrical models of the motions (Jones 1997a, b, 1998, 2000; Goldstein 2007). However, the success of the *Handy Tables* and, consequently, that of Theon's *Little Commentary on the Handy Tables* lies not just in the tabular format and its user-friendliness; it also derives from the stylistic resources within the language of Greek mathematics. The transmission of Theon's *Little Commentary* is huge in comparison with other commentaries, because his text employed a prose that was most accessible to its readers and could completely omit the theory. In a way, it is a fully practical text.

From the second to the fourth century, the relevance of the tables for Ptolemy's mathematical practice is present in the *Almagest* and increased in the commentaries thereon. This historical phenomenon is explainable by two interrelated factors: first, the difficulty of Ptolemy's mathematical theory (and the laziness of the majority of students and practitioners); second, the material requirement to have tables and to merely learn how to use them (practitioners of astrology did not need any knowledge of mathematical theory and astrological activity was an easy source of income). To further explore material aspects, the enhanced focus on tables in the history of Ptolemaic mathematical practice is parallel to the passage from scroll to codex, which has shaped the format and organization of the mathematical content of the tables. Therefore, the history of Ptolemy's mathematical practice is inextricably linked to the material features of scrolls and manuscripts, which are indeed "stratified social objects" (Ronconi 2018).

The changes that occurred in the practice of tables form part of a social history which is contradictory in comparison to Ptolemy's ideals of philosophy of mathematical practice. For Ptolemy, the true mathematical practice consists of a combination of a full command of mathematical astronomy and astrology, and it is aimed at reaching a contemplative status of divine realms (in a Platonic sense). In both branches of the Ptolemaic science of the heavens, the role of tables is indeed crucial, for the true philosopher must be able to master the theorems and proofs to build tables in addition to having the knowledge to interpret the horoscopes that one can obtain from them. However, as noted, the practical dimension of tables became prevalent, and most practitioners aimed at learning how to use them.

In sum, the astronomical tables, as an object of study of mathematical practice, are the place in which ideal, social, and material layers of Ptolemaic mathematics meet. It is no accident, then, that history would go on to see the table become the most influential object for the reception of Ptolemaic astronomy in later centuries, in the Islamicate, Byzantine, and European contexts of the Middle Ages, as well as in Early Modernity.

The commentaries on the *Almagest* and the *Handy Tables* are part of the culture of "deuteronomic texts" (Netz 1998), which preserved mathematics and its canons in Late Antiquity but also changed mathematical practice. In the case of Ptolemy and his commentators, the change is evident in the role that tables assumed from the *Almagest* through to Theon's commentary on the *Handy Tables*: initially thought of as objects inserted into a discursive mathematical prose, and as goals of the mathematical prose of the *Almagest*, they became the very first object of the mathematical practice, thus deemed worthy of commentaries thereon and sufficient knowledge to be mastered in order to become a professional astronomer.

Abstract

We present the history of Menelaus' *Spherics* (second c. AD), explaining its importance and quoting in detail some of the significant propositions. We include this work in the general context of Greek and Arabic mathematics, highlighting the far-reaching connections with modern mathematical ideas.

1 Introduction

Menelaus' *Spherics* (second c. AD) constitute one of the most remarkable achievements of Ancient Greek mathematics, along with Euclid's *Elements*, Apollonius *Conics*, Diophantus' *Arithmetica*, Archimedes' treatises on geometry and statics, Theodosius' *Spherics*, Pappus' *Collection*, to name only some of the most important Greek mathematical works. Among these treatises, Menelaus' *Spherics* is certainly the least understood by historians and the least familiar to mathematicians of the modern period. As a matter of fact, we know that Fermat was nourished by the work of Diophantus, that Christiaan Huygens was deeply immersed in the writings of Archimedes and Apollonius, that Euler was an assiduous reader of Diophantus and Pappus and that he was well acquainted with Theodosius' *Spherics*, not to mention of course Euclid's *Elements*, a work which all mathematicians of the past thoroughly studied. But very few of the modern mathematicians mention Menelaus' *Spherics*,[1] a fact that might seem surprising, especially since a relatively large number of medieval Arab mathematicians were well acquainted with this work.

I can see two reasons for which Menelaus' *Spherics* remains unknown. First, there are problems inherent to the available versions: no Greek manuscript has survived, and the ones we possess, in Arabic or translated from the Arabic, present intricate differences in form and wording. Another reason is that this work is difficult to access from the mathematical point of view. Indeed, the existing manuscripts do not contain proofs of several of the difficult propositions. I will say more on this below.

Menelaus' *Spherics* opened up a new research field. Saying this, we are not talking about the subject of the geometry of the sphere which, as a general topic, already existed (we mentioned Theodosius' *Spherics*, but the sphere was studied before Theodosius, by Autolycus, Euclid, Archimedes, and others), but of the field known today as the "intrinsic geometry of surfaces," which can be described, precisely like Menelaus investigated the geometry of the sphere, as the study of the properties of curvilinear triangles on a surface which is not the Euclidean plane. Indeed, the vast majority of Menelaus' propositions are concerned with such

[1] An exception is Marin Mersenne, who was fond of old mathematical texts and who was aware of this work. Indeed, Mersenne published in (Mersenne 1626) a Latin edition of the third book of the *Spherics*, together with works of Autolycus, Archimedes, Apollonius, Theodosius, Diophantus and Pappus. But one century later, Anders Lexell, who was Euler's closest collaborator, and who was a specialist of spherical geometry, writes in his memoir (Lexell 1784): "From the time where the *Spherical elements* of Theodosius were handed in written form, it is very difficult to find, in the treatises of the geometers, other elements concerning further refinements of the theory of the figures drawn on the surface of the sphere, than those that are usually exposed in the *Elements of Spherical Trigonometry* and that are aimed at solving spherical triangles." It is not completely clear to what work with the title *Elements of Spherical Trigonometry* Lexell refers (this may be Euler's *Principes de la trigonométrie sphérique tirés de la méthode des plus petits et des plus grands* (Euler 1753)), but it is obvious that he was not aware of Menelaus' work, written two centuries after that of Theodosius, nor of the works of Naṣīr al-Dīn al-Ṭūsī and the other Arab mathematicians of the eleventh to thirteenth century who worked extensively on spherical trigonometry.

properties. Menelaus' major achievement is that he highlighted for the first time the notion of spherical triangle, and he developed the bases for its study.

The Arabs included this work into their body of knowledge and they understood its novelty. Let us quote right away Aḥmad ibn Sa'd al-Harawī (tenth century) from the very beginning of his edition of Menelaus' treatise (English translation in (Rashed & Papadopoulos, 2017, p. 500)):

> The way that Menelaus followed in that book is marvelous; nobody preceded him and nothing had been known to his predecessors on that subject. Did he foresee that this kind of geometrical science is unique in itself, that it has laws suitable to it and lemmas that lead to the goal which are different from those that one is willing to demonstrate by using straight lines and the determination of planes by their intersections?

The sentence about "straight lines and the determination of planes by their intersections" refers to the fact that Menelaus avoided as much as possible the use of Euclidean solid geometry which is the ambient geometry of the sphere; the expression "straight lines and planes" refers to Euclidean lines and planes. Let us also quote Menelaus himself, from the oldest fragment known of the *Spherics*, which we also edited and translated into English in (Rashed & Papadopoulos, 2017, p. 504):

> I have invented a kind of proof which is excellent and admirable. Several things relative to surface <properties> on the spherical surfaces appeared to me; I don't think they were offered to anybody else. And I ordered the lemmas and the proofs in an order so that it will be easy for those who are fond of science to rise up and attain universal and honorable sciences. In this way, with the help of particular propositions that occur to them from the experiences they acquire from that art, they will become skillful and outstanding in the universal propositions, given the multitude of universal propositions that can occur to them, and that become for them proofs and indications for the inaccessible and the difficult directions in the principles of Spherics, their role and what ensues from them.

The field that Menelaus opened in his *Spherics* can be especially appreciated in the context of non-Euclidean geometry, a domain of mathematics that became a particularly active research field in the last quarter of the twentieth century.

In the pages that follow, I will review this work in its context, discussing at the same time the mathematics it contains, the history of the texts that we possess, and the impact of this work on the Arab mathematicians of the period ninth to thirteenth century, who are certainly, among the mathematicians who read this work, those who have most understood its importance.

The content of the rest of this chapter is the following:

In Sect. 2, I briefly review works on the geometry of the sphere by two predecessors of Menelaus, namely, Theodosius of Tripoli and Autolycus of Pitane, pointing out relations between these works and Euclidean geometry, making connections with the work of Menelaus, with a later work by al-Ḥasan Ibn al-Haytham and hinting to some relations with the development of modern analytic spherical geometry.

Section 3 contains some preliminary general facts about Menelaus' *Spherics*, including its division and its main characteristics.

Section 4 is the heart of this chapter. I discuss in it some significant propositions of Menelaus' *Spherics* and at the same time I give an overview of the major themes that are addressed in this work. I believe that before commenting on the history of this book, one has to understand the subject it treats, and for this, a knowledge of at least some of the important statements and methods of proof is necessary.

I have divided this book, as in my edition with Rashed of al-Harawī's rectification (Rashed and Papadopoulos 2017), into seven major themes. The reader interested in a more complete discussion of the mathematical content of this work is referred to Part II (pp. 125–395) of our edition.

It may be noticed that some of the statements of Menelaus' propositions are analogues of propositions in Euclid's *Elements* (e.g., the triangle inequality, equality and inequality criteria for triangles, etc.), but one must be aware of the fact that this is only an apparent similarity in the sense that the proofs of the spherical propositions are very different from those of their Euclidean analogues. This is due to the fact that the properties of the underlying surfaces are very different: On the one hand, we have the Euclidean plane, in which two lines may intersect or not, and where any two lines starting at the same point diverge, and on the other hand, we have the sphere, in which any two lines intersect and where two lines starting at a point start by diverging and then converge to the same point. Furthermore, in the Euclidean plane, the angle sum in a triangle is constant and equal to two right angles, whereas on the sphere, the angle sum in a triangle is non-constant and is always greater than two right angles. There are many other substantial differences between the two geometries.

In Sect. 5, I discuss the influence of Menelaus' *Spherics* on Pappus. This is a rare occasion where the influence of this work on a later author from Greek Antiquity is visible.

Sections 6 and 7 constitute an important part of this chapter; they concern the influence of Menelaus' *Spherics* on Arabic mathematics of the period that starts at the ninth century and that ends at the fifteenth, where a considerable amount of work was done in translating this treatise and in trying to complete the proofs of the difficult propositions that are contained in it. This effort led to a development of important mathematical theories by the Arabs, especially in spherical geometry.

In Sect. 8, I discuss the connection of the *Spherics* with astronomy, a relation which, in my opinion, has been exaggerated by modern authors.

In the following, when I quote mathematical propositions, I have sometimes paraphrased the original text to make it more easily readable by a modern mathematician. The translations close to the original together with the original text of Menelaus' *Spherics* are contained in the volume (Rashed and Papadopoulos 2017).

2 Two Predecessors: Theodosius and Autolycus

Before talking about Menelaus' *Spherics*, I will make a short review of the works of two forerunners, Theodosius of Tripoli (first c. AD) and Autolycus of Pitane (fourth century BC). I will start with Theodosius, the immediate predecessor of Menelaus,

mentioning his influence on the latter, and then, I will consider Autolycus, on whose work was based that of Theodosius.

Theodosius' *Spherics* was written in the first century BC, that is, two centuries before Menelaus. The two works, which carry the same title, are concerned with the properties of the sphere. Theodosius' treatise was obviously not foreign to Menelaus. In fact, Menelaus in a more than one sense has placed himself in the continuity of Theodosius: It suffices to recall that at the beginning of Book II al-Harawī's rectification (a version of this work to which we shall often refer), Menelaus declares that his goal is to improve and generalize some propositions of Theodosius (Rashed & Papadopoulos, 2017, p. 684). Furthermore, Menelaus, at some places of his *Spherics*, refers either explicitly or at least implicitly to Theodosius' work, and uses some of his propositions. We have commented at length on this fact in our edition (Rashed and Papadopoulos 2017) of al-Harawī's rectification, and we have also highlighted there the major differences between the two works.

The best modern-language edition of Theodosius' *Spherics* is still Ver Eecke's (Theodosius, Les Sphériques de Théodose de Tripoli 1927). It is very close to the text from which it is translated, it reproduces faithfully the mathematical content of the work, and it is accompanied by a solid mathematical commentary.[2] Let me start with some general remarks on this work.

Theodosius, in his *Spherics*, makes a distinction between a *theorem* and a *construction*. Such a distinction, which has already been made explicit and commented upon by Proclus in his *Commentary to the first book of Euclid's* Elements, is highlighted by Heiberg and by Ver Eecke.[3] The latter, after the number of each proposition, writes whether it is a theorem or a construction. An example of a construction in Theodosius' *Spherics* is Proposition 2 of Book I, whose statement is: *To find the center of a given sphere*. This is an analogue of Proposition I of Book III of Euclid's *Elements* whose statement is: *To find the center of a given circle*. An important remark that fits here is that in Menelaus' *Spherics*, which is the main topic of the present chapter, all the propositions are meant to be constructive.

Theodosius' *Spherics* is divided into three books. None of the statements of the propositions in the first two books is close to any statement of a proposition of Menelaus' *Spherics*. In this respect, the two treatise are very different. If we want to summarize in very few words the difference between them, we can say that the first one is concerned with circles drawn on the surface of the sphere whereas the second one is concerned with triangles drawn on the surface of the sphere. This is especially true for the first two books of Theodosius.

Let us highlight some statements of Theodosius' *Spherics*.

Book I starts with definitions: that of the sphere (by which is meant the solid sphere), its surface, its center, and the notion of diameter. After the definition of the

[2] There are editions and commentaries done by authors with a poor knowledge in mathematics, and I prefer not to dwell upon this.

[3] Ver Eecke's edition is based in part on Heiberg's, see the comments in (Theodosius, Les Sphériques de Théodose de Tripoli 1927) p. LII of the Introduction.

latter, it is said that it is a rotation axis of the sphere, a sentence which Ver Eecke considers as a later addition ([36, p. 1, Footnote 3]). Indeed, the property that a diameter of the sphere is a rotation axis is not used in the treatise. It is used in Autolycus' work which we review below.

Theodosius defines the pole of a circle on the surface of the sphere as a point on this surface such that all the Euclidean segments starting at this point and ending at a point on the circle are equal. In particular, no attempt is made to define the pole intrinsically on the surface of the sphere (for instance, as a center with respect to lengths of arcs of great circles on that surface).

Theodosius then gives the definition of "two planes having the same inclination." His definition is the same as Euclid's. We recall that the definition of the angle made by two planes is contained in Euclid's Book XI (Definition 6), and that the definition of two pairs of planes having the same inclination is the content of the next definition of the same book. We also note that unlike in Euclid's *Elements*, besides this relative notion of inclination, there is no absolute notion of angle made by two planes in Theodosius' *Spherics*, neither in the definitions nor in statements or in the proofs. In his propositions and in his proofs, Theodosius only talks about *perpendicular* great circles and *oblique* great circles. The notion of angle between two lines is only used for the Euclidean lines in the solid sphere, and never for two arcs of circles on the surface of the sphere. These constitute fundamental differences between the *Spherics* of Theodosius and Menelaus. Indeed, Menelaus uses the dihedral angle between two planes to define the angle made by two circles on the sphere, and hence, to define the notion of angle at the vertex of a spherical triangle, and he applies this notion in an essential way in every proposition and in every proof, with very few exceptions.

After the definitions, the first book of Theodosius' *Spherics*, in Ver Eeckes' edition, consists of 23 propositions.[4] These propositions concern basic properties of the sphere and its intersections with planes. For instance, Proposition I.1 says that the intersection of the sphere with a plane is a circle. We already mentioned Proposition I.2, which is a construction problem: *To find the center of a given sphere*. A great circle is the intersection of the sphere with a plane passing through the origin. Proposition I.11 says that on the sphere, two great circles cut each other in two equal parts. Proposition I.12 is a converse and is less trivial: it says that if two circles on the sphere cut each other into halves, then these two circles are great circles. Proposition I.13 says that if, on a sphere, a great circle cuts another circle with right angles, then it cuts it into two equal parts and passes by its poles. Proposition I.16 says that the distance from a great circle to a pole is equal to the side of a regular inscribed quadrilateral (i.e., a square). Proposition I.17 is a converse. Proposition I.18 is a construction problem: *To construct a segment equal to the diameter of a given circle on the sphere*. Proposition I.21 is also a construction problem: *To find the pole of a given circle on the sphere*.

[4] The attribution of the last two propositions to Theodosius, according to Ver Eecke, is doubtful, see [36, Footnotes p. 29 and 30].

From the mathematical point of view, all this is Euclidean geometry; there is no spherical geometry at all.

Let us pass now to Book II.

This book, in Ver Eecke's edition, also consists of 23 propositions. Most of them deal with properties of *small* circles. The book starts with the definition of tangent circles: two circles are tangent to each other if the line that is the intersection of the two planes that contain them is tangent to both of them. Proposition II. 6 says that if a great circle is tangent to a small circle, then it is also tangent to another small circle equal to the first small circle. I have reproduced the figure of this proposition from an Arabic manuscript, Ms. 3464, Topkapi Saray, Ahmet III (Istanbul). This is the drawing on the top in Fig. 1. I would like to take this opportunity to make a comparison with the figure of the same proposition, as redrawn in the plate of the figures of Clavius' English edition of the *Spherics* (Clavius's commentary on the spheriks of Theodosius Tripolitæ 1721), which I reproduced here in Fig. 2. In this plate, this is No. 33.[5] The figure in the ancient Arabic manuscript shows a sense of abstraction which, in my opinion, is absent from the realistic figures in the more recent editions of Clavius, Ver Eecke, etc.

Let me mention two other propositions from the second book of Theodosius' *Spherics*, which are both construction problems. Proposition II.14 says the following:

Given a circle on the sphere which is not a great circle and given a point on it, to describe a great circle tangent to the given circle at the given point.

Proposition II.15 is more involved:

Given on the sphere a circle which is not a great circle and given a point of the sphere situated in the region between this circle and a parallel equal circle, to describe a great circle tangent to the first small circles and passing through the given point. These propositions have a taste of Apollonian constructions of circles tangent to each other in the plane. The figure that comes with the last construction, in the Istanbul 3464 Ms., is reproduced in Fig. 3 below. I have included it here to suggest the complication of the construction. This is also Fig. 42 in Clavius' version (Fig. 2 here).

The content of Book II also belongs to the realm of three-dimensional Euclidean geometry.

Book III of Theodosius' Spherics is concerned with important monotonicity properties that we discuss at length in (Rashed and Papadopoulos 2017). Such properties constitute the culmination of both Spherics, in terms of degree of difficulty. Let me explain by an example what I mean by a monotonicity property. I take as example Proposition III.9 in Theodosius. The corresponding figure, from the manuscript mentioned above, is reproduced here in Fig. 4. The 3 sub-figures correspond to three cases in the proof, and we do no not need to worry about this now. In each case, the action takes place in a hemisphere, bounded by the exterior great circle

[5] In Clavius' edition, the total number of propositions contained in each book is not the same as in Ver Eecke's edition.

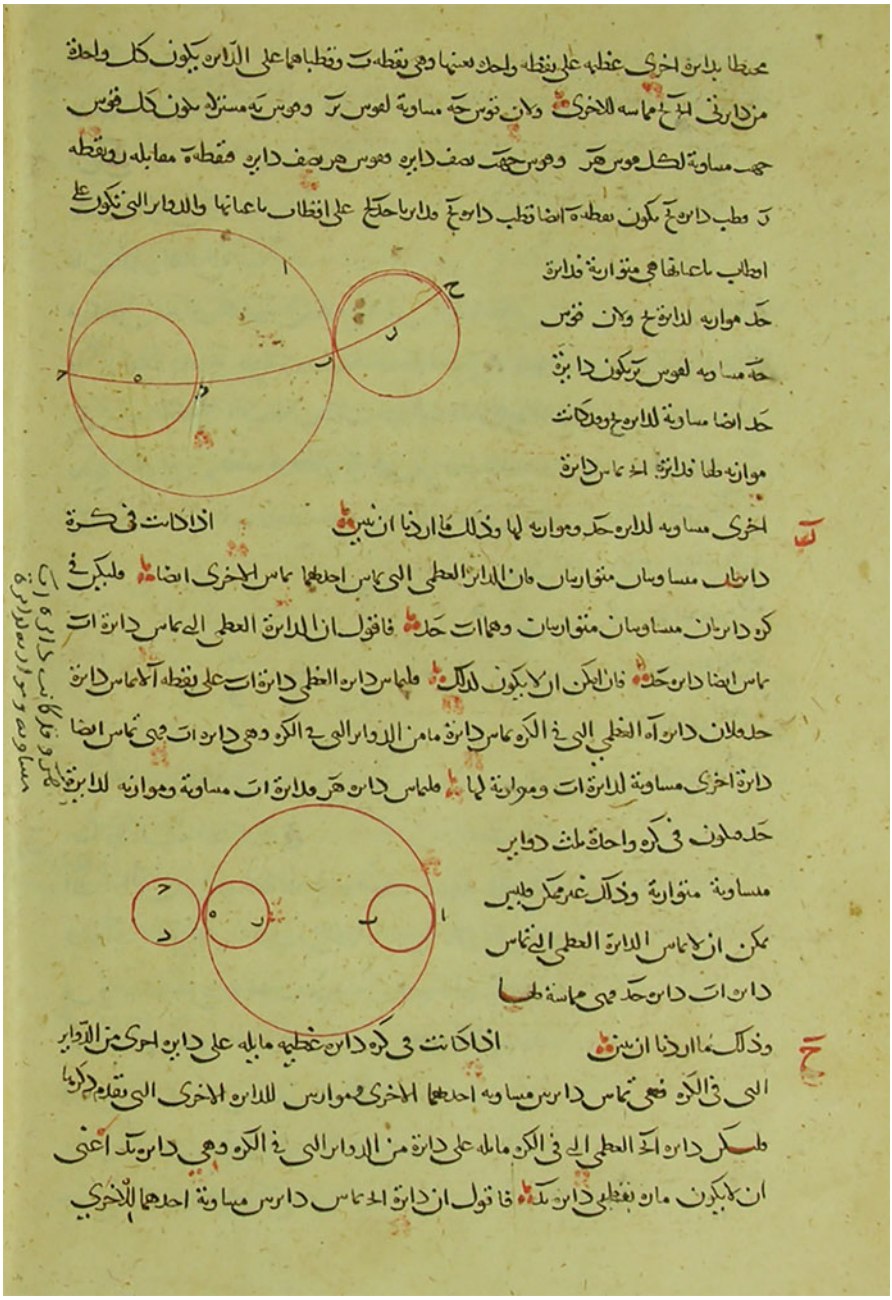

Fig. 1 From Theodosius' *Spherics*. On the top, the figure for Proposition II.6. Ms. 3464, fol. 30, Topkapi Saray, Ahmet III

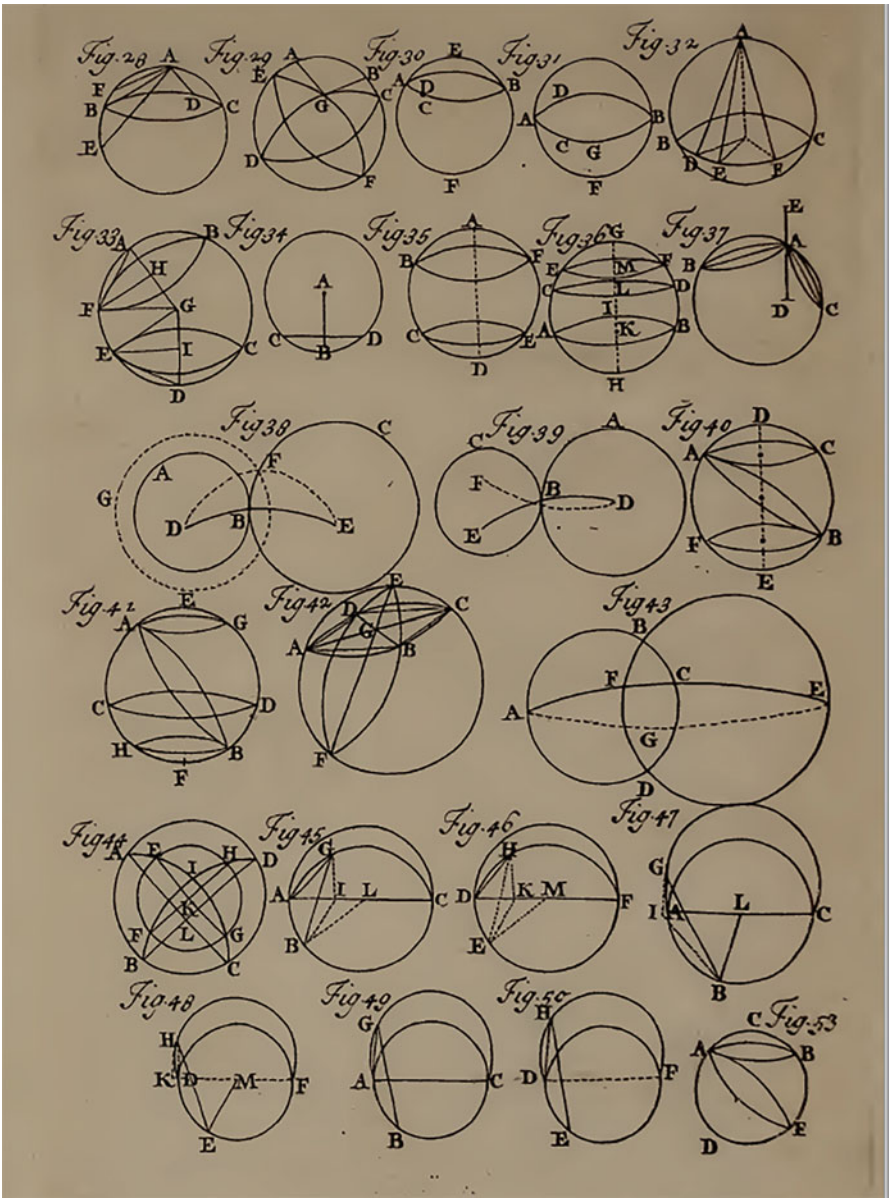

Fig. 2 A plate of figures for Book II of Theodosius' *Spherics*, Clavius' edition (Clavius's commentary on the Spherics of Theodosius Tripolitæ 1721)

represented, and the proposition concerns two arcs of great circles intersecting each other with an acute angle, one which we shall call the equator, and another one, the oblique arc (referring naturally to Fig. 4). In each of the three sub-figures, the point

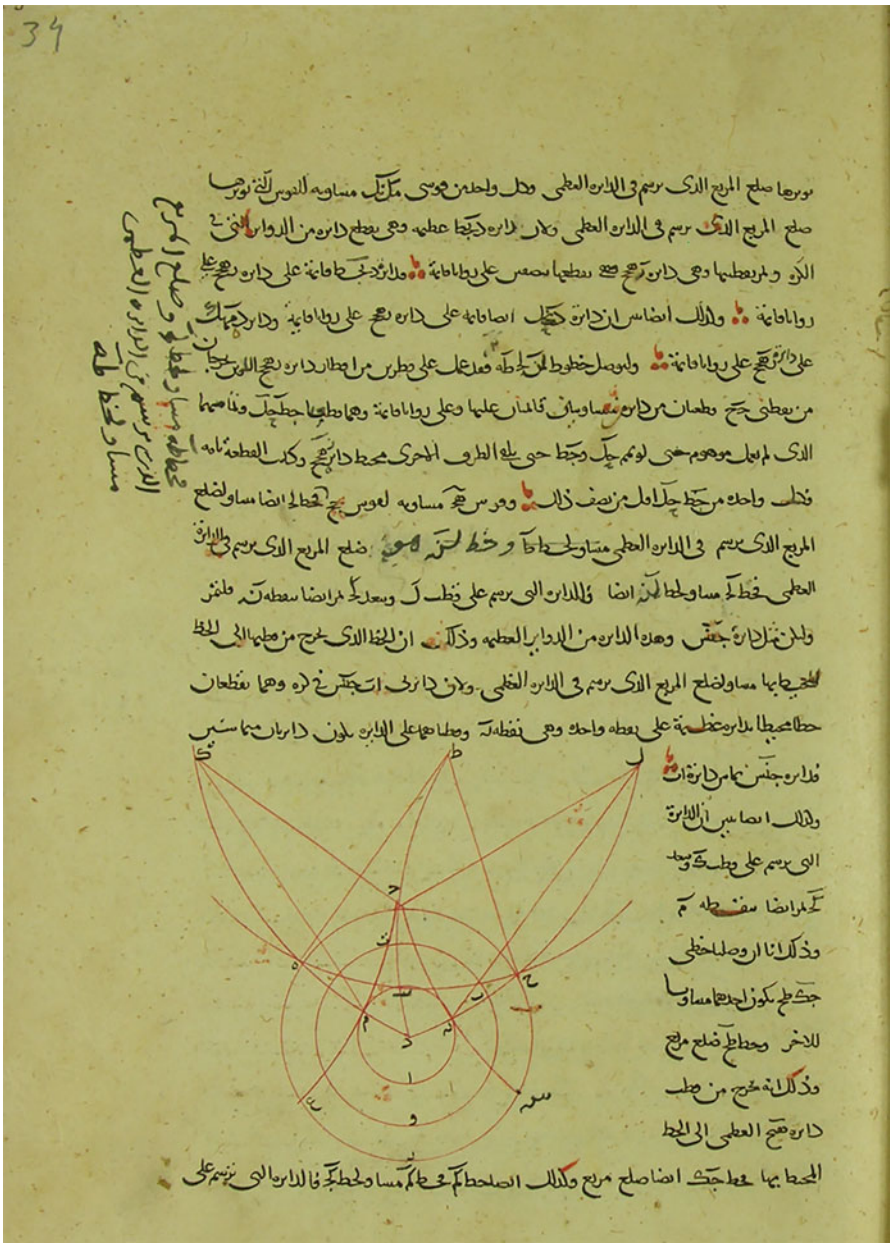

Fig. 3 From Theodosius' *Spherics*, Proposition II.15. Ms. 3464, fol. 30, Topkapi Saray, Ahmet III

on the upper left is a pole of the equator. On the oblique arc we take three points and we consider the two consecutive segments they bound. (There are several segments represented in the figure, and they are all used in the proof, but the statement

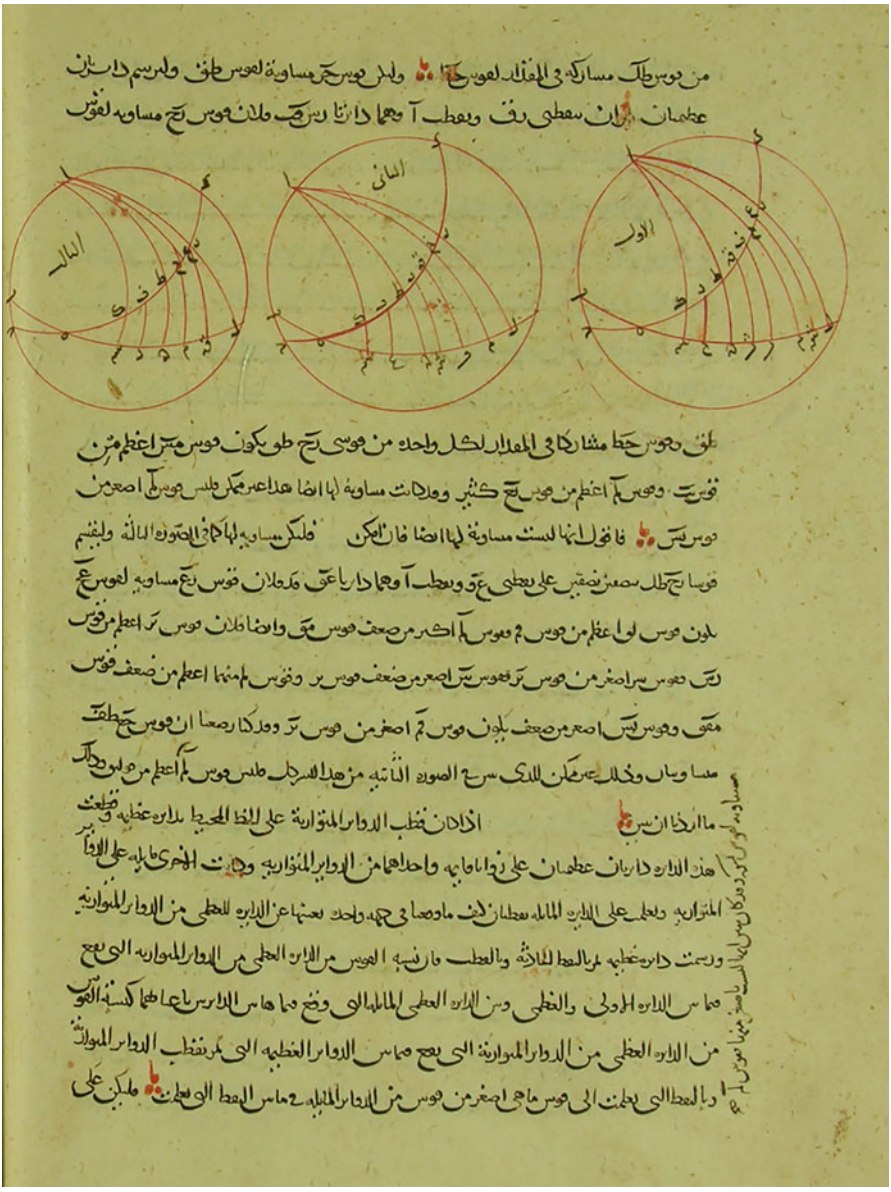

Fig. 4 From Theodosius' *Spherics*, Proposition III.10. Ms. 3464, fol. 50, Topkapi Saray, Ahmet III

involves only two of them.) We project these two segments perpendicularly (that is, using lines emanating from the pole), onto the equator. The proposition says that the ratio of the segment which is closer to the acute angle to its projection is greater than the ratio of the other segment to its projection. The word "monotonicity" that we used to describe the theme of this proposition refers to such an inequality. More

precisely, this word refers to the fact that if we start, instead of two consecutive segments on the oblique line, with a sequence of more than two consecutive segments on this line, then the sequence of ratios of one segment to its projection are all different and they vary monotonically: the more a segment is close to the acute angle of the triangle, the more the corresponding ratio is greater. We note that in the analogous Euclidean situation where we project perpendicularly segments on a Euclidean straight line onto another straight line, the conclusion of the statement is that the ratios are all equal.

Despite the fact that his methods were criticized by Menelaus who obtained more general results and who proved them using intrinsic methods, Theodosius remains, to the best of our knowledge, the first mathematician who highlighted such monotonicity properties which are proper to spherical geometry. We mentioned above that from the purely mathematical point of view, in Books I and II of Theodosius' *Spherics* all the statements are Euclidean. On the contrary, this proposition and other similar ones in Book III brings us to the heart of spherical geometry.

Between the Ancient Greek period and the modern one, monotonicity properties in Theodosius' Book II have been featured by Ibn al-Haytham, the preeminent tenth-century Arab mathematician, see (Rashed 2006–2014), in particular pp. 49–105 of the French edition. Roshdi Rashed, the author of this edition of Ibn al-Haytham, considers (rightly) that the developments by Ibn al-Haytham that were based on this proposition of Theodosius and similar ones constitute an early chapter in infinitesimal geometry. Note by the way the related multiplicity of lines in Fig. 4, which suggest a passage to the limit.

Let me mention here that several modern treatises on hyperbolic geometry start with propositions similar to Theodosius' III.9 that we just mentioned, and that such propositions are used in the foundations of the infinitesimal theory of non-Euclidean theory. For instance, in the doctoral dissertation of Louis Gérard, *Sur la géométrie noneuclidienne* (Gérard 1892), defended in 1892 and written under the direction of Poincaré, a monotonicity property similar to III.9 is used for establishing a functional equation which gives directly the trigonometric formulae of non-Euclidean geometry. In fact, the development in Gérard's thesis is done in the context of Lobachevsky geometry, but the same arguments, with inequalities in the reverse direction, give the trigonometric formulae for spherical geometry. I mention this here in order to suggest the power of these inequalities. Later authors have also used the same approach in the analytic development of non-Euclidean geometry, see, e.g., Barbarin's book (Barbarin 1902), one of the early French treatises on non-Euclidean geometry, in which the author makes at the same time a comparison between the spherical and the hyperbolic cases, starting precisely with these monotonicity properties.

From Proposition III.9 and its figure, it is also clear that spherical triangles without the name are present in Theodosius' Book III. Ver Eecke, on p. x-xi of the Introduction to his edition of Theodosius' *Spherics*, rightly states that the latter was surely aware of some of the properties of spherical triangles, but that he did not include this object in his work because he did not succeed in identifying their important properties.

Book III of Theodosius' *Spherics* contains 14 propositions, some of which are much more involved than the one we mentioned. Menelaus, in his *Spherics* gave

improved and stronger versions of some of these propositions. We shall review this in the next section, but let me mention here, in this connection, the beginning of Book II of Menelaus' *Spherics*, in al-Harawī's edition. We read the following on the critique of Menelaus toward Theodosius, regarding the method used to prove these propositions (Rashed & Papadopoulos, 2017, p. 684):

> Aḥmad ibn Abī Sa'd al-Harawī said that Menelaus overcame the difficulties of this science, something which was not within the reach of somebody else. Despite the fact that he mastered it, and albeit the majesty of what he was undertaking, he bypassed numerous lemmas which are needed by someone who examines this book and does not have the rank of Menelaus.
>
> We can see him criticizing Theodosius in his book on the Spherics; he sees that the method that he followed is not satisfactory, since it comprises complications and the drawing of numerous <straight> lines, and that Theodosius did not take into account, by this method, the properties of the figures which take place in the sphere, that is, the states of the angles generated by the intersection of circles.
>
> [I swear] on my life that everything that Theodosius proved in that book, Menelaus proved it in an easier way, and he intended that the proof is by the direct method.[6]

Theodosius' work was influenced by that of Autolycus, in particular, his two treatises *On the moving sphere* and *On risings and settings* written about 300 hundred years before.

Autolycus lived in the fourth century BC, about the same time as Euclid. His treatise *On the moving sphere* contains 12 propositions and is considered as the oldest complete Greek treatise that reached us. The expression "moving sphere" in the title denotes the Celestial sphere which, according to the theory that was in use at that time, rotates uniformly around an axis that crosses the Earth which sits at the center of the universe and which passes through the poles.

From the mathematical point of view, the twelve proposition of Autolycus are easy. I will just limit myself to three propositions from Autolycus' work, my aim being just to give an idea of some of the background of the two *Spherics*, especially the one of Theodosius. The reference I use is (Autolycus de Pitane 1979).

Proposition 1 says the following:

> *If a sphere rotates with a uniform velocity around an axis, all the points situated on the surface of the sphere and that are not on the axis describe parallel circles that have the same poles as the sphere and that are perpendicular to the axis.*

Proposition 6 says:

> *If on the (moving) sphere the fixed great circle (that is, the horizon) is oblique to the axis, it is tangent to two equal parallel circles: the one, situated on the side of the visible pole, will always be visible, and the other one, situated on the side of the invisible pole, will always be invisible.*

[6] "By the direct method" means without using a proof by contradiction.

One may compare this proposition to Theodosius' Proposition II.8 which we quoted above.

Proposition 12 of Autolycus says:

> *If on the (moving) sphere a fixed circle always cuts into two equal parts an arbitrary moving circle of the sphere and if none of the two is neither perpendicular to the axis nor passes by the pole of the sphere, then the two circles are great circles.*

The reader may notice the relation between the last proposition and Proposition I.12 of Theodosius' *Spherics* which we quoted above.

Some propositions of Autolycus' *Moving sphere* are used in Theodosius' astronomical treatises, *On habitations* and *On the days and nights* which we mention in Sect. 8.

We pass now to Menelaus' work.

3 Menelaus' *Spherics*: Preliminary Remarks

Talking about Menelaus' *Spherics*, one must necessarily mention the Arab commentators of this work, since this work reached us only through a certain number of Arabic versions, all of them containing more or less substantial differences among themselves.

We start by talking about the division of this work.

There is no general agreement on the division of Menelaus' *Spherics*. Naṣīr al-Dīn al-Ṭūsī, in the preface of his edition which we quote in (Rashed & Papadopoulos, 2015, p. 13), writes the following:

> This treatise consists of three books in some copies, and of two in some others. Concerning the three books, in most cases, the first one contains thirty-nine propositions, the last one twenty-five propositions, and the middle one, in many copies, contains twenty-four propositions, and in the copy of Ibn 'Irāq, twenty-one propositions. And in some of them, the first one contains sixty-one propositions, the second one nineteen propositions, and the third one twelve propositions. Regarding the copies with two books, the first one contains sixty-one propositions and the last one thirty propositions. And there are differences in some propositions, because some made two propositions a single one and conversely. But in general, the total number of propositions in the treatise is between eighty-five and ninety-one. I referred in the margin to some of the books and the number of propositions they contain, in red and in black, and sometimes I did it in the text.

Ibn Abī Jarrāda, in a manuscript we quote in (Rashed & Papadopoulos, 2017, p. 17) (see also Sect. 6 below), mentions a division into four books.

We have discussed at length the divisions of the various versions of the *Spherics* that survive in Chapter I of our edition of al-Harawī's rectification (Rashed and Papadopoulos 2017), which is divided into two books. At the beginning of Book II, a sentence explains this last division (Rashed & Papadopoulos, 2017, p. 684):

> As we have shown the lemmas which we needed (i.e., in the first 61 propositions), let us return now to what Theodosius wanted to show; we prove it using a universal assertion, without admitting in it the impossible.[7] We shall then show his error and rectify what is spoiled.

We conclude from this that Menelaus suggests that his goal in Book II is to improve some propositions of Theodosius. A rapid inspection of the two treatises shows that the propositions in question are those of Book III of Theodosius' *Spherics*. Indeed, Book II of Menelaus' Spherics contains a certain number of propositions that are concerned with the comparison of projections of segments of a great circle onto another such segment, in the spirit of Proposition III.9 of Theodosius' *Spherics* which we recalled above.

Although al-Harawī's rectification of the *Spherics* is divided into two books, the numbering of the proposition is continuous, from 1 to 91.[8] In what follows, it will be practical for us to use this numbering.

Now about the content.

The most important object of study in Menelanus' *Spherics* is the spherical triangle.[9] This is a figure made by three arcs of great circles called its *sides*, each two sides intersecting at a point called a *vertex* of the triangle. A side of a triangle is always assumed to be less than a semicircle. In this way, a side is the unique shortest arc between its vertices. This justifies the fact that in what follows, we shall sometimes call *segment* an arc of great circle which is smaller than a semi-circle, and *angle* an angle made by two segments at an intersection point.

Menelaus avoided as much as possible proofs that use solid Euclidean geometry. This is the point of view of intrinsic geometry of surfaces which we mentioned in the introduction. Furthermore, Menelaus always sought for new proofs. In the few cases where a proof similar to that of an analogous proposition in Euclid's *Elements* is possible in the spherical setting, he either does not give any proof at all (like in Proposition 6 which says that if we draw from the two vertices of the base of a triangle two arcs of great circles that meet within the triangle, then the sum of these arcs is smaller than the sum of the two legs of the triangle), or he gives a different proof (like in Proposition 8 which says that if two triangles have two pairs of equal sides such that the angle contained by one pair belonging to one of these triangles is greater than the angle contained by the corresponding pair in the other triangle, then the base of the triangle that has a greater angle is greater than the base of the other triangle).

It is conceivable that Menelaus did not give a proof of the famous *Sector Figure* (Proposition 66) because he did not have a proof which does not use the ambient

[7] This means by a direct method, without using proofs by contradiction.

[8] Regarding the number of propositions, one should note that there are statements for which Menelaus gives two different proofs, and each proof is counted as a new proposition (this is the case, for example, of Propositions 8 and 9). Thus, in some sense, there are less than 91 propositions.

[9] Two Arabic expressions مُثَلَّث (threefold) and شَكل ذو ثَلَاثَة أضلَاع ("trilateral figure") are used by the Arabic translators of Menelaus for the Greek term *τρίπλευρον* ("trilateral"). Let us recall that Euclid, in the *Elements* (Definition I.3), defines trilateral figures as those contained by three straight lines.

Euclidean geometry. It is also possible that Ptolemy, who uses extensively this proposition in his *Almagest*, gave a proof of it (see (Halma, 1813, pp. 50–55)) because of the absence of proof in Menelaus' treatise. We shall mention several times this proposition in what follows.

Furthermore, a large number of arguments of Menelaus rely heavily on polarity properties on the sphere that do not hold in the Euclidean place.

Thus, in most of the cases, the proofs of Menelaus' propositions of spherical geometry cannot be used for their Euclidean analogues. We shall give explicit examples in the next section.

4 The Propositions

There is more than one way of grouping the propositions of Menelaus' *Spherics* into topics: such a grouping depends on the importance that we attach to each particular theme and on the relations we can make between the various topics. I have collected the propositions of Menelaus' *Spherics* into seven groups, corresponding to seven themes, which I review now.

Group 1: Construction of Angles; Propositions 1, 41–44
I start with Proposition 1: *Given an arbitrary angle, and given an arbitrary point on a given line, we can construct an angle equal to the given angle having its vertex at the given point and a side on the given line.*

This proposition is of paramount importance, and it is abundantly used in the proofs of the rest of the propositions of the *Spherics*. Its proof, unlike the vast majority of the other propositions, uses the solid geometry of the ambient space. More precisely, it relies on constructions from Theodosius' *Spherics* and a criterion from Euclid's *Elements* for the equality of two angles seen from the center of a circle.

A remark is necessary here. We mentioned that most of Menelaus' proofs are intrinsic, that is, they use notions defined on the surface of the sphere (lines, angles, circles, etc.) and not from the ambient space. However, this cannot be true for *all* propositions. The reason is that Menelaus did not start with axioms for spherical geometry, since he thought of the sphere as a surface embedded in Euclidean 3-space, therefore the axioms of solid Euclidean geometry are sufficient for the study of such an object. Thus, some of the propositions, and in particular the first one, necessarily rely on Euclidean geometry. Establishing an autonomous set of axioms for spherical geometry is a modern idea.[10]

Let us now pass to another proposition from the first group, namely, Proposition 41. The general idea is to construct, in a spherical triangle, a segment (that is, an arc of great circle) from a vertex to its opposite side, making with this side an angle equal

[10] An early formulation of a set of axioms for spherical geometry is in (Halsted 1885).

to one of the angles of the triangle at the extremity of this side. The construction is not possible in the general case, and I will explain why, but let me first state the proposition under Menelaus' hypotheses:

> *Given a triangle ABC such that AB + BC is smaller than a semi-circle and such that the angle A is obtuse, and given a point D on BC, to construct a line from D that cuts the side AB with an angle* $\widehat{DIC}$ *equal to the angle A of this is triangle.*

The proof is contained in (Rashed & Papadopoulos, 2017, pp. 628–630). I have reproduced here Menelaus' figure (Fig. 5), just to suggest the fact that the construction is involved. This proposition is used in later propositions of the *Spherics*, and in particular in the last propositions.

Let me make a few comments on Proposition 41.

The Euclidien analogue of this proposition does not need any particular hypothesis: one takes the parallel to AB passing through D; it makes with AC an angle equal to the angle at A of the triangle ABC. But in the spherical case, parallel lines do not exist, and the problem is much more complicated. Without specific assumptions, the desired line does not always exist: See Fig. 6 for the particular case where each of AB and BC is a quarter of a circle. In this case, a great circle from D cannot make with AC a right angle, because D is not a pole of AC (since the pole is at B). In the case where we allow $AB + BC$ to be greater than a semi-cercle, the situation is not better: Take for example the case where the angle A is acute and C right, with AB and BC both greater than a quarter of a circle and let D be a pole of AC (Fig. 7). Then every line from D to the side AC makes a right angle with it, therefore this angle cannot be equal to the angle at A.

In Proposition 42, the same construction is done under the hypothesis that the angles at B and C are both acute. This proposition is used later (e.g., in the proof of

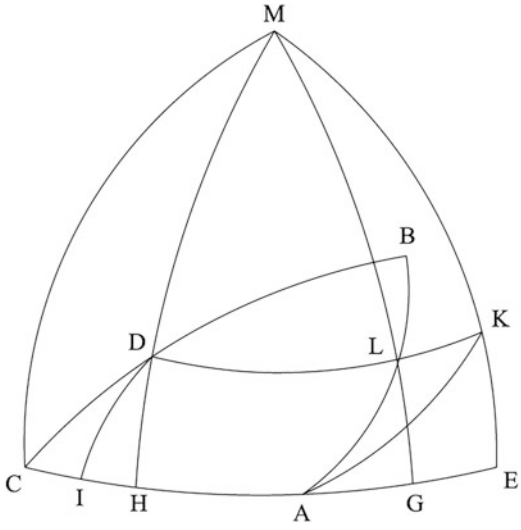

Fig. 5 Figure for Proposition 41

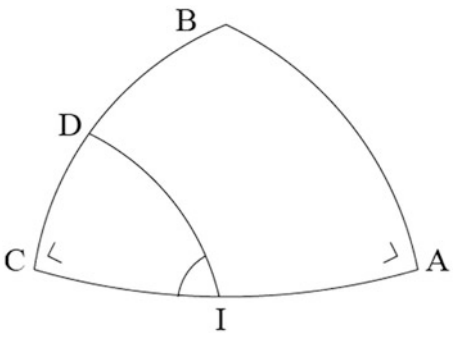

Fig. 6 Proposition 41 fails with the assumption that *AB* and *BC* are equal to a quarter of a circle

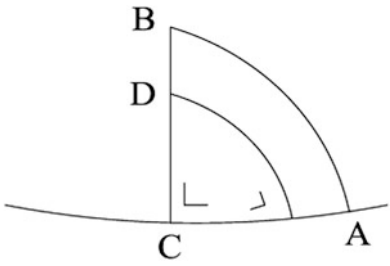

Fig. 7 Proposition 41 fails when *AB* and *AC* are greater than a quarter of a circle

Proposition 45). I have reproduced Menelaus' figure in Fig. 8 here. I have also reproduced (Fig. 9) the page of an Arabic manuscript containing the three propositions, 42, 43, 44 on the same subject. Notice the concision of the writing (the three propositions fit in one page).

Group 2: Comparison Between Triangles; Propositions 4, 8, 9, 13–19 and 20–23 This group consists of congruence and inequality criteria for spherical triangles. More precisely, there are two sorts of theorems in this group: (1) congruence theorems, i.e., theorems saying that if we have two triangles such that some elements (side lengths or angles) of one are equal to the corresponding elements of the second, then the two triangles are congruent; (2) non-congruence theorems, i.e., theorems saying that if we have two triangles such that some elements (side lengths or angles) of one are greater than the corresponding elements of the second, then some other element of the first is greater (or smaller) than the corresponding element of the second.

An example of a congruence theorem is Proposition 19, which has no analogue in Euclidean geometry. It says that if two spherical triangles have equal angles, then they are congruent.

We note incidentally that Menelaus never makes statements such as "the triangles are congruent," or "the triangles are equal," or equivalent expressions. Instead, he always gives precise statements, saying what side in the first triangle is equal to what

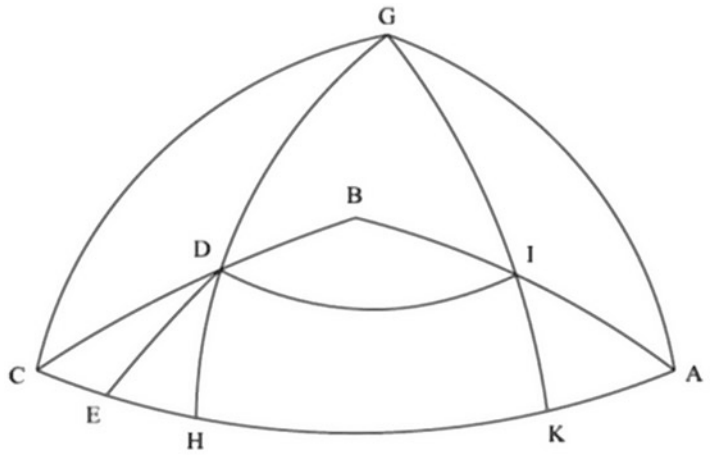

Fig. 8 Proposition 42

side in the second triangle and what angle in the first one is equal to what angle in the second one.

Examples of non-congruence theorems are Propositions 8 and 9, which are in fact a single theorem concerning two triangles having two pairwise equal pairs of sides. They say that if in one of these triangles, the angle contained by two equal sides (the legs) is greater than the angle in the second triangle contained by a pair of legs equal to the pairs of legs in the first triangle, then the first triangle has a greater base than the second. This proposition also holds in Euclidean geometry (Euclid's Proposition I.24).

Group 3: Geometry of Triangles; Propositions 2, 3, 5–7, 10–12 and 24–26
These propositions concern the geometry of individual triangles. For instance, Propositions 2 and 3 concern isosceles triangles. They say that if a triangle has two equal sides (the legs), then these legs subtend with the base equal angles, and conversely, if a triangle has two equal angles at the base, then the two legs subtending them are equal. These are analogues of Propositions I.5 et I.6 of Euclid's Elements. The proofs though are very different in the spherical case; they are based on the duality between lines and their poles, and they also use some propositions in solid geometry from Theodosius' *Spherics*. Proposition 5 is the triangle inequality for spherical triangles. Let us dwell on Proposition 11, which is used in a crucial way at several places in the *Spherics*:

Let ABC be a spherical triangle. Consider the exterior angle $\widehat{BCD}$*. Then we have the following three equivalences:*

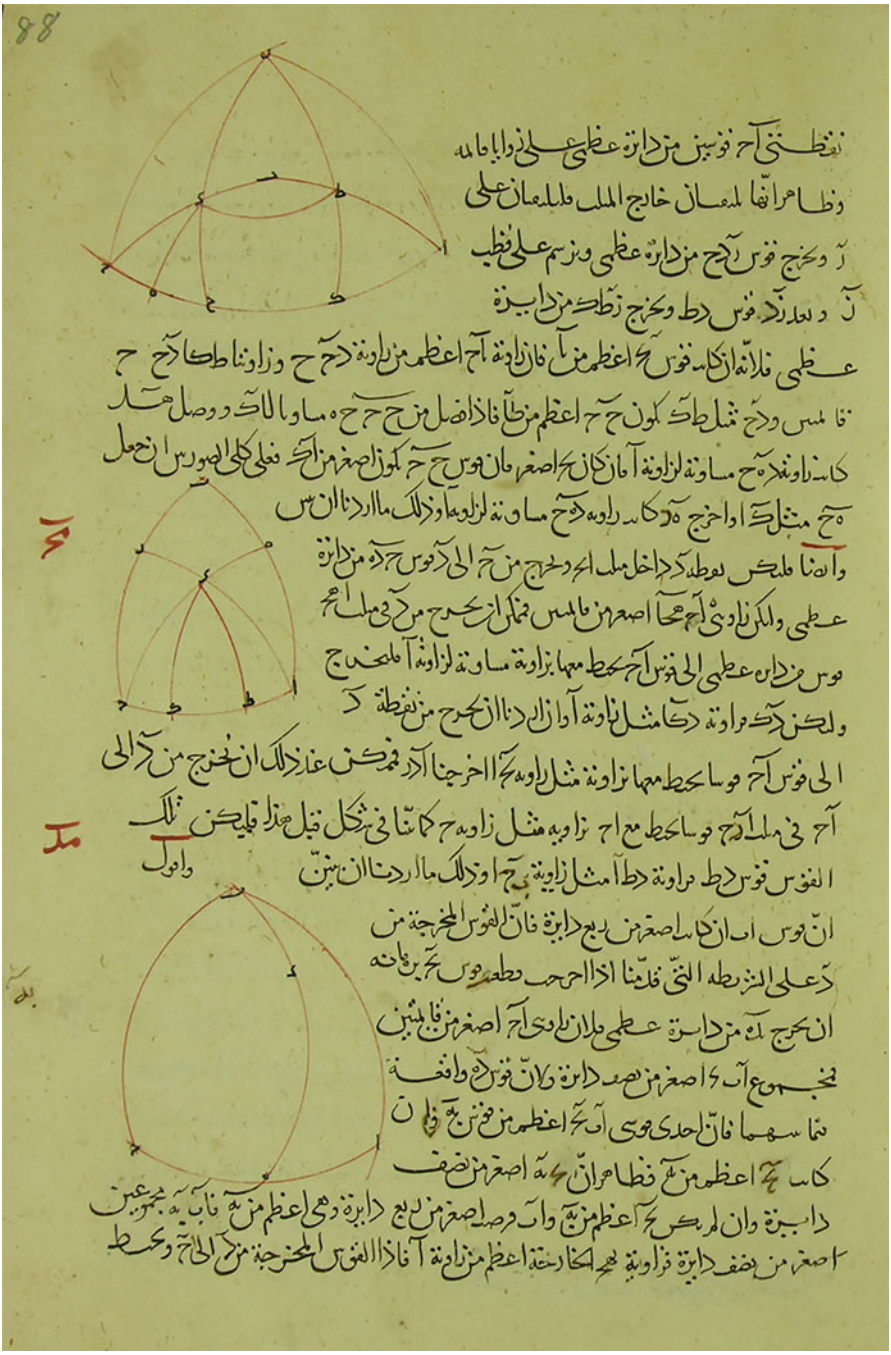

Fig. 9 Propositions 42, 43 and 44. Ms. 3464, fol. 88, Topkapi Saray, Ahmet III

1. $\widehat{BCD} = \widehat{A}$ *if and only if* $AB + BC$ *is a semi-circle;*
2. $\widehat{BCD} > \widehat{A}$ *if and only if* $AB + BC$ *is smaller than a semi-cercle;*
3. $\widehat{BCD} < \widehat{A}$ *if and only if* $AB + BC$ *is greater than a semi-cercle.*

Let us prove the first statement. We produce the sides AB and AC until we obtain a lune. One of the vertices of this lune is A, and we may set the point D to be second vertex (Fig. 10). If $\widehat{BCD} = \widehat{A}$, then $\widehat{BCD} = \widehat{D}$. In the triangle CBD, since $\widehat{C} = \widehat{D}$, we have $BC = BD$ (this is the congruence criterion of Proposition 3). Since $AB + BD$ is a semi-cercle, $AB + BC$ is also a semi-cercle.

The converse is obtained by reversing the arguments and using the congruence criterion of Proposition 2. The proofs of (2) and (3) are of the same type, based on the notion of lune and using Proposition 7 (inequality criteria for triangles).

Let me remark that if one proves (1) and (2), then (3) follows immediately by a *reductio ad absurdum*, but Menelaus does not allow this kind of reasoning.[11] This is why a proof of (3) is needed.

Proposition 12 of the *Spherics* is of paramount importance in spherical geometry; it says that the angle sum in any spherical triangle is greater than two right angles. It is a direct consequence of Proposition 11. We reproduce this proof, because it is also a noteworthy illustration of the intrinsic methods of Menelaus.

To prove Proposition 12, let ABC be a spherical triangle and let us consider the exterior angle $\widehat{BCD}$. It suffices to prove that $\widehat{BCD} < \widehat{A} + \widehat{B}$.

We suppose without loss of generality that $\widehat{BCD} > \widehat{A}$ (otherwise the conclusion we seek is obviously true). Then, we construct an angle $\widehat{DCE} = \widehat{A} < \widehat{DCB}$ with E on the extension of the segment AB, as in Fig. 11. Now Proposition 11 applied to the

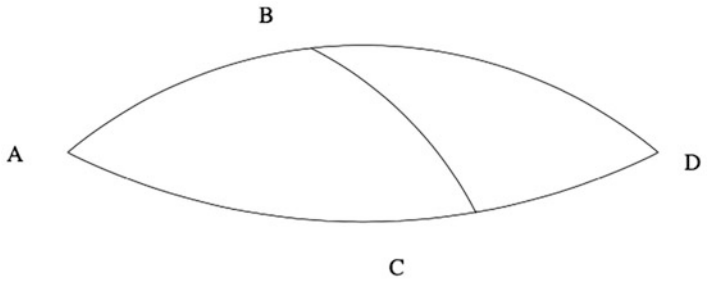

Fig. 10 Proposition 11

[11] Regarding this fact, let us quote Ibn Abī Jarrāda: "I said that Menelaus presented numerous lemmas for the proof of this proposition; but al-Harawī had shown some of them by a *reductio ad absurdum*; and we said that this does not belong to Menelaus' method. I showed all what was presented in the course of the proof without a *reductio ad absurdum*." (see the exact reference in (Rashed and Papadopoulos 2017) p. 41).

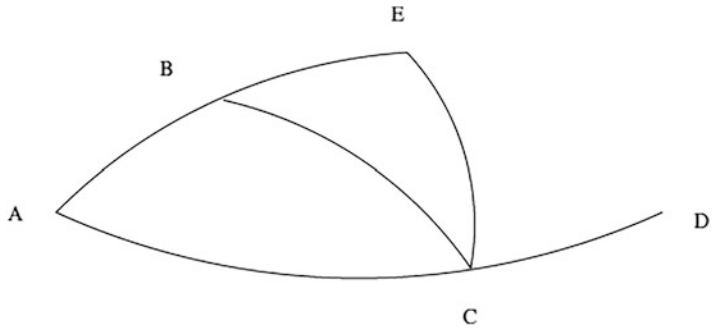

Fig. 11 Proposition 12

exterior angle $\widehat{DCE}$ of the triangle AEC implies that $AE + EC$ is a semicircle. Thus, $BE + EC$ is smaller than a semicircle. Applying again Proposition 11, this time to the triangle BCE, gives $\widehat{CBA} > \widehat{BCE}$. Adding $\widehat{A}$ to both sides gives $\widehat{BCD} < \widehat{A} + \widehat{B}$, which is the desired result.

Group 4: Division of Triangles; Propositions 27–40

This group consists of a set of propositions that concern inequalities obtained by dividing a spherical triangle by a segment (that is, an arc of great circle) connecting a vertex to the opposite side. The arc may be a side bisector, or an angle bisector, and there are also other kinds of division of a triangle, for instance, by an arc of great circle joining the midpoints of two sides. I will report more precisely on some of these propositions.

I start with a proposition which I find particularly interesting, namely, Proposition 27. It says the following:

> *In a spherical triangle ABC, let D and E be the midpoints of AB and BC, and DE an arc of great circle joining them. Then DE > AC/2.*

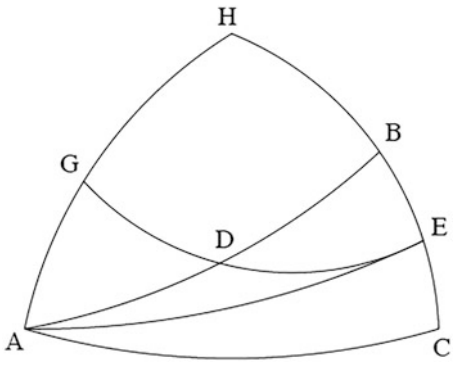
The importance of this kind of proposition in modern metric geometry cannot be overemphasized. It is equivalent to a concavity property for distances in spherical geometry, and more generally, in a space of positive curvature. Herbert Busemann took the conclusion of Proposition 27 as a definition of a metric of positive curvature, see (Busemann 1948; Busemann 1955; Busemann 1961).[12]

The proof of this proposition is a beautiful example of the intrinsic methods of Menelaus:

We produce ED until a point G such that $DG = DE$ and we produce AG and CB until they meet at a point H (Fig. 12).

[12] Busemann was not aware of the fact that the property was stated explicitly in a theorem of Menelaus. I highlighted this fact in (Papadopoulos, 2019).

Fig. 12 Proposition 27



Since $DG = DE$, $AD = DB$ and $\widehat{EDB} = \widehat{ADG}$, the two triangles EDB and ADG are congruent (This is one of the congruence theorems, Proposition 10 of the *Spherics*). Thus, we have $EB = AG$ and $\widehat{EBA} = \widehat{DAG}$.

From Proposition 11 on exterior angles which we recalled above, applied the triangle HBA and its exterior angle $\widehat{B}$, $AH + HB$ is a semi-circle. Thus, $AH + HE$ is greater than a semi-circle. Now we join A and E by a segment of great circle. Applying again Proposition 11 to the triangle HEA, we get $\widehat{CEA} < \widehat{EAG}$.

Now the two triangles CEA and EAG have a common edge EA, and we have $CE = AG$, and $\widehat{CEA} < \widehat{EAG}$. Therefore, $AC < EG$ (this is Proposition 8 of the *Spherics*). Since $DE = \frac{1}{2}GE$, then $DE > \frac{1}{2}AC$ and the proposition is proved.

Let us note that to perform the construction in the proof of Proposition 27, the sides of the triangle ABC must be small enough (for instance, we do not want the point H to fall inside the triangle ABC, which could happen if the segment AH is very long). We also note that in the definition of positive curvature one can assume the triangles small (the definition is local).

It is also important to know that there is an analogue of this proposition in the setting of hyperbolic geometry (the other classical non-Euclidean geometry), with the inequality in the conclusion reversed.

A more precise form of Proposition 27 can be proved using spherical trigonometry and a formula of Euler giving the area of a spherical triangle. I have included this proof in the first appendix to this chapter.

Among the other propositions in the same group, Propositions 28 and 29 concern again a triangle ABC with a segment DE joining the midpoints of AB and CB, but here, instead of comparing the segment DE to the side AC, one compares angles. More precisely, the propositions give the inequality $\widehat{BDE} < \widehat{BAC}$ under various conditions on the angles of the triangle ABC. Note that in the Euclidean case, we have the equality $\widehat{BDE} = \widehat{BAC}$.

A recent paper provides analogues of propositions 28 and 29 of Menelaus' *Spherics* in the setting of hyperbolic geometry, see (Senapati 2019). I am mentioning this to point out that such statements are still actual.

Group 5: Monotonicity; Propositions 45–62, 64, 65, 81–91
This group contains 32 propositions that express monotonicity properties. We already explained, in Sect. 2, what we mean by such properties and we talked about their importance. At the basis of such a property, we generally have a spherical triangle and projections of segments contained in one side onto another side. Such projections may use arcs of great circles making equal angles with the base side on which we project, like in Proposition III.9 we quoted from Theodosius *Spherics*, but there are other kinds of projections: using arcs of great circles perpendicular to the base, using small circles parallel to one side, etc. All these monotonicity results provide inequalities that show fundamental differences between spherical geometry and the two other classical geometries (Euclidean and hyperbolic). Furthermore, like for Proposition 41 which we recalled above, various kinds of hypotheses on the shapes of the triangles (angles or side lengths) are necessary in the statements of these propositions.

There is a progression in the results of Group 5 in terms of the sophistication of the statements and difficulty of the proofs. Some of these propositions are improvements of propositions of Theodosius on the same topic. I will mention two of these propositions, limiting myself to the statements.

Proposition 82 says the following:

Let ABC be a triangle with a right angle at A and acute angle at B, and with BC at most equal to a quarter of a circle. Consider on BC two arcs BD and EG and take the perpendiculars DH, EI, GK to the base AC (Fig. 13). *Then,*

if $BD = EG$ *then* $AH > IK$ *and* $AB - DH < EI - GK$;

if $AB - DH = EI - GK$, *then* $BD > EG$;

if $BD + (AB - DH) = EG + (EI - GK)$, *then* $BD < EG$;

if $BD - (AB - DH) = EG - (EI - GK)$, *then* $BD < EG$.

Furthermore, in every case, we have

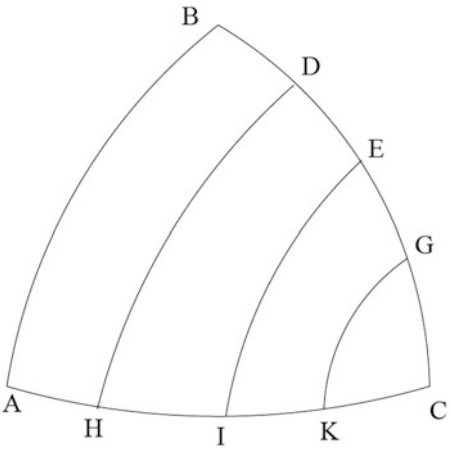


Fig. 13 Proposition 82

$$\frac{\text{crd } 2BD}{\text{crd } 2EG} > \frac{\text{crd } 2(AB - DH)}{\text{crd } 2(EI - GK)}.$$

Proposition 89, in the same group, says the following:

Let AB and BC be two arcs of great circles. Consider two points D and E on AB and take the perpendiculars DC, EH on BC (Fig. 14). *Then,* $\frac{\text{crd}2CH}{\text{crd}2DE}$ *is equal to the ratio of the product of the diameter of the sphere by the diameter of the (small) circle parallel to BC and tangent to AB to the product of the diameters of the two circles parallel to BC and passing by D and E.*

In Fig. 15, we have reproduced the page containing the last three propositions (89 to 91) from Ms. 3464; the reader can notice again the conciseness of the writing. Let me mention in this regard that I know of no written proofs of these three propositions, or of any of the last eleven propositions of the treatise. Furthermore, all the texts that reached us contain some ambiguities in the statements of these propositions. We have discussed the problems raised by these propositions in our edition (Rashed and Papadopoulos 2017).

Group 6: The Sector Figure and Its Applications; Propositions 66–70 and 72–80

Proposition 66 is the so-called Sector Figure. establishes a relation between six sides of a figure called "complete quadrilateral." This is the figure obtained by producing two pairs of opposite edges of a convex spherical quadrilateral until they pairwise meet at a point.[13] A picture of a complete quadrilateral is given in Fig. 16, where we start with the quadrilateral *ADEG* and we produce *AG* and *DE* until they meet at the point *B*, and *AD* and *GE* until they meet at the point *C*. Notice that each convex spherical quadrilateral gives rise to four complete quadrilaterals, depending on the choice of two adjacent sides. Using the notation of Fig. 16, the proposition says that we have:

$$\frac{\text{crd } 2AG}{\text{crd } 2BG} = \frac{\text{crd } 2AC}{\sin \text{ crd } 2CD} \cdot \frac{\text{crd } 2DE}{\text{crd } 2EB}.$$

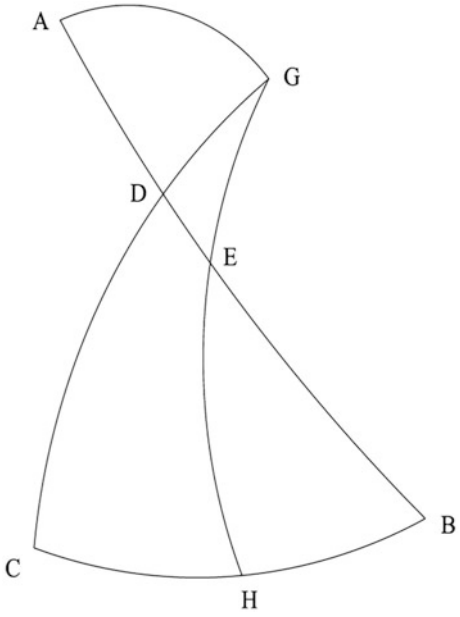
Expressed in the language of sines—which Menelaus did not have, but which was used by the Arab commentators of the *Spherics*—the relation is:

$$\frac{\sin\ 2AG}{\sin\ 2BG} = \frac{\sin\ 2AC}{\sin\ 2CD} \cdot \frac{\sin\ 2DE}{\sin\ 2EB}.$$

In some sense, this spherical proposition is close to the spherical Sine Rule for triangles; indeed the Sine Rule can be deduced easily from the Sector Figure, and conversely, there is a very short proof of the Sector Figure using the spherical Sine

[13] Convexity is understood here with respect to the intrinsic geometry of the sphere: A figure is said to be convex if (1) it is contained in an open hemisphere; (2) for any two points in this figure, the arc of great circle joining them is contained in the figure.

Fig. 14 Proposition 89



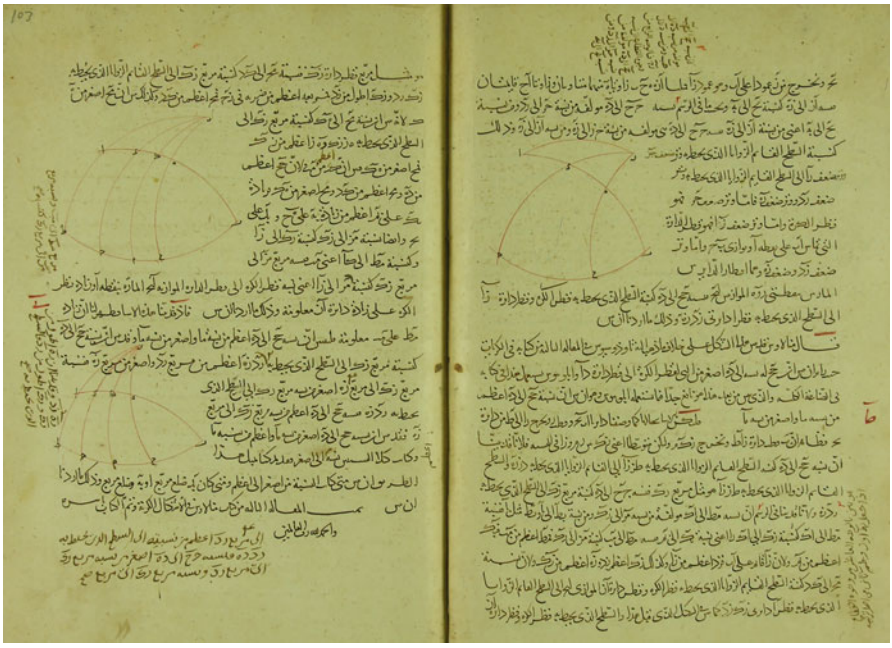


Fig. 15 Propositions 89 to 91 of the *Spherics*, Ms. 3464, fol. 99, Topkapi Saray, Ahmet III

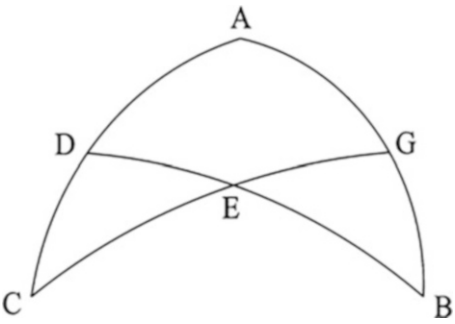

Fig. 16 The Sector Figure (Proposition 66)

Rule. One should note however that the discovery of the spherical Sine Rule occurred only in the eleventh century. In the meanwhile, the Sector Figure has been the only trigonometrical tool[14] used in astronomy. In particular, the proposition was heavily used by Ptolemy in the *Almagest* as the main ingredient for his astronomical calculations. Furthermore, it is the only result of the *Spherics* which is quoted under the name "Menelaus' Theorem."[15]

Proposition 66 occupies a particular place in the *Spherics*. It is situated among a series of propositions whose proofs are completely intrinsic to the surface of the sphere, but the proof given to this proposition in al-Harawī's redaction and in all the other Arabic manuscripts that survive is, like the one given by Ptolemy in his Almagest, purely Euclidean. (In fact, the proofs given by the Arabs are either Ptolemy's or a small variation it.) At the same time, such a proof was considered as faulty by the various Arab commentators and editors of the *Spherics* because it is not in the spirit of Menelaus' methods. Whether Menelaus had a proof of this proposition that does not rely on solid Euclidean geometry remains a mystery.

The other propositions in this group are proved using the Sector Figure. They involve divisions of spherical triangles by arcs of great circles joining vertices to the sides that subtends them. These results concern angle and external angle bisection (Propositions 73 and 79), angle division into three equal parts (Propositions 74 and 75), division by altitudes (Propositions 78, 80), and various other kinds of divisions. These propositions may all be proved using the spherical Sine Rule, and the Sector Figure Theorem is used in the absence of this theorem. We have discussed in detail all these propositions in our commentary in (Rashed and Papadopoulos 2017). In particular, Proposition 80 needs a careful discussion, and we comment on it here. In al-Harawī's version, the proposition says the following:

[14] We are using here the the word "trigonometry" for a formula that gives relations between the elements of a figure which is not necessarily a triangle.

[15] There are other names for this proposition. Ptolemy, in the *Almagest*, used the expression "secant figure," which is also the name that was generally adopted by the Arabs الشَكل القَطّاع in their commentaries on Menelaus' and Ptolemy's works and in the treatises they wrote on spherical geometry.

The altitudes that are produced from the angles of a triangle to their opposite sides intersect in one point.

The statement as it stands is not correct and needs a hypothesis. Let me explain this. Consider the example of a spherical triangle whose three angles are right. In this case, any arc of great circle drawn from a vertex to the opposite side that subtends it is an altitude. Obviously, three arbitrary such arcs drawn from the three vertices to the opposite sides do not necessarily intersect in a common point. Thus, the theorem fails in this case. There are much more general cases where the theorem fails.

The statement becomes correct if we add to it a further hypothesis. One possibility is the following:

Suppose that in a given triangle two altitudes intersect in a point within the triangle. Then there exists a third altitude passing through this point.

With such a hypothesis, the proof in al-Harawī's edition of Menelaus, of the fact that the three altitudes intersect in one point, becomes correct. This proof involves several applications of the Sector Figure Theorem.

Group 7: Proposition 71

I have dedicated a special section to Proposition 71 because I consider it as very special, both mathematically and historically, and I will explain why.

First, the statement is particularly interesting. It expresses a non-trivial property of spherical triangles, and I have not seen anywhere else, in the old and modern literature, a statement that bears any resemblance to it. Secondly, the proof of this proposition has given rise to an abundant literature by the Arab mathematicians who have revised and commented Menelaus' text. It seems that it was precisely in trying to prove this proposition that these mathematicians discovered the Sine Rule and the other formulae of spherical trigonometry, see the comments in (Rashed and Papadopoulos 2017) and Sect. 7 below. Moreover, the proof uses an important property that was obviously known to Menelaus, namely, the invariance of the spherical cross ratio, although he used it without proof. The invariance of the cross ratio is one of the main tools of projective geometry.

I have given a detailed proof of this proposition and reviewed several points in the history of the important mathematical activity that took place around it, between the ninth and the thirteenth centuries, in my two papers with Rashed (Rashed and Papadopoulos 2014; Rashed and Papadopoulos 2015).

Let me recall the statement of this proposition:

Consider two triangles ABE and LMO with right angles at B and M, and where the angles A and L are acute and equal. Then,

$$\frac{\text{crd}\,(AE+AB)}{\text{crd}\,(AE-AB)}=\frac{\text{crd}\,(LO+LM)}{\text{crd}\,(LO-LM)}.$$

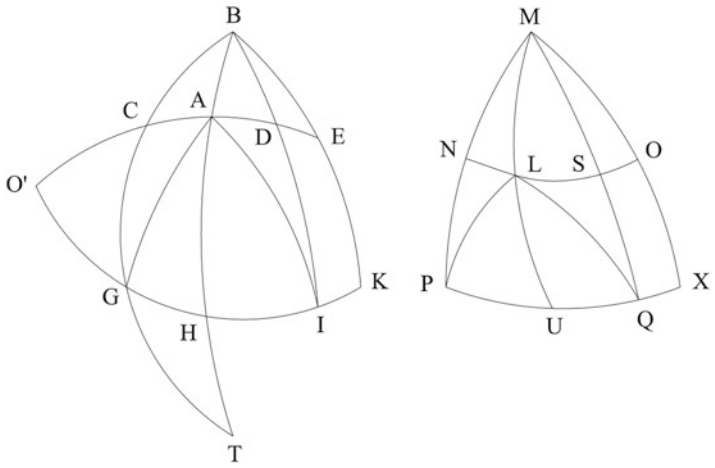

Fig. 17 Proposition 71

I have reproduced the figure that accompanies this proposition in Fig. 17 here.

As a matter of fact, inspired by this kind of result in spherical geometry, several theorems in hyperbolic geometry are proved in the recent paper (Papadopoulos and Su 2017). In particular, a more precise analogue of Proposition 71, in the setting of hyperbolic geometry, is given there (Theorem 2.1), based on hyperbolic trigonometry. Going backwards, a more precise form of the same proposition in the setting of spherical geometry can be given using the same outline, and we have reproduced it in the first appendix to the present chapter. Let me also mention here that Menelaus' theorem as well as the invariance of the cross ratio which is used in the proof of Proposition 71 have been adapted and used in the case of hyperbolic geometry, see (Papadopoulos and Su 2017; Papadopoulos and Yamada 2013). I am saying all this to give a hint of the freshness of the ideas behind this and other propositions of the *Spherics*.

5 Pappus

Pappus of Alexandria is among the rare mathematicians from Greek Antiquity who have embraced Menelaus' intrinsic methods. Book VI of his *Mathematical collection* contains a sequence of theorems on spherical geometry, some of which are proven using the intrinsic geometry of surfaces, in the pure style of Menelaus. As a matter of fact, the first proposition in this book concerns the triangle inequality, for a spherical triangle. Pappus' statement is the following:

> *If, on a spherical surface, three arcs of great circles which are all smaller than the semicircle mutually cut each other, then two of these arcs, taken in an any way, are greater than the remaining arc.*

The reader may notice that there is no mention of spherical triangle in this statement, but right after the proof of this proposition, Pappus notes: "Menelaus, in his *Spherics*, calls such a figure a trilateral (τρίπλευρον)." Pappus uses this word in the subsequent propositions. Another remark that fits here is that whereas Menelaus' proof of the triangle inequality is purely intrinsic, Pappus' proof uses the ambient Euclidean solid geometry (it is based on Proposition XI.20 of the *Elements*, which is a triangle inequality that concerns the three dihedral angles that form a solid angle.) The reason for which Pappus' proof must necessarily use Euclidean geometry is that this is the first proposition he gives on spherical geometry. As we already said, regarding Menelaus, spherical geometry, for both authors, based on the axioms of Euclidean geometry, and the first proposition, in any case, must use the Euclidean setting.

But the proofs of the next propositions of Pappus are intrinsic to the sphere. The statements are not always equivalent to those of Menelaus, and some of Pappus' propositions complement some propositions of his predecessor.

Let us now mention a few propositions of Pappus.

Proposition 2 says the following (Ver Eecke, 1982, p. 371):

> *If two arcs of great circles are drawn internally, above one side of a trilateral, then they are smaller than the remaining two sides of the trilateral.*

In other words, the proposition says that if we take an interior point in a triangle and if we join by two arcs of great circles that point to the vertices of the base, then the sum of these two arcs is smaller than the sum of the two legs of the triangle. This proposition is equivalent to Proposition 6 of the Spherics whose statement is (Rashed & Papadopoulos, 2017, p. 518):

> *If we produce from two extremities of a side among the sides of a triangle two arcs of great circles that meet within the triangle, then they are smaller than the remaining sides.*

Then, follow 9 propositions which are proved using Menelaus' methods. Some of the statements are close to propositions in Menelaus' Spherics, with slightly different hypotheses regarding the bounds on the lengths of the sides, and some other statements are contained in Theodosius *Spherics* (with proofs using Menelaus' intrinsic methods). As an example of Pappus' intrinsic methods, let us consider his proposition VI.4, which is equivalent to Proposition 38 of Menelaus (with a slightly different hypothesis concerning the lengths of the sides). The latter belongs to Group 4 of the Spherics, concerning the division of a triangle.

Menelaus' statement is the following (Rashed & Papadopoulos, 2017, p. 618):

> *If the sum of two unequal sides in a triangle is smaller than a semicircle, if we separate from the two extremities of the remaining side two equal segments, and if we produce from the two resulting points two arcs till the angle that the two sides contain, then they contain with the two sides two unequal angles, the greater at the smaller and the smaller at the greater, and the two produced arcs are smaller than the two sides of the triangle.*

Pappus' statement is the following (Ver Eecke, 1982, p. 373):

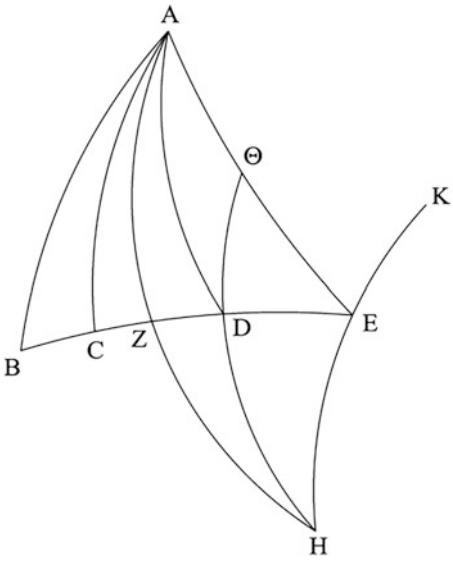

Fig. 18 The figure for Pappus' Proposition VI.4

Let four arcs of great circles AB, AC, AD, AE cut an arc of great circle BE, let the arc BC be equal to the arc DE, and let each of the arcs AB, AC, AD, AE be smaller than a quadrant. Then, the sum of the arcs BA, AE is greater than the sum of the arcs CA, AD.

We reproduce Pappus' proof in order to show the method (see Fig. 18).

Let us cut the arc *CD* into two equal parts at the point *Z*. Let us draw through the points *A*, *Z* the arc of great circle *AZH*, and let us set the arc *ZH* to be equal to the arc *AZ*. Let us draw through the points *H*, *E* the great circle *HEK* and through the points *H*, *D* the great circle *HD*Θ. Since the arc *HZ* is equal to the arc *ZA* and the arc *DZ* is equal to the arc *ZC*, it follows that the arc *DH* is also equal to the arc CA. For the same reason, the arc *EH* is also equal to the arc *BA*. But since the two arcs *AD*, *DH* are established internally on one of the sides *HA* of the trilateral *HEA*, it follows that the arcs *AD*, *DH* are smaller than the arcs *AE*, *EH*. Thus, the arcs *AE*, *EH* are greater than the arcs *AD*, *DH*. But the arc *EH* is equal to the arc *AB* and the arc *HD* is equal to the arc *AC*. Therefore, the sum of the arcs *BA*, *AE* is greater than the sum of the arcs *CA*, *AD*. This is what we had to prove.

I know of no other mathematician than Pappus before the modern times (that is, before the nineteenth century) who integrated in his writings Menelaus' methods of intrinsic geometry of the sphere.

6 Translations, Rectifications and Difficulties

Everything we know about the history of the translations and the various versions of Menelaus' *Spherics* is reported on in the first part of the edition (Rashed and Papadopoulos 2017), pp. 3–123 and in the two articles (Rashed and Papadopoulos

2014; Rashed and Papadopoulos 2015). I will summarize here some important points on that history.

Several Arabic versions of the *Spherics* were written starting in the ninth century. Al-Harawī's version, which relies on a version by al-Māhānī and which is a rectification[16] rather than a translation, is published for the first time, together with an English translation, in the volume (Rashed and Papadopoulos 2017). Besides al-Harawī's version, this volume contains the first critical edition of a fragment containing the 36 first propositions of a translation done in the same century, which we think is the oldest translation that survives. We know that another translation was also done in the same century, by the Arab mathematician and Hellenist Abū 'Uthmān al-Dimashqī. A Latin translation by Gerard of Cremona (1114–1175) and a Hebrew one by Jacob ben Makhir Ibn Tibbon (ca. 1273) were done from Arabic texts. According to the latter, there existed another Arabic translation by Ishāq ibn Ḥunayn, or by his father Ḥunayn ibn Ishāq. Besides these translations, there are also rectifications by Abū Naṣr Manṣūr Ibn 'Alī Ibn 'Irāq (born around the year 950), Naṣīr al-Dīn al-Ṭūsī (thirteenth century), Ibn Abī Jarrāda (thirteenth century), Muḥyī al-Dīn al-Maghribī (thirteenth century), al-Yazdī (fifteenth century), and certainly others. A German translation of the rectification by Irāq was published in 1936 by M. Krause, (Krause 1936). These versions differ on several points, with additions of lemmas and intermediate propositions, etc., but the overall mathematical content is the same. There are also writings and developments based on Menelaus' *Spherics* by Ibn Hūd, Thābet ibn Qurra, al-Bīrūnī, al Qiftī, Ibn al-Haytham, and others. We have discussed all this in the volume (Rashed and Papadopoulos 2017) where we have also made comparisons between significant passages of the existing Arabic versions that flourished from the ninth century on and continued till the thirteenth, and the Latin and Hebrew versions.

We have quoted, in the introduction of the present chapter, an excerpt of the Preamble of al-Harawī's rectification, in which the latter expresses his wonder and admiration for Menelaus' geometric reasoning, which he considers as completely new. In the same Preamble, al-Harawī mentions the difficulties inherent to the various translations, due to the fact that the geometers of his time were not capable of understanding several propositions and proofs of this treatise. He writes (Rashed & Papadopoulos, 2017, p. 24):

> When, from that book, the geometers received what they were not used to, and to nothing similar from all other kinds of geometries they knew, they found it difficult. The bad

[16] the Arabs used the words Iṣlāḥ إِصلَاح, which means "reform," or "revision" (an example is the treatise by Abū Naṣr Manṣūr ibn 'Alī ibn 'Irāq, *Iṣlāḥ Kitāb Mānālāwus fī al-ashkāl al-kuriyya*, Leiden, Or. 930), and Taḥrīr تَحرير, which means "redaction" (an example is Nasīr al-Dīn al-Ṭūsī's Taḥrīr Kitāb Mānālāwus fī al-ashkāl al-kuriyya [Hyderabad, 1359 H.]).

> translation and the fact that it was far from being understandable added to their apprehension, so they discarded it and they did not work on it. Nevertheless, no one among them denied the eminence of that book, but they acknowledged that what he showed in this way is easier and more valuable that anything which anybody else invested in.
>
> It was said that a group of geometers had the intention to rectify it, and since they were unable to do it, they asked the help of al-Māhānī, who rectified the first book and some propositions of the second, and he stopped at a proposition of which they said that its aim was difficult, and whose explanation was also hard.
>
> [. . .] I meditated on what al-Māhānī rectified and I saw during this short period of time that there were defects, and I carefully reviewed what needed to be corrected in the expression, in the meaning, and in the proof. And I persisted until the end of the book, until the proposition which the geometers imagined that al-Māhānī left aside and was not able to rectify. I also found a rectification that was far from being correct due to some modern geometer who claimed he rectified part of it, and left aside the rest. In the thing he said that he rectified there are some corrupt things, from which it was clear to anybody who examined them that he did not understand the purpose of this man [i.e., Menelaus].

According to the testimony of Naṣīr al-Dīn al-Ṭūsī, the situation of the existing versions of the *Spherics* in the thirteenth century was not better, except for the one by Ibn 'Irāq. He writes:[17]

> When I reached the book of Menelaus on the spherical figures, I found it in many different copies, with undetermined problems, together with disappointing rectifications, like the rectifications of al-Māhānī, of Abī al-Faḍl Aḥmad ibn abī Sa'ad al-Harawī and others, some of which are incomplete and others wrong. I was puzzled for what concerns the proof of some problems, until I obtained the rectification of Abū Naṣr Ibn 'Irāq.

It is likely that Ibn 'Irāq's is a rectification of the translation due to the Hellenist and mathematician Abū 'Uthmān al-Dimashqī. We refer again the reader to our discussion in (Rashed and Papadopoulos 2017).

In addition to his redaction of the *Spherics*, Ibn 'Irāq wrote a short treatise which concerns Proposition 71 which we discussed above (in our classification on Sect. 3, we included it in Group 8), titled *The Rectification of a Proposition of the Book of Menelaus on the Spherics*. A translation of this treatise is provided in the article (Rashed and Papadopoulos 2014).

Ibn Abī Jarrāda, a contemporary of Tūsī, considered that the most popular rectification that existed at his time was still that of al-Māhānī/al-Harawī, which, despite the fact that, according to him, it has many short-comings. Let us quote him (see (Rashed & Papadopoulos, 2017, p. 18)):

> I found that book (Menelaus' *Spherics*) so altered as none of the other geometry books, for reasons that were specific to it, among which are the difficulties in the proofs, for someone who was supposed to clarify them, because of the necessity of these conditions. And among these difficulties is the fact that Menelaus over-summarized it, as he mentioned in the Preamble. And also, among these difficulties, the multiplicity of the problems hidden in the course of the proofs, and of the abandoned ones to which he refers. Among these, that he

[17] Reference in (Rashed & Papadopoulos, 2017, p. 16)

> meant by the ratio of the arcs the ratio of the double of their chords in the entire third book and in part of the fourth, and he meant by the ratio of the arcs their own ratio in other parts of the fourth book, thinking, because of his extreme power in that field, that this would not be hidden to anyone who will undertake the clarification of his book. That was his basis, and it became difficult to anyone who came after him to recognize this. Part of <the difficulties> is also the fact that he refers in the proofs of the propositions of the fourth book to what he has proved in one of his books, titled *The Measurable Figures*, a book which is unknown, or else it is foreign and did not reach us.
>
> A group <of people> proposed to rectify this book; all of them had failed the aim, they stopped before reaching their goal and they did not comply with Menelaus' method. Among them are those who were not able to penetrate it. There are also those who rectified one part of the book, in the given order, and were incapable of going through it, like al-Māhānī, who reached a proposition which he was incapable of solving, and thus he did not complete it. Among them are also those who pretended they have rectified all the book, deluding and disappointing anyone who examines it. They relied on the fact that when one encounters a difficulty in understanding it, he attributes this lack either to himself or to the corruption of the transcription.
>
> Even though [al-Harawī's] rectification is the most famous one among those which the book was subject to, the best that he brings is where he limits himself to repeat Menelaus' expression. But as soon as he proposes himself to prove a neglected <problem> or to clarify a difficulty, or something similar, then he leaves the conditions of Menelaus, like in the first lemma by which he proved the proposition where al-Māhānī stopped, proving it with common sections whereas what he brought does not suffice for the completion of that proposition. Or as he did in the thirty-seventh proposition of the first book: he resorted to a *reductio ad absurdum* for what is hidden in the proof of Menelaus. Regarding the fourth book, which is the third in his rectification, he did not understand anything of it except the ninth proposition and he attributed everything which is in that book concerning the ratios of arcs to the ratios of chords of the double. Everything that I mentioned should be clear to anyone who examines the rectification of al-Harawī.

This translation and rectification work on Menelaus' *Spherics* generated an important mathematical activity that changed the course of Arabic mathematics. This is the subject of the next section.

7 On the Impact on Arabic Mathematics

Among Menelaus' propositions that had a major impact on Arabic mathematics is the Sector Figure (Proposition 66). Several treatises were written on the applications of this proposition. One such oldest known complete treatise is of Thābit ibn Qurra (d. 901), titled *A Treatise on the Sector Figure*, is reviewed and commented on in detail by H. Bellosta in her article (Bellosta 2009). We quote from the Introduction to this treatise (Bellosta, 2009, p. 365):

> I know that people never discussed any geometrical proposition used in astronomy as much as they did for this proposition. They did not overrate its reputation and the reason of their interest for it; this is what we know from the number of times it was used and the extreme need that we have for it in the spherical science. This is certainly the main direction on which

> many works in astronomy are based. Even though others than Ptolemy obtained this proposition and talked about it, nobody, to our knowledge, improved its statement or < gave> any arrangement or revision that matches its proof.

Other developments concerning the Sector Figure were reported on by Abū al-'Abbās al-Nayrīzī and Abū Ja'far Muḥammad ibn al-Ḥusayn al-Khāzin, in their commentaries of the Almagest. There is a large literature on the impact of this proposition on Arabic mathematics. The reader may refer to the work of M.-Th. Debarnot (Debarnot 1996; Debarnot 2002), and the latter's edition of the tenth century work of al-Bīrūnī (Debarnot and Al-Bīrūnī 1985). We have commented on this proposition and its applications in the commentary contained in our edition of the *Spherics*; see (Rashed & Papadopoulos, 2017, pp. 292–337).

In the thieteenth century, Naṣīr al-Dīn al-Ṭūsī, wrote a treatise on the Sector Figure (Naṣīr al-Dīn al-Ṭūsī 1891). in which he showed how a complete trigonometric system of spherical geometry can be derived from this proposition. Al-Ṭūsī's treatise was translated into French and edited by Alexandre Carathéodory[18] in 1891 (Naṣīr al-Dīn al-Ṭūsī 1891). See the detailed review in (Papadopoulos 2018). It is only in the eighteenth century that Leonhard Euler published a treatise containing such a complete system, obviously, without being aware of al-Ṭūsī's work, see (Euler 1753). Naṣīr al-Dīn uses in his work the notion of polar triangle. This notion and the spherical Sine Rule were already introduced in the tenth century by Ibn 'Irāq and Abū al-Wafā' al-Būzjānī (940–998). We have recalled, in (Rashed & Papadopoulos, 2017, pp. 795–801), the story of these discoveries and we have pointed out the confusion that reigned in the eighteenth and nineteenth century literature concerning the history of spherical trigonometry, in particular concerning the discovery of the polar triangle.

Naṣīr al-Dīn's treatise is a remarkable historical document that gives a very good idea of the state of spherical geometry, as developed by the Arabs between the ninth and the thirteenth centuries. At the end of Book IV, Naṣīr al-Dīn says that the Ancients have used the quadrilateral figure with confidence, without treating the large number of cases, and he mentions as examples Menelaus' *Spherics* and Ptolemy's *Almagest*. But the moderns, he says, in order to avoid engaging themselves in the examination of the multitude of ratios and the lengthy considerations that the use of compounded ratios requires, imagined and studied other figures, which replace the quadrilateral, which are as much useful and which do not lead to a multitude of cases. The presentation of these methods is the subject of Book V of his treatise.

We already mentioned another theorem of the *Spherics* that had a large impact on Arabic mathematics, especially on the development of spherical geometry with works by al-Būzjānī, al-Khujandī, Ibn Labbān, Ibn 'Irāq, and al-Bīrūnī. This is Proposition 71. As we already recalled, Menelaus did not give a proof of this

[18] Alexandre Carathéodory was a great-uncle of the famous mathematician Constantin Carathéodory.

proposition, but only an outline of a proof. Writing a complete proof became a big challenge that was taken up by several mathematicians, in Baghdad and elsewhere, between the ninth and the thirteenth centuries. We already mentioned that the proof of this proposition uses an invariance property of the spherical cross ratio, and to prove this invariance, the mathematicians of the tenth century used the spherical Sine Rule which they had established. It is conceivable that the development of this rule was motivated by the research in spherical geometry due to the effort to prove this proposition of Menelaus. In fact, the search for a proof of this proposition acted as a motivation for reshaping the whole field of spherical trigonometry. Likewise, it is possible that the discovery by Ibn ʻIrāq of the notion of polar triangle was also motivated by his work on the proof of Menelaus' Proposition 71. In his *Rectification of a Proposition of the Book of Menelaus on the Spherics*, which is edited and translated in the paper (Rashed and Papadopoulos 2014), Ibn ʻIrāq presents a set of propositions on spherical geometry that are useful in the proof of this proposition, but that are also of independent interest. At the same time, he gives a proof of the proposition under assumptions that are weaker than the ones that Menelaus made. While he worked on the proofs, Ibn ʻIrāq declared that not only Proposition 71, but the whole treatise of Menelaus' *Spherics* needs to be corrected. He reported on the attempts by al-Māhānī and al-Harawī on correcting Menelaus' treatise and he discussed several points in their proofs. We have discussed these points in our article (Rashed and Papadopoulos 2014).

Understanding the proof of Proposition 71 became an important matter, not only for mathematicians, but also for astronomers and other scientists. The last section of our chapter concerns astronomy.

8 On the Impact on Astronomy

In his introduction to his rectification, al-Harawī writes (Rashed & Papadopoulos, 2017, p. 501): "Ptolemy relies on this book, especially in the second book of the *Almagest* concerning angles and triangles produced by intersections of great circles." In the same introduction (Rashed & Papadopoulos, 2017, p. 504), he writes: "This book has an immense value in astronomy and the properties of the figures that occur when the horizons intersect the ecliptic, the orbs of the meridian, the equator and the circles called the ephemerides that the sun draws at the beginning of the zodiac." Concerning Menelaus' Proposition 66 (the Sector Figure), al-Harawī; writes (Rashed & Papadopoulos, 2017, p. 684):

> And he worked out in that book the figure which Ptolemy calls the "sector", and he constructed upon it several figures. But Ptolemy uses, from that book, numerous propositions in the second book of his treatise the *Almagest*, without attributing them to anybody and without proving anything. Indeed, all what he uses, for what concerns angles, arising from the intersection of the ecliptic and the horizons, and other things, can be proved by this book. The lemmas we need are among those which Ptolemy introduced, on the intersection of two lines and on the composition of the ratios which are made up thereof. And we find that

> Menelaus moved in that book to the Sector Figure in a way which does not fit his method, since he did not set for this passage any lemma or any discourse and he also did not make it the starting of a book. So either the lemmas of that figure were known by them, widespread, or they disappeared from that book.

The astronomer Ibn al-Haytham, who was familiar with the Sine Rule and who used it, also used the Sector Figure Theorem in his astronomical works.[19]

With all this, we must say that the astronomical side of Menelaus' *Spherics* has been so much exaggerated to the point that some authors have considered that the work (or at least part of it) was written for its use in astronomy. The confusion started with authors like Bjørnbo and Heath who (mistakenly) declared that a substantial part of the *Spherics* is astronomical, or that it has been written for the purpose of astronomy.[20] These statements have been repeated tirelessly and superficially by several modern authors. The first historians to put forward these ideas were probably convinced that among the Greeks, the only sphere worth studying was the celestial sphere, an idea that we, mathematicians, find hard to believe, knowing that the sphere and its intersections by planes is as natural a field of mathematics to study, as are the cones and their intersections by planes, which are the subject of study of Apollonius' *Conics*, and, in fact, as the ordinary plane with its straight lines. It is probable that Heath was influenced in his opinion by A. A. Bjørnbo (Bjørnbo 1902). In (Rashed & Papadopoulos, 2017, p. 3) we have given a list of authors from before the 1950s who repeated the statement that Menelaus' *Spherics* (or at least a substantial part of it) is a work on astronomy. The names of many modern authors may be added to this list, we prefer not to dwell on this.

Another statement of Heath which led to a misinterpretation is that he declared that Book III of Menelaus' *Spherics* belongs to "trigonometry,"[21] a statement which is also absurd. Heath writes in (Heath, 1921, p. 265): "It will have been noticed that, while Book I of Menelaus gives the geometry of the spherical triangle, neither Book I nor Book II contains any trigonometry. This is reserved for Book III." In fact, spherical trigonometry has been developed only several centuries later. The only reasonable meaning that can be given to Heath's statement is that Book III (like Books I and II) constitute a study of spherical triangles, but if such a study

[19] See e.g. Proposition 5 of the treatise of Ibn al-Haytham titled *The Configuration of the Motion of Each of the Seven Wondering Stars*, p. 294 sqq., in: Roshdi Rashed, *Les mathématiques infinitésimales du IXe au XIe siècle*, vol. V: *Ibn al-Haytham. Astronomie, géométrie sphérique et trigonométrie*, London, 2006.

[20] Heath's statement, concerning Menelaus' *Spherics*, in (Heath, 1921, p. 265), is bewildering: "Book II has practically no interest for us. The object of it is to establish certain propositions, of astronomical interest only, which are nothing more than generalizations or extensions of propositions in Theodosius *Sphaerica*, Book III."

[21] In Heath's treatise (Heath 1921), the study of Menelaus' book is part of the chapter called *Trigonometry*.

is termed as trigonometry, then several books of Euclid's *Elements* should also be termed as *trigonometry*. In fact, Heath says (p. 260) that "Greek trigonometry in its highest development [is] in the *Spherica* of Menelaus," which is correct, but it is only a relative statement. It is correct if we mean by this "trigonometry" in its etymological sense, the study of triangles, but then we have to include also Books I and II of the work.

On the other hand, taking about Greek astronomy, it is fair to recall that Theodosius wrote (at least) two astronomical treatises in which the celestial phenomena are studied from a geometric point of view, namely, *On habitations* and *On the days and nights*. The treatise *On habitations* contains 12 propositions which are all concerned with how the stars in the celestial sphere are seen from different places of the Earth. A brief paraphrase of the propositions is contained in Delambre's *Histoire de l'astronomie ancienne*, (Delambre 1817), vol. 1, pp. 235–7. I have reproduced in Fig. 19 a page containing Proposition 9 of the Habitations, which concerns a comparison between the location of the stars that are visible and the duration of the visibility of these stars, at two places that are not situated on the same meridian. For a recent edition of the Arabic translation of the *On habitations*, due to Qusṭa ibn Lūqā appeared in 2011, together with the Latin translation (done from the Arabic) Gerard of Cremona and an English translation, see (Kunitzsch and Lorch 2011).

This being said, I would like to stress, first, on the fact, that Heath remains one of the most valuable specialists of Greek mathematics in modern history, and secondly, that, by an ironic twist of history, it is true that Ptolemy, in his great astronomical treatise, relied heavily on a proposition of Menelaus' *Spherics*, which is not an astronomical work, rather than on the astronomically oriented *Habitations* or *Days and nights* of Theodosius, or on the *Moving sphere* or the *Risings and settings* of Autolycus, the reason being of course that this proposition of Menelaus could be used in an effective way in astronomical calculations.

9 As a Word of Conclusion

In the preceding pages, I have talked about the history of Menelaus' *Spherics*, discussing its relation with ancient and modern research on geometry.

In the next two appendices, I have included modern proofs of two propositions of Menelaus, using spherical trigonometric formulae. Such modern proofs are straightforward and they sometimes give more precise statements than the synthetic arguments. However, there is an enormous chasm between these automatic proofs and the depth of Menelaus' geometric proofs, in which the etymology of the word *Theorem*[22] as a contemplation finds it full force. It is in such instances which after all are rare in the history of mathematics that one can recognize the seal of a real mathematician.

[22] From the Greek, θεωρέω, "I watch," the same origin than the word *theatre*.

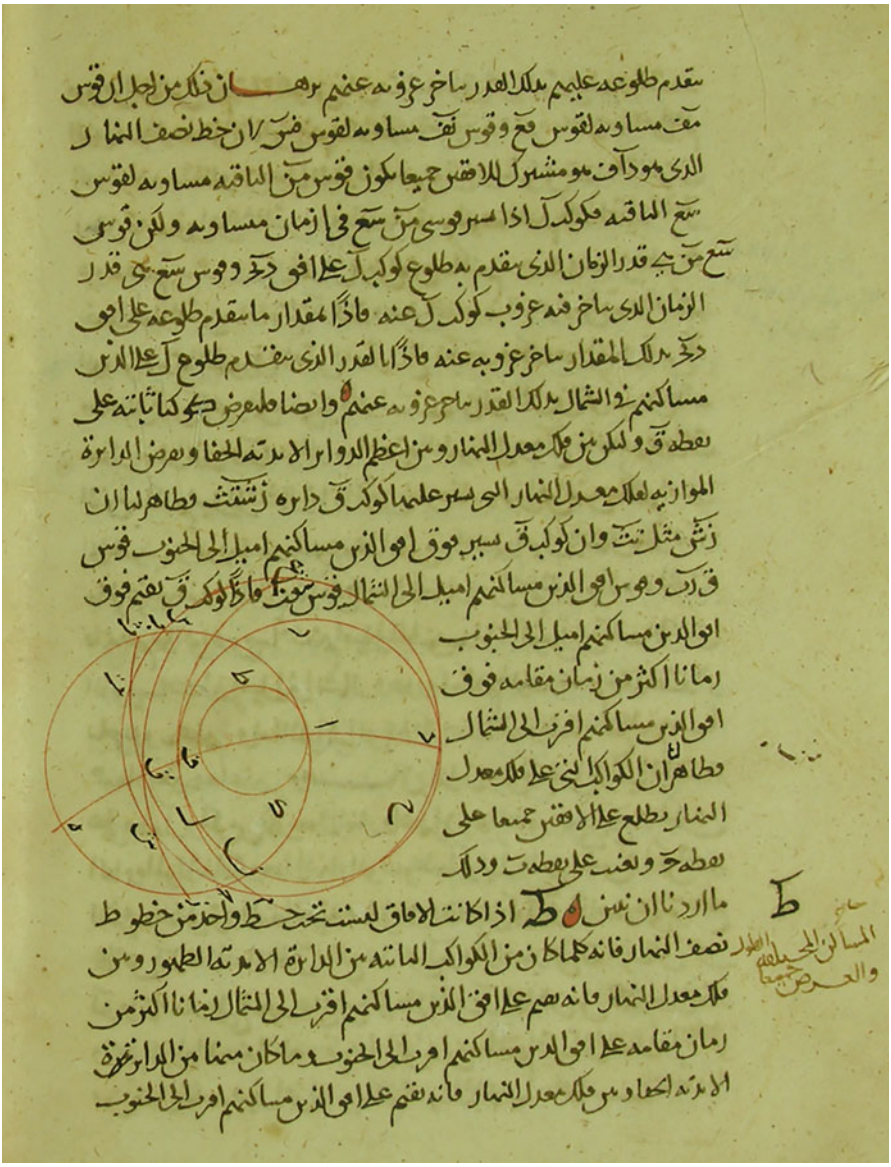

Fig. 19 From Theodosius' *Habitations*; at the bottom of the page, the statement of Proposition 9 and the corresponding figure. Version of Qusṭa ibn Lūqā, Ms. 3464, fol. 121, Topkapi Saray, Ahmet III

Acknowledgments This work obviously owes a lot to Roshdi Rashed with whom I collaborated for the edition (Rashed and Papadopoulos 2017), and I take this opportunity to express my admiration for all the work he has done for the history of Greek and Arabic mathematics.

Appendix I: A Proof of Proposition 27 by Spherical Trigonometry

We start with a formula of Euler from his memoir (Euler 1797) which says that the area of a spherical triangle ABC in terms of the lengths of sides a, b, c is equal to:

$$\frac{1+\cos b+\cos a+\cos c}{4\cos\frac{b}{2}\cos\frac{a}{2}\cos\frac{c}{2}}.$$

Consider now a triangle ABC, let D and E be the midpoints of AB and BC, and DE the arc of great circle joining them.

The cosine formulae in the triangles ABC and ADE give:

$$\cos B=\frac{\cos a\cos c-\cos b}{\sin a\sin c}$$

and

$$\cos B=\frac{\cos\frac{a}{2}\cos\frac{c}{2}-\cos DE}{\sin\frac{a}{2}\sin\frac{c}{2}}.$$

Equating the two values of $\cos B$, we obtain

$$\cos DE=\frac{(\cos b-\cos a\cos c)\left(\sin\frac{a}{2}\sin\frac{c}{2}\right)+\cos\frac{a}{2}\cos\frac{c}{2}\sin a\sin c}{\sin a\sin c}.$$

Replacing in the right hand side $\cos a$ and $\cos c$ by their values in terms of $\sin\frac{a}{2}$, $\sin\frac{c}{2}$, $\cos\frac{a}{2}$ and $\cos\frac{c}{2}$, and after some cancellations, we get:

$$\begin{aligned}\cos DE&=\frac{\cos b+2\cos^2\frac{a}{2}+2\cos^2\frac{c}{2}-1}{4\cos\frac{a}{2}\cos\frac{c}{2}}\\&=\frac{\cos b+(1+\cos a)+(1+\cos c)-1}{4\cos\frac{a}{2}\cos\frac{c}{2}}\\&=\frac{1+\cos b+\cos a+\cos c}{4\cos\frac{a}{2}\cos\frac{c}{2}}\\&=\frac{1+\cos b+\cos a+\cos c}{4\cos\frac{b}{2}\cos\frac{a}{2}\cos\frac{c}{2}}.\cos\frac{b}{2}\end{aligned}$$

Using Euler's formula we get

$$\cos DE=\cos\frac{1}{2}\mathrm{Area}(ABC)\cos\frac{b}{2},$$

which implies $DE<AC/2$.

Appendix II: A Proof of Proposition 71 by spherical Trigonometry

The following formula gives a more precise version of Menelaus' proposition 71:

Theorem Given a spherical triangle ABC with right angle at A and acute angle at C, and such that AC is smaller than a quarter of a circle, then we have:

$$\frac{\sin(BC + AC)}{\sin(BC - AC)} = \frac{1 + \cos C}{1 - \cos C}.$$

In particular, the ratio of sines in the conclusion depends only on the angle C, which implies the result of Proposition 71.

The proof is given in the setting of hyperbolic geometry in the paper (Papadopoulos and Su 2017). That proof is based on some non-Euclidean trigonometric transformations. It is easily adapted the spherical case, replacing the hyperbolic functions sinh and cosh by the functions sin and cos. We use the following lemma, which follows from the spherical cosine and Sine Rules.

Lemma We have

$$\tan BC = \cos C \cdot \tan AC.$$

Then we expand $\sin(BC + AC)$ and $\sin(BC - AC)$:

$$\frac{\sin(BC + AC)}{\sin(BC - AC)} = \frac{\sin BC \cos AC + \sin AC \cos BC}{\sin BC \cos AC - \sin AC \cos BC}$$
$$= \frac{\dfrac{\sin AC}{\cos AC} + \dfrac{\sin BC}{\cos BC}}{\dfrac{\sin BC}{\cos BC} - \dfrac{\sin AC}{\cos AC}}.$$

Using the lemma, the last term becomes

$$\frac{1 + \cos C}{1 - \cos C},$$

which is what we wanted to prove.

Abstract

The debate about the foundations of mathematical sciences traces back to Greek antiquity, with Euclid and the foundations of geometry. Through the flux of history, the debate has appeared in several shapes, places, and cultural contexts. Remarkably, it is a locus where logic, philosophy, and mathematics meet. In mathematical astronomy, Nicolaus Copernicus's axiomatic approach toward a heliocentric theory of the universe has prompted questions about foundations among historians who have studied Copernican axioms in their terminological and logical aspects but never examined them as a question of mathematical practice. Copernicus provides seven unproved assumptions in the introduction of the brief treatise entitled *Nicolaus Copernicus's draft on the models of celestial motions established by himself*, better known as *Commentariolus* (ca. 1515), published circa 30 years before the final composition of his heliocentric theory (*On the revolutions of the heavenly spheres*, 1543). The assumptions deal with the renowned Copernican hypothesis of considering the Earth in motion and the Sun, not affected by motion,

near the center of the universe. Although Copernicus decides to omit the proofs for the sake of brevity, the deductions in the *Commentariolus* are supposed to be drawn from the initial seven assumptions. Questions on the nature (are they postulates or axioms?) and the logic (is there an internal rigor?) of those assumptions have yet to be fully explored. By examining Copernicus's seven assumptions as a question of mathematical practice, it is possible to hold historical, philosophical, and logical aspects of Copernican axiomatics together and understand them as part of Copernicus's intuition and creativity.

1 Introduction

The first written draft of the heliocentric theory by Nicolaus Copernicus dates back to circa 1515 and is attested in an unpublished manuscript, which was known – already among Copernicus's peers and acknowledged then among later generations of scholars and historians – as *Commentariolus* (brief commentary). The full title sounds *Draft on the hypothesis on celestial motions established by Nicolaus Copernicus* (*Nicolai Copernici de hypothesibus motuum caelestium a se constitutis commentariolus*). This work was likely composed between 1510 and 1515. It would later attract the attention of historians of astronomy, especially in the twentieth century (Swerdlow 1973; Goddu 2010, 243–274, 291; Folkert et al. 2019, 7–111). In history, among the scholars who had in their hands a copy of the *Commentariolus*, some renowned astronomers and mathematicians are to be mentioned: Joachim Rheticus, Duncan Liddel, and Tycho Brahe (Dobrzycki and Szczucki 1989; Omodeo 2016, 11; Folkert et al. 2019, 8–14). This aspect is particularly telling of the relevance that the *Commentariolus* assumed in the sixteenth century, let alone for the wide circulation and discussion of Copernican theory in Europe. Particularly noteworthy is the so-called Aberdeen edition, because it contains the pages of *Commentariolus* and *De revolutionibus orbium coelestium* (*On the revolutions of the heavenly spheres*, Copernicus's major work, see Copernicus 1978) in parallel, according to apparent affinity between the topics. This shows that the generation immediately following Copernicus considered the two works to be complementary and not mutually exclusive, though they do not exactly match: in fact, Copernicus refined, polished, and improved his theory between the composition of *Commentariolus* and the publication of *De revolutionibus* in 1543 (Dobrzycki 1973; Folkert et al. 2019: 8–9).

The *Commentariolus* has left historians puzzled on several issues. On the one hand, the aspects regarding the details of the motion of the Earth and the mathematics implicit in the text as well as the question on the derivation of the heliocentric

hypothesis (i.e., whether Copernicus arrived at the models independently or was possibly inspired by geometric models developed by Arabic astronomers) are still debated to this day (Swerdlow 1973; Blåsjö 2014; Ragep 2016; Swerdlow 2017; Blåsjö 2018). On the other hand, the seven propositions that introduce the heliocentric hypothesis in the *Commentariolus* have been the object of much scholarly discussion (Swerdlow 1973; Rosen 1976; Goddu 2010; Vesel 2014; Lerner and Segonds 2015; Folkert et al. 2019, 24–28). On the latter issue, the basic questions are as follows: What kind of propositions are they? Postulates, axioms, or something else? How should they be conceived and what kind of meaning does Copernicus attach to *axioms*? Do they have an internal rigor? Was Copernicus looking for logical rigor?

Copernicus does indeed adopt an axiomatic approach to his mathematical–astronomical theory, but the nature of his principles has confounded historians of science and generated a debate which continues to this day. Questions about Copernicus's axioms have hitherto been confined to historians of science, and studies of mathematical practice have never been employed to tackle such a problem.

This chapter examines Copernicus's axiomatic approach as a question of mathematical practice. First, it illustrates the main features of pre-modern axiomatics, evaluates the interpretations on *Commentariolus*'s principles advanced so far by historians, and eventually offers a new interpretive framework in which historical, philosophical, and logical details are comprehensively considered.

2 Axiomatics Before Axiomatics

One may ask: What does Copernicus have to do with axiomatics? Copernicus and his time seem far too distant from us today to suggest that there is any link to questions concerning "axiomatics" (in the modern sense of the term). In fact, the kind of questions that recent literature on mathematical practice has been tackling regarding axioms and their use is present already in the history of the reflections, discussions, and debates on the foundations of mathematical sciences (Schlimm 2013). These debates have their roots in Greek antiquity. For instance, there are traces of debates on foundational issues of mathematics in ancient and Hellenistic times (Acerbi 2010; Acerbi 2013; De Risi 2016). For centuries, the most successful reference work for Western mathematical sciences has been Euclid's *Elements*, and this work has also been taken as emblematic of axiomatic rigor. On the one hand, the theorems taken from the *Elements* were employed to build mathematical theories; on the other hand, the hypothetico-deductive structure of *Elements* was deemed the prototype of reason and certainty. On these grounds, it soon became an important object of study not only for mathematicians, but also for philosophers and logicians. The *Elements*' deductive system is based on principles, from which all subsequent deductions are to be drawn. A set of principles opens Euclid's *Elements*, Book One: definitions of the subject addressed, postulates, and axioms (common notions). The distinction between postulates and axioms was a topic of debates and controversies already in ancient times. However, the ancient conception of axiomatization was very different from our own. For centuries, mathematicians, logicians, and

philosophers did not look upon the definition of axioms as logically necessary, but rather saw them in light of the need to justify a "weak" science, which would not need to justify its principles if it was already consistent and, roughly speaking, logically coherent. This explains why the foundations of arithmetic had been (largely though not entirely) neglected until the nineteenth century, while the foundations of geometry were discussed since Antiquity, making Euclid's *Elements* the canon for Western mathematics (De Risi 2016).

Euclid's prevalence notwithstanding, the questions raised about principles were quite heterogeneous. Notably, influential scholars of the Greek tradition, such as Archimedes, Aristarchus, Apollonius, and others, did not assume principles in the same manner as Euclid did in the *Elements* and, in applied mathematics, such as optics, Euclid himself did not employ the same axiomatics as in the *Elements* (Capecchi 2018: 6–13). However, there was no homogeneity on the nature of principles even at a more general level. Notably, Aristotle's definition of postulates does not coincide with the Euclidean use, and Proclus, reprising Geminus (first century BCE), differs from other Greek philosophical schools (Bobzien 1996; Acerbi 2010; Acerbi 2013; Bobzien 2019).

In sum, the history of axiomatics has never been monolithically Euclidean. However, the focus on axiomatization of arithmetic in the nineteenth and twentieth centuries, after the works of Dedekind, Klein, Hilbert, Peano, Frege, and so on and the reflections on axiomatics by logicians like Carnap, Gödel, and Tarski and his followers, has led historians, philosophers, and logicians to study traces of "axiomatics before axiomatics" in mathematical sciences (optics, astronomy, mechanics), logic, and philosophy of antiquity till early modernity (Henkin et al. 1959; Hintikka et al. 1981; Novaes 2020; Cantù and Luciano 2021). Some influential works are worthy of note in this regard. Arpad Szabó was pioneering in his studies of the interplay of philosophical and mathematical influences in the development of Greek axiomatics and claimed that the Eleatic school influenced the rise of the deductive method in early Greek mathematics (Szabó 1964). Contrary to Szabó, Wilbur R. Knorr argued that the deductive procedures evident in fifth-century Greek works are intrinsic to mathematics and that the influence of the Eleatic dialectic on the development of axiomatics in arithmetic and geometry could only have occurred later, in the environment of the fourth-century Academy, in which the interest in mathematics merged with a renewal of the logical and philosophical views espoused by the Eleatics (Knorr 1981). Later on, Patrick Suppes shed light on axiomatics in Greek and Hellenistic science, pointing out their similarities with contemporary philosophical and scientific endeavors:

> the admiration many of us have for the rigor and relentlessness of the axiomatic method in Greek geometry has given us a misleading view of the role of this method in the broader framework of ancient Greek mathematical sciences. By stressing the limitations of the axiomatic method or, more explicitly, by stressing the limitations of the role played by the axiomatic method in Greek mathematical science, I do not mean in any way to denigrate what is conceptually one of the most important and far-reaching aspects of Greek mathematical thinking. I do want to emphasize the point that the use of mathematics in the mathematical sciences and in foundational sciences, like astronomy, compare rather closely with the contemporary situation. (Suppes 1993, 25)

As the above claims suggest, the possibility of external influences (from philosophy or logic) on an axiomatic method in mathematical sciences is a widely explored topic, and questions on this issue are also raised by the use of axioms in *Commentariolus*. Whereas this text has indeed pushed historians to search for possible philosophical influences on Copernicus's axiomatic approach, the possibility of this approach as intrinsic to Copernicus's mathematical practice has yet to be considered.

3 Questions About Copernicus's Axioms

Philadelphia, PA, 1973. At a symposium marking the 500th anniversary of Copernicus's birth, the eminent historian of science Noel Swerdlow presents a paper on the *Commentariolus* along with a translation into English and a commentary thereon. He states that Copernicus incorrectly called the seven sentences in the first section of the *Commentariolus* "axioms" and that those assumptions are illogically structured – the question on axioms in the *Commentariolus* became a topic of interest immediately following Swerdlow's translation of the Latin text (Swerdlow 1973). I will therefore report Swerdlow's translation since it is the one from which the discussions on axioms proceeded.

Swerdlow's critique refers to the first passages of *Commentariolus*, where Copernicus claims that Claudius Ptolemy and his predecessors were not coherent with the axiom of uniform circular motion, for they introduced geometrical devices which ultimately contradicted that principle and made cosmology excessively complicated. Ultimately, his predecessors failed to conceive of the universe as an integral whole (Goddu 2009). In the following, the words of Copernicus, writing in first-person singular, account for this state of the art:

> Therefore, when I noticed these [difficulties], I often pondered whether perhaps a more reasonable model composed of circles could be found from which every apparent irregularity would follow while everything in itself moved uniformly, just as the principle of perfect motion requires. After I had attacked this exceedingly difficult and nearly insoluble problem, it at last occurred to me how it could be done with fewer and far more suitable devices than had formerly been put forth if some postulates, called axioms, are granted to us, which follow in this order:
>
> First Postulate There is no one center of all the celestial spheres (*orbium*) or spheres (*sphaerarum*).
>
> Second Postulate The center of the earth is not the center of the universe, but only the center towards which heavy things move and the center of the lunar sphere.
>
> Third Postulate All spheres surround the sun as though it were in the middle of all of them, and therefore the center of the universe is near the sun.
>
> Fourth Postulate The ratio of the distance between the sun and earth to the height of the sphere of the fixed stars is so much smaller than the ratio of the semidiameter of the earth to the distance of the sun that the distance between the sun and earth is imperceptible compared to the great height of the sphere of the fixed stars.
>
> Fifth Postulate Whatever motion appears in the sphere of the fixed stars belongs not to it but to the earth. Thus the entire earth along with the nearby elements rotates with a daily motion on its fixed poles while the sphere of the fixed stars remains immovable and the outermost heaven.

> Sixth Postulate Whatever motions appear to us to belong to the sun are not due to [motion] of the sun but [to the motion] of the earth and our sphere with which we revolve around the sun just as any other planet. And thus the earth is carried by more than one motion.
>
> Seventh Postulate The retrograde and direct motion that appears in the planets belongs not to them but to the [motion] of the earth. Thus, the motion of the earth by itself accounts for a considerable number of apparently irregular motions in the heavens. (Translation Swerdlow 1973, 435–436)

In response to Swerdlow's criticism, Edward Rosen attempted to do justice to Copernicus's axiomatics (Rosen 1976). The problem would also be taken up again later (Goddu 2010; Vesel 2014; Lerner and Segonds 2015; Folkert et al. 2019; Goddu 2019, 162–163; more on this below). In sum, the questions on Copernicus's axiomatic approach touch on two key areas: *terminology* and *logic*.

3.1 Terminology

Let us recall Copernicus's words in *Commentariolus*:

> [. . .] it at last occurred to me how it could be done with fewer and far more suitable devices than had formerly been put forth if *some postulates, called axioms*, are granted to us, which follow in this order. (Swerdlow 1973, 435, emphasis added)

The original Latin text reads *petitiones quas axiomata vocant*, where *petitio* conveys a variety of meanings: requirement, statement, assumption, axiom, and postulate.

According to Swerdlow (1973, 437):

> The seven postulates, incorrectly called axioms since they are hardly self-evident, take the place of the general description of the universe in the opening chapters of the *Almagest*, the *Epitome*, and later, *De revolutionibus*. [. . .] There is no reason to doubt that he also believes these postulates to be true.

Swerdlow was undoubtedly referring to a precisely connotated meaning of axioms and postulates, where axiom is exclusively connected to self-evidence. This distinction is not modern; it traces back to the debates on Euclid's *Elements*, more precisely to the Greek philosopher Geminus (first century BCE), as attested in Proclus's *Commentary on the First Book of Euclid's Elements* (Acerbi 2010). According to Geminus-Proclus, the postulates of Euclid's *Elements* can be divided into two groups, reflecting their different nature: constructions are required in postulates 1–3, while postulates 4–5 state properties of particular geometric objects. As for the axioms (or common notions), they were generally conceived as assumptions conveying self-evident truths, hence requiring no proofs. Yet, not every author of mathematics assumed principles in the same manner as Euclid did. As anticipated above, Archimedes used axioms as true statements to describe the physical world, for example, Archimedes's *On the Sphere and the Cylinder* opens with axioms (Netz 2004, 34–36); Aristotle thought that "an

axiom is a primary proposition which must be possessed by whoever is to gain any knowledge"; "the axioms are the primary propositions from which a proof proceeds" (Aristotle 2002, I, 2: 72a17; I, 10: 76b14–15); the Stoics considered axioms as kinds of assertibles but did not employ the category of self-evidence in their logic, much to Proclus's disappointment (Ierodiakonou 2006).

Edward Rosen, author of translations of several Copernican treatises, *Commentariolus* included, accused Swerdlow of anachronism (Rosen 1976): Copernicus was not taking part in any Hilbertian program. Rosen's reply was beneficial to future generations of Copernicus scholars. André Goddu (Goddu 2010) undertook detailed research on the making of Copernican cosmology and his possible sources, detected his logical and philosophical backgrounds, and surmised a plausible method of reasoning in a Socratic-dialectic process, used by Copernicus in setting out his axioms. Goddu claimed that axioms are to be intended in the sense of common notions, assumptions to be taken for granted, where no self-evidence is needed:

> Copernicus began *Commentariolus* controversially with "petitiones" that he also called "axioms." If we set aside the personal attacks by some commentators, the experts agree, even if inadvertently, that he did not mean the word "axiom" in the sense of self-evident principles but rather in the sense of assumptions or common notions. As Copernicus himself made abundantly clear, the rest follows only if the seven postulates or assumptions are granted him. It is evident that he arrived at these seven propositions by working his way back to them as the ones necessary and sufficient from which to derive the remaining propositions. (Goddu 2010, 243)

Matjaž Vesel proposed a different interpretation. The axioms are set out and Copernicus draws his conclusions directly from them, and his source should be Proclus's commentary on Timaeus:

> I believe Copernicus' manner of exposition and the nature of *petitiones quas axiomata vocant* find their explanation in Proclus' *Commentary on Plato's Timaeus* II, 3 [. . .]. Proclus explains that Plato is not an empiricist: Plato will not start with experiences and then draw conclusions from them. Plato's *methodos* is hypothetical, or, rather, Plato uses the method of the hypothesis. He sets out fundamental *axiômata* and *hypotheseis* and draws conclusions from them. Proclus presents first a list of five axiomata, and then follows another list of seven *axiômata*. Describing Plato's "hypothetical method" Proclus does not refer to Plato's own description of hypothetical method but explicitly refers to the *methodos* used by geometers. They first postulate, define and name their key principles before proceeding to their demonstrations based on them. And he cites an example from Euclid. On the basis of the fundamental principles or hypotheses Plato's Timaeus then proceeds, in Proclus' reading of the text, to a number of "demonstrations" (*apodeixeis*) based on them and required in order to solve the problems [. . .]. Copernicus' method in the Commentariolus is highly reminiscent of Proclus: he first establishes seven *petitiones quas axiomata vocant* and then promises to provide mathematical *demonstrationes* in a larger book. (Vesel 2014, 269–270)

Michel-Pierre Lerner and Alain Segonds agree in part with Swerdlow on the first objection, for they claim that Copernicus's axioms are not self-evident (Lerner and Segonds 2015, 233). To some extent, they agree with Goddu when he writes that "the postulates are not axiomatic in the Euclidean sense, there is not a logically

deductive relationship between the postulates, and the results described later in the text derive from the postulate of a moving Earth" (Goddu 2019, 163).

All things considered, two things are noteworthy here. First, there is no occurrence of the equivalence *petitio* as a synonym of *axioma* in the Euclidean tradition (De Risi 2016). It is likely that Copernicus knew that axioms were known and evident to everybody, which could explain why he names his principles such. Second, the word *axioma* in Latin was extremely rare around 1515, when Copernicus composed the *Commentariolus*. Indeed, the only occurrence is in Giorgio Valla's *De expetendis et fugiendis rebus* (Valla 1501: Book 10, ch. 110), an encyclopedic work of sciences and arts. Valla was a humanist who was keen on transliterating Greek words into the Latin alphabet (De Risi 2016, 643; Goddu 2010, 229–236). In the passage in question, Valla is rephrasing the distinction between postulates and axioms, drawing from Proclus:

> But a postulate prescribes that we construct or provide some simple or easily grasped object for the exhibition of a character, while an axiom asserts some inherent attribute that is known at once to one's auditor. (Proclus 1970, 142)

It is likely that Copernicus read this work by Valla and thus wished to communicate to his readers that some humanists call the mathematical principles "axioms" and that it is not a case of distinguishing the Euclidean meaning of postulates and axioms because he is using axioms as a generic term for a principle to be taken for granted. In addition, as a trainee of mathematics and logic in Italy and Poland, Copernicus was certainly aware of the Euclidean meaning.

All this confirms that Swerdlow's interpretation has aprioristically assumed that axioms must be intrinsically connotated with self-evidence. As mentioned, Copernicus does not adhere to any Hilbertian project, nor is he dealing with geometry in the fashion of Peano's program on the foundations of geometry (Rosen 1976). Therefore, there is good reason to leave aside the option of "self-evidence" and instead look for an interpretation in the literature that Copernicus had at his disposal.

What has gone unnoticed so far is that Copernicus could refer to the Greek tradition of mathematical sciences, which was keen on using the axiomatic approach. For instance, several Greek works of mathematical sciences often adopted seven unproved assumptions to open treatises, such as Euclid's *Optics* (Burton 1945) and Archimedes's *On the Equilibrium of Planes* (Heath 2002, 189–190). It is likely that Copernicus arranged his treatises on seven principles in order to refer to that tradition, which could well have served as a model for him. Archimedes's *On the Equilibrium of Planes* was circulating in Italy thanks to the Latin translation of William of Moerbecke and that work opens with the word *petimus* (the verb linked to *petitio*, meaning "we require," "we state some principles"), which is followed by exactly seven principles (Clagett 1976, 116). Moreover, *Elementa Jordani* (*Elements of mechanics* by Jordan of Nemore) provides seven initial unproved assumptions (Clagett and Moody 1952, 154–155). Further research will clarify whether Copernicus could have had access to these sources, but it is likely that he could have assimilated, if not read, this literature in excerpts or classes at the universities he attended in Poland and Italy.

3.2 Logic

The second point of criticism aimed at Copernicus's axiomatic approach deals with the internal logic of his assumptions. According to Swerdlow:

> He [i.e. Copernicus] has, however, made more assumptions than were necessary. Since his adoption of heliocentric theory followed from his study of possible rearrangements of planetary models, only postulates 3 and 6 are temporally prior to his planetary theory. In fact only postulates 3 and 6 are logically prior while postulates 2, 4, 5, and 7 are consequences of 3 and 6, and postulate 1 stands by itself. Thus, if 3 and 6 are true, then 2, 4, 5, and 7 can be proved. Postulates 3 and 6 cannot be proved, and the evidence for their truth is the sense of the heliocentric theory itself, that is, the fixing of the order and distances of the planets, and the explanation of the second anomaly, gratuitously given here as the seventh postulate. It is also worth noting that the postulates, with the exception of the first, have no connection with the objections to Ptolemy's representation of the first anomaly stated earlier nor with Copernicus's own model for the first anomaly, but are concerned only with the heliocentric theory. Since Copernicus has raised no objection to Ptolemy's representation of the second anomaly, the introduction of these postulates at this point appears unmotivated. Perhaps this flaw and the logical error of stating postulates 2, 4, 5, and 7 as postulates rather than deductions from postulates 3 and 6 are intelligible if one considers that the *Commentariolus* may well have been written in haste with no revision. (Swerdlow 1973, 437)

It is true that some axioms can be derived from others, but the whole problem cannot be comprehended if one does not advance another question, which in the logic of historical inquiry precedes Swerdlow's question: Is Copernicus seeking internal rigor in his assumptions? And what kind of rigor is required in the sixteenth century for a brief text of mathematical astronomy? Is he striving to give a list with as few assumptions as possible?

There is indeed a logic in Copernicus's axioms, although they are – strictly logically speaking – redundant, and this logic was brilliantly exposed by Edward Rosen (1976). The passage is reported here in full, and axioms are mentioned by numbers between parentheses.

> (1) undermines Eudoxus' principle of homocentricity by denying that everything in the universe is centered on the earth: "There is no one center." Consequently there are multiple centers, of which the earth is one. (2) puts the earth at the center, not of the universe, but of the moon's motions. Another center is the sun, placed by (3) near the center of the universe. The distance between these two centers, earth and sun, is said by (4) to be imperceptible in comparison with their distance from the stars. (5) The stars do not move, their apparent daily motion being due to the earth's axial rotation. (6) The sun does not move, its apparent motion being due to the earth's orbital revolution. (7) The apparent retrogression of the planets is likewise only an appearance due to the motion of the terrestrial observer. By common consent, (7) is Copernicus' single most valuable contribution to technical astronomy. (Rosen 1976, 47)

Later, the examination of Copernicus's logical background will allow André Goddu to convincingly describe the Copernican heliocentrism as an attempt toward envisioning the universe as an integral whole, thus in need of a "unique,

non-arbitrary, and commensurable structure benefitting the exquisite craftsmanship of its architect" (Goddu 2009, 332). Copernicus was indeed trained in *mereology*, the branch of medieval logic which deals with the relations between the whole and the parts (Goddu 2009).

Moreover, as anticipated above, the need for axioms in Copernicus's times was not seen as a logical necessity; indeed, it could even be seen to signal a lack of rigor, since a science should be justified without principles. The main axiom of astronomy was that celestial bodies move along uniform and circular motions, and Copernicus did not need to mention it in his list. In sum, Copernicus and his contemporaries would not deem the "redundancy" of axioms to be a mistake or a problem in the context of *Commentariolus* and the literature to which it refers (Ptolemy and ancient astronomers).

By considering all terminological and logical concerns in relation to Copernicus's assumptions, it is evident that Swerdlow (1973) was moving his objections from applying a part of the developments of modern axiomatics to a sixteenth-century context. It is therefore expedient to explore what contemporary studies on axiomatics might have to say about Copernicus's mathematical practice. Moreover, it is worth examining whether one should look for an external source or to study the axioms in *Commentariolus* as an integral part of Copernicus's creativity, a key feature in his development of the mathematical theory for heliocentrism.

4 Copernicus's Axiomatic Approach

Historians have focused on the terminology and the logic that the seven assumptions bring to the fore, but nobody has yet stressed that there is another axiom, which precedes the seven axioms and which was the common assumption for all scholars dealing with astronomy since antiquity. The additional axiom runs as follows: all celestial bodies move according to uniform and circular motions (Taub 1993; Feke 2018). In this instance, reflections on axiomatics in mathematical practice provide new tools to build an interpretive framework which unifies the shared fundamental axiom along with the seven axioms and their historical and philosophical aspects.

Dirk Schlimm (2013) has analyzed the use of axioms in contemporary mathematical practice and argued that "axioms can play many roles in mathematics and that viewing them as self-evident truths does not do justice to the ways in which mathematicians employ axioms" (Schlimm 2013, 73). As the ancient world was not monolithically Euclidean in assuming principles in mathematical sciences, so the contemporary mathematical, philosophical, and logical disciplines are similarly not attached to the notion of self-evidence and perfect rigor when it comes to issues of axiomatics. As for questions of redundancy and internal logic among axioms, Schlimm's study offers a significant remark: "Popular criteria for axioms, e.g., that they should be as few, simple, and self-evident as possible, are highly idealized desiderata and by no means necessary conditions for systems of axioms" (Schlimm 2013, 39).

Most importantly, before the time of Hilbertian and formalistic interpretations of Copernicus's axioms, professional mathematicians were also raised on the axiomatic approach. Notably, the renowned collective of mathematicians under the name of Nicolas Bourbaki stated that the essential aim of the axiomatic method "is exactly that which logical formalism by itself can not supply, namely the profound intelligibility of mathematics" (Bourbaki 1950, 223). The same Bourbaki argued that formalization is "but one aspect of this [axiomatic] method, indeed the least interesting one" (Bourbaki 1950, 223).

All this speaks in favor of considering Copernicus's method as axiomatic even from a contemporary perspective. On this account, nothing should prevent historians from regarding Copernicus's *petitiones* as proper axioms.

As noted previously, historians of astronomy have inquired into Copernicus's possible sources in his use of axioms. By dealing with this puzzle in mathematical practice, another question arises: Does Copernicus need a source for establishing axioms? On the one hand, the historian can answer that Copernicus is likely seeking to contribute to the Greek tradition of mathematical sciences, with which he could have come into contact via Latin translations of Archimedean works, in which axioms are used in a somewhat generic sense and as true statements about the universe and nature. Thus, Copernicus is striving to give a list of seven assumptions to engage with that tradition, conforming to a model. On the other hand, Copernicus knows his mathematics: his intuition might well form part of his practice, that is, from the experience he assimilated with ancient astronomical mathematics and the observations he conducted. Copernicus's axiomatic approach might be the outcome of his mathematical practice, not necessarily the derivation from philosophical notions or other scientific sources he could have encountered during his career. This hypothesis is further supported by an idea that several professional mathematicians have shared on the intelligibility of mathematics and its intrinsic creativity. For instance, André Weil has claimed that:

> The views of Greek philosophers about the infinite may be of great interest as such; but are we really to believe that they had great influence on the work of Greek mathematicians? Some universities have established chairs for "the history and philosophy of mathematics": it is hard for me to imagine what those two subjects can have in common. (Weil 1980, 230)

5 An Interpretive Framework

It is clear that Copernicus employs a non-Euclidean approach in axiomatics, driven by the needs of reforming Ptolemy and his predecessors toward a new vision of the universe as an integral whole. Interestingly, Copernicus would refine his heliocentric theory after completing *Commentariolus*, outlining his definitive theory only in 1543 (in *De revolutionibus orbium coelestium – On the revolutions of the heavenly spheres*). The latter work does not list the seven axioms but presents their content along with theorems and proofs. On this account, it is likely that the seven axioms fed Copernicus's creativity and were engines for new discoveries during the composition of the final heliocentric theory. Further research will surely shed light on this issue.

The details of Copernicus's axiomatic approach could be described by adopting the guidelines set out by Dirk Schlimm in his study on the use of axioms in contemporary mathematical practices (Schlimm 2013). Such an attempt toward a new interpretation is also needed to counteract a Copernican literature which has been almost Euclidean or has tended to see Copernican axioms in a single dimension, that is, as dependent on an external source, and not in terms of their intrinsic mathematical and practical dimension – here one could well recall Bourbaki's and Weil's words on mathematical intuition and creativity. According to Schlimm, there are four main points in a comprehensive study on the use of axioms (Schlimm 2013, 39–40; points quoted in the following).

(a) "Axiomatics is an epistemic and methodological tool that can be employed in various ways. In other words, there is no single role that axioms play in mathematical practice; rather, the same set of axioms can be employed in different roles."

This is in accordance with the non-monolithically Euclidean axiomatics since Greek Antiquity, which is useful to recall in order to understand why Copernicus considered "postulate" as being equivalent to "axiom."

(b) "Popular criteria for axioms, e.g., that they should be as few, simple, and self-evident as possible, are highly idealized desiderata and by no means necessary conditions for systems of axioms."

This point has been extensively developed in treating the logic of Copernican axioms.

(c) "The practical usefulness of axioms goes well beyond the context of justification and the aim of clarifying and providing foundations for mathematical theories; they are also engines for discovery in mathematics."

This point can be seen in the fact that Copernicus continued to develop his theory after redacting *Commentariolus*. It took him around 30 years to publish his final heliocentric theory.

(d) "The dimensions of *presentation*, *role*, and *function* allow us to characterize different uses of axioms and to compare them along these three axes, with the purpose of clarifying discussions of axiomatics in mathematical practice."

Schlimm provides this framework for one interpretation among many, but this is in keeping with the historical case presented above. While it is evident how points a, b, and c have been already touched on in Copernicus's case, point d needs to be further articulated. It is necessary to recall that the Copernican axioms are seven plus the common fundamental axiom of ancient astronomy. On this account, the *function* of the axioms is to set the foundations for the geometry describing a heliocentric universe and to develop it further; the Copernican axioms *present* the main points of a new

theory, marking a strong break from the astronomers of the past. The axiom of uniform and circular motion and the seven others have different *roles*. To describe this feature, it is worth introducing the distinction between *structural* and *foundational* axioms as suggested by Solomon Feferman (Feferman 1999) and adapt it to a context of sixteenth-century mathematical astronomy and logic. As for the structural axioms, Feferman claims:

> When the working mathematician speaks of axioms, he or she usually means those for some particular part of mathematics such as groups, rings, vector spaces, topological spaces, Hilbert spaces, etc. These axioms have nothing to do with self-evident propositions, nor are they arbitrary starting points. They are simply definitions of kinds of structures that have been recognized to recur in various mathematical situations. (Feferman 1999, 100)

This is an apt definition for the seven Copernican assumptions, for in Copernicus's case there are seven not self-evident propositions to define a heliocentric structure of the universe, and he conceives them as non-arbitrary assumptions about physical hypotheses to envision the universe as an integral whole (Goddu 2009). As such, it makes sense to define them as *structural* in their context.

Concerning foundational axioms, Feferman states that:

> in contrast to the working mathematician's structural axioms, when the logician speaks of axioms, he or she means, first of all, laws of valid reasoning that are supposed to apply to *all* parts of mathematics, and, secondly, axioms for such fundamental concepts as number, set, and function that underlie all mathematical concepts; I call the latter *foundational axioms*. (Feferman 1999, 100)

Commentariolus contains the fundamental axiom of ancient astronomy, which underlies all the other assumptions, namely, all motions of celestial bodies must be uniform and circular. This could well serve as a foundational axiom in Copernicus's composition, and it is also coherent with his vision of a whole and integral universe (Goddu 2009). On these grounds, adapting Feferman's distinction to *Commentariolus* would build a comprehensive interpretive framework for Copernicus's axiomatic approach.

A Schlimm-Feferman framework integrates aspects of mathematical practice with the historical questions noted above on terminology and logic. In such a framework, the foundational axiom of uniform and circular motion can be deemed the one which triggers Copernicus's creativity. As Copernicus would continue to further elaborate his theory leading up to the publication of his major work, circa 30 years later, the seven axioms can be considered engines of discovery and aids to mathematical creativity.

6 Conclusion

Copernicus's axiomatic approach toward a heliocentric theory of the universe, as exposed in his *Commentariolus*, has triggered a range of questions among historians, who have studied his axioms in their terminological and logical aspects. Terminologically, given the rarity of the term *axioma* in Latin literature before the first half of the

fifteenth century, Copernicus likely encountered the term in some Latin humanist work (probably Giorgio Valla's *De expetendis*) and thus became aware that somebody was referring to *petitiones* as *axiomata*. As a result, he added the term *axioma* with the intention of conveying that some humanist authors may call mathematical principles *axiomata*. Humanism was indeed the cultural climate in which Copernicus was living during the years of his Italian apprenticeship. He did not need to enter the post-Euclidean debate on the difference between postulate and axiom because he was not writing a treatise on geometry but a draft on astronomy, that is, mathematics applied to a branch of natural philosophy: he considered his models as physically real, not instrumental.

It is notable that there was no controversy concerning Copernicus's axioms prior to 1973. What Swerdlow provided was a kind of formalistic criticism that morphed into a debunking of Copernicus's logic, which proved to be anachronistic: such criticism was based on a strict interpretation of axiomatics applied to history, which, in turn, does not reflect the current scenario of axiomatics in logic and mathematics. For instance, the rigor and logic for which Swerdlow was advocating with regard to axioms did not correspond to what professional mathematicians such as Nicolas Bourbaki and André Weil were thinking on axiomatics and the potential of the axiomatic method in the second half of the twentieth century.

Moreover, this case study has shed light on the similarities between axiomatics in early modern and contemporary times, a sort of bridge with the axiomatics of the present and the past, a task which was already undertaken some time ago by Patrick Suppes. Indeed, Suppes claimed that:

> There was certainly a sense of methodology deeply embedded in Euclid, Archimedes, and Ptolemy, but it was not a sense of methodology that was completely explicit or totally worked out, just as Aristotle's own general principles are never exemplified in any detailed and complicated scientific examples of an extended sort. The gap between philosophical analysis, canons of axiomatic method, and actual working practice was about the same order of magnitude that it is today. What is surprising, I think, from a philosophical standpoint is that the gap seems, if anything, to have widened rather than narrowed over the past 2000 years. (Suppes 1993, 40)

The gap between historical–philosophical, logical, and mathematical (practical) plans is what is evident in the history of the scholarship on Copernicus's *Commentariolus*. Studies on mathematical practice have proven beneficial to better comprehend the Copernican axiomatic approach and provide some order to such plans. In sum, to speak about Copernicus's assumptions as axioms and to consider the assumptions (*petitiones*) as synonymous with axioms (*axiomata*) is to give a correct translation of the Copernican text even from a contemporary and not mono-dimensional (self-evident) perspective on axiomatics, thereby avoiding the pitfalls of anachronism.

Unlike past considerations of Copernican axioms, this study has pointed out that the seven unproved assumptions set out by Copernicus are linked to the axiom of uniform circular motion. To better comprehend this feature in *Commentariolus*, an interpretive framework based on Schlimm and Feferman sheds new light on the different features of Copernican axioms and enables an understanding of them through the lens of pluralism. The utility of the Schlimm-Feferman framework is at least twofold: first, it holds

together the plurality of the uses of axioms (by considering the use of the term in the literature before Copernicus) and the difference in the kinds of axioms (foundational and structural); second, it points to the potentiality of Copernicus's axioms as tools for mathematical creativity and engines of discovery in light of Copernicus's final elaboration of the heliocentric theory.

Ultimately, Copernicus's mathematical practice adds another nuance to the possibility of considering the importance and applicability of mathematics and its history: as Wittgenstein famously observed, "mathematics is a colorful conglomerate of techniques of proof." [Full original quotation: "Ich möchte sagen: Die Mathematik ist ein BUNTES Gemisch von Beweistechniken.-Und darauf beruht ihre mannigfache Anwendbarkeit und ihre Wichtigkeit."] (Wittgenstein 1956, p. 84, author's translation). Indeed, the Copernican axioms set out in *Commentariolus* would form the basis on which to draw proofs at a later stage, in *De revolutionibus* (1543), but the history of mathematical creativity toward heliocentrism – between the compositional stages of *Commentariolus* and *De revolutionibus* – remains to be written. At any rate, if the *Commentariolus* per se does not explicitly contain techniques of proof, historians dealing with the Copernican axioms have certainly given birth to a colorful conglomerate of interpretations. Taking a closer look at axiomatics, drawing on the work of mathematicians, logicians, and philosophers of mathematical practice, has offered a new interpretation and has hopefully brought some order and clarity to such a historical conglomerate.

Visual Representations of Euclidean Geometry: Diagrammatic Reasoning in Oliver Byrne's Work

Andrea Pedeferri

Abstract

Around the half of the nineteenth century the Irish mathematician and civil engineer Oliver Byrne published a peculiar version of *Euclid's Elements* where he displays Euclid's proofs in form of pictures with little to no explanatory text (or the usual letter symbols) associated. That is, Byrne uses graphical representations (encoded using standardized colors and shapes), corresponding with diagrammatic parts of geometrical entities, which inhere in propositions. In this way, Byrne proves by *picturing* Euclid's propositions. A recent, renewed interest in the importance of mathematical practice had led to a reconsideration of the role and scope of diagrams and diagrammatical reasoning in mathematics. In this context, Byrne's peculiar use of diagrammatical representations can be seen as both closer to the original Greek and Euclidean ideals of rigor and justification in mathematics, as well as an effective example of how visualizations in mathematics may serve as efficient cognitive-representational tools.

Keywords

Geometry · Euclid · Diagrams · Diagrammatic reasoning · Geometrical visualizations

Towards the middle of the nineteenth century, Irish mathematician and civil engineer, Oliver Byrne, published a peculiar version of *Euclid's Elements*: *The First Six Books of the Elements of Euclid* in which coloured diagrams and symbols are used instead of letters for the greater ease of learners. The work's prolix title affords some idea as to its quirks. This eccentricity aside, what renders Byrne's edition both unusual and appealing is that he displays Euclid's proofs in pictorial form, providing

https://doi.org/10.1007/978-3-031-40846-5_25

little to no associated explanatory text, nor any expected algebraic symbols. That is, Byrne uses graphical representations (encoded using standardized colors and shapes), corresponding with diagrammatic parts of geometrical entities, which inhere in propositions. In this way, Byrne proves by *picturing* Euclid's propositions. The proofs are carried out through the graphical disclosure of inferential process by way of diagrams. The result is visually striking. However, as Byrne points out, this protocol

> [. . .] has a greater aim than mere illustration; we do not introduce colours for the purpose of entertainment, or to amuse by certain combinations of tint and form, but to assist the mind in its researches after truth, to increase the facilities of instruction, and to diffuse permanent knowledge. (Byrne 1847)

In addition to the *pedagogical* import of Byrne's new presentation of geometrical proofs and constructions, the equipotency of his methodology with respect to traditional approaches to geometry resulted in the work's dismissal as a mere curiosity (as can be found in works, for example, by McLean, Cajori, and DeMorgan). However, his most celebrated work, this version of the *Elements*, would eventually gain notoriety, albeit owing largely to its esthetic appeal; its novel color combinations predating the likes of Piet Mondrian.

A recent, renewed interest in the importance of mathematical practice had led to a reconsideration of the role and scope of diagrams and diagrammatical reasoning in mathematics. In this context, Byrne's peculiar use of diagrammatical representations can be seen as both closer to the original Greek and Euclidean ideals of rigor and justification in mathematics, as well as an effective example of how visualizations in mathematics may serve as efficient cognitive-representational tools.

From this perspective, Byrne's work acquires a significance far exceeding its pedagogical value. To this end, Byrne provides an interesting case study to the history of diagrammatic mathematical representations, as well as the study of diagrammatic reasoning in mathematics, interest in which is currently enjoying a revival. Byrne's work is moreover refreshing insofar as it constitutes a departure from traditional accounts of Euclidean geometry, as proffered on the mathematic scene in Victorian Britain.

A mathematician and civil engineer, Oliver Byrne was born in 1810 in Ireland. He lived a rather adventurous life between England and the USA, dying in hardship in 1880. Although he was not part of the British academic environment (at least not consistently), his work enjoyed reasonable levels of circulation, as evidenced in several reviews and commentaries, which can be found in contemporary journals and books. Although Byrne's writings are highly peculiar, even *eccentric*, they form part of – and should be read within – the context of developments and debates that permeated the field of mathematics in Britain at the time. While Byrne did not play a significant role in the development of mathematics in the nineteenth century, it is nonetheless interesting to note how his works sit with some of the most important debates on the Victorian mathematical scene. In Byrne's books and contributions especially, we find – more or less directly – echoes of discussions and controversies

regarding how to teach mathematics, as well as the role of *Euclid's Elements* in secondary and postsecondary education. Byrne's interest in the practical applications of mathematics and geometry (particularly in the field of civil engineering) greatly influenced his work, together with a marked pedagogical intent. His approach was modeled on creating usable mathematical practices. Still, whatever underwrote his interest in discovering new techniques for mastering geometry and logarithms, we can detect a push towards more flexible representations and uses of inferential processes and proofs. This is especially evident when we examine his edition of the *Elements* and a number of other works, in particular *The Young Geometrician* or *Practical Geometry without Compasses*. While the former constitutes an attempt to "make visible" the inferential structure of proofs, the latter is a peculiar but highly practical approach to geometry, whose methodology is characterized by visual, "mobile" representations of geometric constructions.

Byrne's adult life coincides with the Victorian era, a period of British political and economic preeminence. The same, however, cannot be said about the state of British mathematics at the time, which could boast none of the successes enjoyed by the bulk of British society. The weak state of British mathematics was not, in fact, peculiar to the Victorian period. In fact, during that time (especially in its second half) we witness a sort of mathematical renaissance across the British Empire. Undoubtedly, however, following the heights achieved by Isaac Newton, British mathematics became stagnant, at least in comparison to many parts of the Continent.

In particular, when we take a closer look at the discipline, we see how *Euclid's Elements* constituted the textbook of choice at all levels of British education, a proclivity that continued until after the mid-nineteenth century. This near-total reliance on Euclid was, however, no longer commonplace on the Continent. In France, for example, even by the seventeenth century several influential scholars and educators began to remove *Euclid's Elements* from courses of study, otherwise invoking only heavily redacted versions of it. This move away from Euclid resulted from the influence of La Logique de Port-Royal, which advocated major revisions in the approach to geometry, pushing towards more clarity and comprehension. This resulted in scholars distancing themselves more and more from Euclid, who was now considered finicky and cumbersome. Meanwhile in Britain, Euclidean geometry was still regarded as the paradigm for the logical structure of mathematics. It was only after the 1860s that Euclid's preeminence began to wane in Britain, prompting a vigorous debate from anti-Euclidean academics and teachers.

Byrne wrote his version of the *Elements* in 1847, in a climate wherein Euclid prevailed over the teaching of geometry in both schools and universities. However, Byrne's book was radically different from long-established editions of Euclid, which were traditionally deployed in educational settings. A comparison with the more traditional and influential accounts of geometry serves to highlight Byrne's innovative approach, which aimed to appeal directly to our geometrical intuitions, in particular through bypassing algebraic representations. In Byrne's time, one of the most popular versions of *Euclid's Elements* was that edition by the Scottish mathematician John Playfair. Playfair's views were sympathetic to those of the Scottish Enlightenment group called the Common Sense philosophers, who lobbied for

Euclidean geometry as the exemplar of true knowledge. Playfair's *Elements* were published in 1795 and were largely based on the foregoing popular edition of Euclid, edited by Robert Simson in 1756, which was regarded as the handbook of elementary geometry in Great Britain. Both Simson's and Playfair's editions aimed to present a more accurate and rigorous version of Euclid's work, which would exemplify how best to do geometry. Geometry was still regarded as the essential component of not only mathematics but, more generally, of how to properly train pupils in the art of reasoning. In his book, Simson writes that his review of the *Elements* was aimed at restoring "the principal Books of the *Elements* to their original accuracy" (Simson 1756). To this end, his main concern was that of fixing the errors that were carried over by previous editions. The presentation of Euclid's work followed the traditional presentation of propositions through lettered diagrams accompanied by explanatory text.

To this end, Playfair's Euclid constitutes a notable improvement. For, it not only represents a modernized reprint of previous editions, but moreover introduces elements of analysis, and so approaches the discipline with greater fidelity to the real-time developments in mathematics beyond British borders. While Playfair's approach retained the traditional diagrammatic representations (with lettered diagrams of Euclid's propositions), as Amy Ackerberg-Hastings points out, he

> intended to rejuvenate the content of the textbook. He believed that the influence of Simson, and of Colin Maclaurin, had led the next generation of British mathematicians to emphasize so-called 'synthetic' methods to such an extent that those mathematicians foolishly ignored the discoveries made by Continental mathematicians in the eighteenth century. (Ackerberg-Hastings 2002)

Playfair was therefore well aware of the divide between British and Continental (especially French) mathematics. Indeed, he charged Britons with focusing too much on the *synthetic* aspect of proofs (that is, the need to work on sets of concrete, finished proofs), by contrast with the Continental focus on abstractions and algebraic generalizations (what he terms the *analytic* method). British mathematicians were very much against Continental analytic methods since they would apparently lead to "the illogical habit of generalizing too soon, of suspending conviction upon some remote analogy, instead of founding it upon irrefragable evidence" (Ackerberg-Hastings 2002). Across his works, Playfair attempts to merge the two approaches. To the traditional Euclidean use of diagrams he adds algebraic symbolism and techniques, thereby appealing to the Continental proclivity for algebra as a valid way of representing the concept of rigor and as a model for pure knowledge. The synthetic-centered approach was structured to provide a model for the "justificatory" aspect of mathematics, while a more analytic-centered approach caters to mathematics' "discovery" aspect, something that British mathematics lacked. However, Playfair's approach did not result in a renewed interest in mathematics' "discovery" side, nor did it change the mainstream British mentality towards geometry. Playfair's own versions of Euclid's proofs were indeed presented following the synthetic method, that is, the traditional model. In general, there was some pushback against

the idea of the "analytic" methods, with arguments centering around those ideas given expression by Thomas Young above.

Therefore, albeit with some interesting differences, the use and understanding of *Euclid's Elements* still fell on the traditional side, which centered upon reading him as the paradigm of rigor and reasoning in the abstract. The geometrical nature of Euclid's work was essentially seen as a model for highlighting the nature of correct inferential processes. This permitted a fairly sharp distinction between "science and [the] art of geometry" (Hydin Price 1981), with the study of the *diagrammatic* nature of Euclidian proofs being largely overlooked. Owing to (and partially evidencing) this, it is interesting to note how, at the time, there were growing criticisms regarding the fact that students in both secondary schools and college were unable to work *practically* with geometrical constructions:

> A person may be a Cambridge Wrangler, and yet unable to make a simple graphical construction with accuracy. The ordinary schoolboy's knowledge of practical geometry is generally worthless or nil (Remark from a review in *Nature*, 1903, p. 147). (Hydin Price, 1981).

Thus, as an improvement upon Euclid, Byrne's work combined both the rigor of the original, albeit combined with a novel, graphical representation of visual constructions, which did not merely constitute a visual corollary but an essential element of the reasoning process. Unfortunately, this was not well communicated by the author and so the public were largely unreceptive to the work. Byrne's *Euclid* has therefore been relegated to near-invisibility. Indeed, even recently renewed interest in his work has focused almost entirely on the *aesthetic* appeal of his book, to the exclusion of his pioneering recasting of the original.

A famous saying that is invoked to describe familiar obstacles in our quest for understanding is that "The essential is invisible to the eye" (the Little Prince may have been the first to make this explicit). The fact that there are certain features of reality (broadly understood as both natural and artificial), which seem to evade the possibility of clear, linguistic attribution or description, is not new. From physical features like the existence of "invisible" forces in nature, which regulate the cosmos, to abstract concepts, which are essential for defining our rationality, such as those of inferential processes, the "invisibility of the essential" is a phenomenon pertaining to many different contexts. This has always been the case, especially in mathematics, given its paradigmatically abstract nature. Indeed, ontological questions regarding what numbers *are* remains to this day an open question. Understandably, then, symbolic languages were initially adopted in disciplines like mathematics, for, besides the necessity of simplicity and rigor, it has always been important to *visually* grasp a domain's essential features, thereby making the invisible visible.

To this end, geometry has always been exemplary. In this domain, the challenge of both representing geometrical shapes and proof processes, which operate on geometrical figures, have typically been met through the use of diagrams. However, especially on the contemporary understanding of mathematics, diagrams have been largely regarded as merely visual aids, that is, as helpful, pedagogical (and sometimes heuristic) complements. Accordingly, they have been habitually confined to the

moment of mathematical discovery, while being considered nugatory with regard to the justificatory process. One of the reasons why diagrams and diagrammatic reasoning in general have been so disregarded (especially in the last century) is a consequence of the influence that the movements (schools) on the foundations of mathematics had on our understanding of mathematics itself. Their core idea that rigor could only be achieved through logical means is brilliantly summarized by Gödel:

> The development of mathematics toward greater precision has led, as is well known, to the formalization of large tracts of it, so that one can prove any theorem using nothing but a few mechanical rules. (Gödel 1931)

In 1931, Gödel summarized in but a few sentences around a century's worth of revolutionary mathematical developments, which had moreover led to the birth of modern logic. The arithmetization of analysis, the birth non-Euclidean geometries, and the elaboration of new axiomatic and formal systems were all examples of achievements making the period one of the most exciting and progressive in the history of mathematics. This optimism was grounded in the idea that logical consistency should be at the core of mathematics. Consequently, the reputed "certainty" of geometry, as based on "evident truths," had to relinquish its former role as the model for the discipline, thereby precluding any "serious" place for diagrams and diagrammatic reasoning in proof processes. For these pedagogical tools were considered to be insufficiently rigorous, owing to which they were consigned to entry-level mathematical practice. (By and large, mathematical practice did not boast any relevant status of its own – whether foundationally or epistemologically.)

The eventual collapse of this approach did not correspond with an immediate sea change of attitudes within the philosophy of mathematics. It nonetheless opened up a space for a reconsideration of the value of mathematical practice in the philosophical analysis of mathematics. As articulated by Mancosu, different lines of thought in the philosophy of mathematics eventually converged to support the "belief that attention to mathematical practice is a necessary condition for a renewal of the philosophy of mathematics" (Mancosu 2010). Accordingly, since diagrammatic reasoning and the use of diagrams were generally regarded as mere aspects of mathematical practice, the newfound interest in the value and importance of these parts of mathematics moreover brought renewed attention to the nature and scope of diagrammatic reasoning itself. Indeed, while the status of *Euclid's Elements* as a paradigm of rigor and rigorous argumentation has been questioned by foundationalists, what is *unquestionable* is that the *Elements* have always been exemplary with regard to the utility of diagrams, as well as to what we have been calling "diagrammatic reasoning."

From the nineteenth century onwards, several challenges have been leveled against *Euclid's Elements*. In particular, attention has historically been directed towards the fact that, in Euclidean propositions, conclusions are drawn directly from diagrams by appealing to intuition rather than through rigorous inferential rules. Moreover, it was difficult to accept the widespread presence of unwarranted generalizations from particular diagrams. These reasons, among others, brought about new and rigorous axiomatizations in order to render geometry independent

of figures. As Pasch claims, "the theorem is only truly demonstrated if the proof is completely independent of the figure" (Pasch 1882).

More recently, however, a new understanding of the importance of mathematical practice has led to reconsiderations regarding appeals to geometrical intuitions in the form of different kinds of visualization. For instance, Mancosu has pointed out that, in order to have a *genuine* philosophical inquiry into mathematics, it is important to address several issues, in particular the role that visual images and diagrams play in mathematical discourse. Thanks to scholarly moves in this direction, Euclid and his *Elements* have been "relegitimized." Indeed, through a series of works, the most influential of which is Manders' *The Euclidean Diagram*, "the role of diagrams in the inferential standards of Euclidean practice" has been rehabilitated (Manders 2010). Within this paradigm shift, it is interesting to note how the peculiarities of Byrne's presentation of Euclid can be read using new theoretical tools and models proposed by many scholars who are sympathetic to this revised position regarding mathematical practice in the philosophy of mathematics.

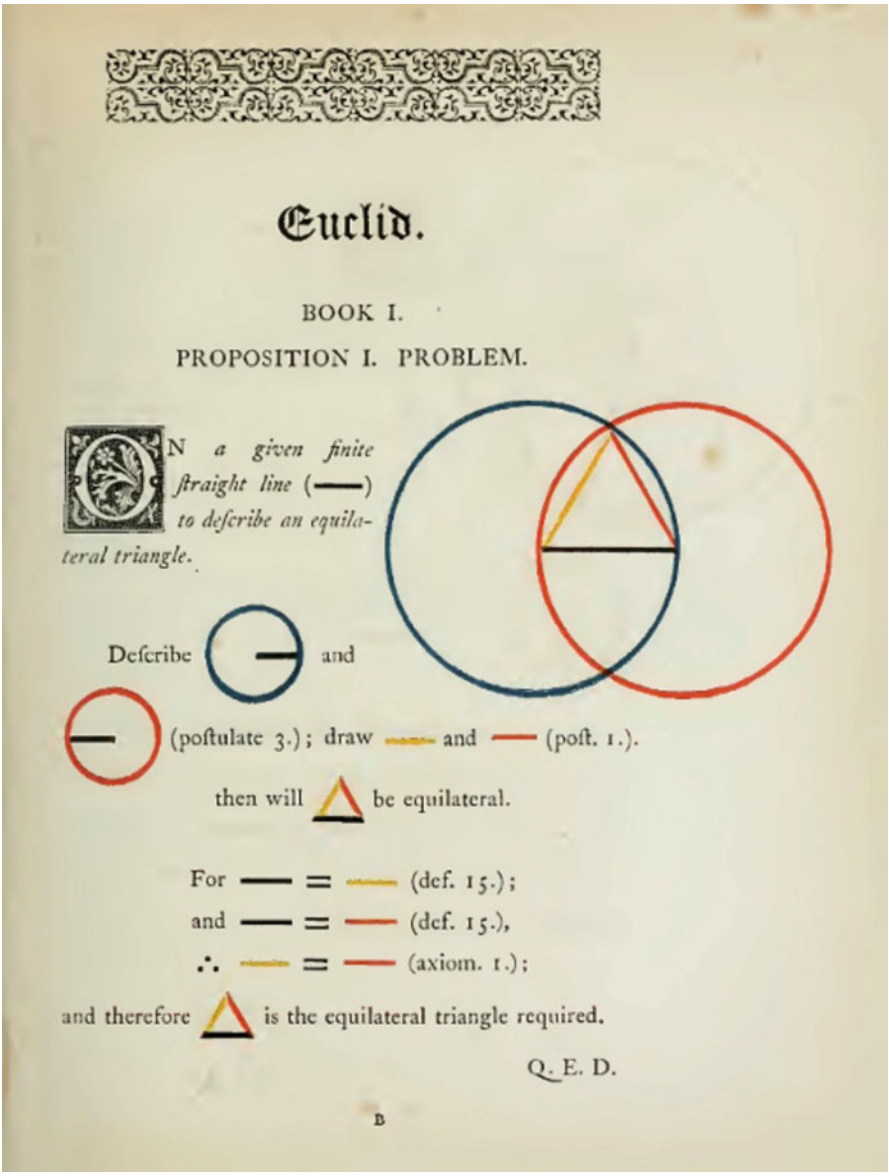
Byrne's use of diagrammatical representations is a peculiar feat within the history of mathematics and of the mathematical practice of his time. However, his innovative use of graphical representations – which appeal directly to our geometrical intuitions, thereby bypassing any algebraic representation – can be taken as an early example of how visualizations in mathematics can be regarded as efficient cognitive-representational tools. As Giardino puts it, these "external and material representations are used as inferential tools, that is, as tools for thinking about what they represent" (Giardino 2018a).

Byrne replaces the traditional, analytical presentation of geometry with color-coded visual illustrations, thereby doing away with traditional letter indices (an example being Euclid's Book 1 Proposition 1, see Fig. 1 below). Byrne's characteristic color proofs represent – directly and intuitively – factual relations between the relevant geometrical entities/constructions and the logical inferences of the proofs themselves. By providing unmediated, visual access to the material references of proofs, as well as their logical structure, Byrne's color proofs facilitate the study of the geometrical objects to which they refer, thereby enhancing both theoretical and applied reasoning about their mathematical contents.

In the Introduction to the *Elements*, Byrne writes:

> This work has a greater aim than mere illustration; we do not introduce colors for the purpose of entertainment or to amuse *by certain combinations of tint and form*, but to assist the mind in its researches after truth, to increase the facilities of instruction, and to diffuse permanent knowledge. (Byrne 1847)

When we compare this to Giardino's definition of diagrams, Byrne's own conception becomes clearer, for on neither account are diagrams mere proxies for mathematical entities. Diagrams have "to be intended [...] as *cognitive tools* that are meant to spatially display information in order to improve memory and promote inference, and not necessarily to depict mathematical objects" (Giardino 2017). Similarly, Byrne writes:



Euclid.

BOOK I.

PROPOSITION I. PROBLEM.

ON *a given finite ſtraight line* (——) *to deſcribe an equilateral triangle.*

Deſcribe ◯ and ◯ (poſtulate 3.); draw —— and —— (poſt. 1.).

then will △ be equilateral.

For —— = —— (def. 15.);

and —— = —— (def. 15.),

∴ —— = —— (axiom. 1.);

and therefore △ is the equilateral triangle required.

Q. E. D.

B

Fig. 1 Proposition I

the formalities and paraphernalia of rigour are so ostentatiously put forward, as almost to hide the reality. Endless and perplexing repetitions, which do not confer greater exactitude on the reasoning, render the demonstrations involved and obscure, and conceal from the view of the student the consecution of evidence. (Byrne 1847)

Byrne's reference to the concealment of the consecution of evidence highlights the gulf that existed between mathematic practice and foundationalist ideals regarding rigorous demonstration. Byrne's words are in fact against the foundationalist idea that a demonstration, or proof, should be a seamless, inferential process, which can be followed step-by-step and inspected, albeit not as something that can be "seen" (Giardino 2017).

Byrne's explanatory introduction of his work shows an apparent naiveté in not providing a rigorous justification for the use of his special colored diagrams. Indeed, he focuses almost entirely on his work's pedagogical perks. However, his diagrams reveal themselves simultaneously as visual representations of the logical inferential procedures of proofs and the actual representations of the *objects* of those proofs. This makes them the perfect example of the dual nature of diagrams as cognitive-representational tools, that is, as mathematical objects that are "intended both as representations and as instruments to think about what they represent" (Giardino 2017).

Byrne is clear that the visual aspect of diagrams is not only helpful but is intimately connected with the practice of mathematics, indeed, with the *moment* of mathematical justification.

His choice of shapes and colors furthermore reveals a subtle conception of how to make the invisible visible. Take, for example, his definition of a line as an object with length without breadth. It is apparent that, in trying to draw a line, we immediately incur the inconsistency of having an object without breadth. Byrne's "solution" is to use colors to reinforce our geometrical intuition about linearity:

> A mathematical line, which is length without breadth, cannot possess colour, yet the junction of two colours on the same plane gives a good idea of what is meant by a mathematical line; [...] Let two colours meet and cover a portion of the paper; where they meet is not red, nor is blue; therefore the junction occupies no portion of the plane, and therefore it cannot have breadth, but only length: from which we can readily form an idea of what is meant by a mathematical line. (Byrne 1847)

Accordingly, diagrams are flexible objects (or, in Giardino's terminology, "kinesthetic") insofar as they may be used and manipulated to trigger a process of discovery, on the one hand, while providing evidence for justification, on the other. The dual role of diagrams and diagrammatic reasoning is what Byrne had in mind when he stated that traditional, propositional descriptions of inferences ended up "hiding reality." Diagrams, by contrast, actively *disclose* reality, permitting more immediate access, owing to which they are better vehicles for revealing demonstrative inferences:

> Geometrical diagrams are not signs, but the materials of geometrical science, the object of which is to show the relative quantities of their parts by a process of reasoning called Demonstration. (Byrne 1847)

Byrnes' experimentation with a new visual representation of Euclid's propositions aims to reconnect Euclid's work with its native sensibility for evident and direct

rigor. Indeed, Byrne does so without taking recourse to one of the distinguishing features of Greek mathematics, viz. the addition of letters to geometrical shapes, thereby forming what are normally called "lettered diagrams." Lettered diagrams combine the instinctive, visual appeal of figures with the analytic rigor afforded by algebraic notation. This hybrid has been instrumental in supporting a key conception of Greek mathematics with regards to the notion of validity, which is far removed from the notion of validity we use today. Nowadays, we link validity to the logical notion of *deductive* validity, that is, the idea of providing conclusive evidence for the truth preservation of an inference, thanks to which a valid inference can be used as a model that may thereafter be generalized. In Greek mathematics, the emphasis was more on the possibility of repeating processes that could deliver the desired results. Lettered diagrams were a key element of those processes, for they allowed the creation and use of geometrical constructions that were, by their nature, reproduceable ad infinitum. Thus, the standard of validity was intimately connected with the idea of practical reproducibility. Byrne's prescinding from the use of letters does not, however, undermine this. On the contrary, it forces the reader to do bona fide diagrammatic reasoning, that is, using the diagrams not only as justificatory buttresses but as structural tools that enable reasoning *within* the diagram.

Proposition 1 is a paradigmatic example of Byrne's peculiar use of diagrams (see Fig. 1). It is well known that Proposition 1, which concerns the construction of regular triangles, has been the target of criticism about logical gaps and inconsistencies, which subverts the supposed rigorousness associated with Euclid's propositions. The most common objection concerns the existence of point C (in lettered diagrams), that is, the logical justification of the existence of the point where two circles intersect. This has been taken as evidence that Euclid's system is "hopelessly flawed," as Daniel MacBeth puts it. However, on MacBeth's view, this is not actually the case. This is because the role of diagrammatic representations becomes something very different from a system of axioms and more like a system whereby the diagram is used to reason in it, owing to which we can "see" that the inferences are correct:

> First, the *Elements* is not best thought of as an axiomatic system but is more like a system of natural deduction; its Common Notions, Postulates, and Definitions function not as premises from which to reason but instead as rules or principles according to which to reason. Secondly, demonstrations in Euclid do not involve reasoning about instances of geometrical figures, particular lines, triangles, and so on; the demonstration is instead general throughout. The chain of reasoning, finally, is not merely diagram-based, its moves, at least some of them, licensed or justified by manifest features of the diagram. It is instead diagrammatic; one reasons *in* the diagram in Euclid, or so it will be argued. (Macbeth 2010)

This conception of diagrams and diagrammatic reasoning is present in Byrne's presentation of Proposition 1, in which we can also clearly see the "justificational adequacy" (Manders 2010, p. 66) of diagram-based reasoning. This is because Byrne's presentation exemplifies what Manders calls the diagram disciplines, that is, *the* "proper exercise of skill in producing (still imperfect) diagrams required by the practice" (Manders 2010). According to Manders, traditional geometrical proofs

have a dual nature represented by two parts of the proof: a verbal part (the discursive text), and a graphical part (the diagram) (Giardino 2017). In Byrne, the absence of most of the discursive text, replaced by his colored figures, causes the two parts to collapse, which provides a direct and strong visual example of how the reader is "obliged" to be engaged in diagrammatic reasoning, that is, reasoning *in* the diagrams and not just *with* them. Manders says, in this regard, that:

> we take participants to be responsible for attaining uniformity of response in reading off features in diagrams. But the production and reading of diagrams cannot humanly be controlled so as to obtain a uniform response to diagrams directly on questions such as equality of lines. If a practice licenses a type of response to artifacts, then in order to attain uniformity of response, it must provide means by which participants can resolve their differences in responses to those physical artifacts they might reasonably produce. In traditional geometry, the division of responsibility between diagram and text, in which the text tracks equality information, is a way to meet this challenge. (Manders 2010)

Byrne's diagrams do the work of putting together those two aspects by allowing participants "to respond in a stable and stably shared fashion" (ibid.) when exposed to such artifacts. This enables readers (participants) to comply with the diagrammatic discipline.

A further example of this is Byrne's presentation of Proposition 10 of Book 3 (Fig. 2). The proposition states that "A circle does not cut a circle in more than two points." The proof is a reduction ad absurdum and it requires the construction of impossible figures. Byrne elegantly represents the "imperfect diagrams" allowing a straightforward engagement with diagrammatic reasoning.

Byrne's diagrams are able to capture another feature of Euclid's diagram-based presentation: the compositional nature of diagrams. Marco Panza (2012) argues that Euclidean arguments are diagram based since the objects of Euclidean geometry have a special relationship with their diagrammatical representations. They are compositional objects made of elementary objects such as "concrete lines representing segments and circles that are drawn through a single construction step" each of which is "one and divisible: these elementary objects can both compose complex diagrams and be decompose in parts" (Panza 2012). Panza refers to proposition 1.11 and 1.12 as a clear example of this interplay between the concrete geometrical objects and their diagrammatical representations. Those two propositions show how to construct a perpendicular to a line through a given point. They differ from each other in that in proposition 1.11 the given point lies on the line while in proposition 1.12 does not. If we look at Byrne's presentations of the two propositions (Figs. 3 and 4), it is clear how the idea of the compositional nature of diagrams finds a perfect representation. Byrne's diagrams allow the reader to both clearly follow the process of construction of the elementary geometrical objects and the process of proving how those objects satisfy the statement of the proposition.

Over the past decade, a distinction introduced by Manders has become very influential – if not standard – in the discussion about use of diagrams in geometry. The distinction is that of *exact* and *co-exact attributions*. Respectively, these are features that we get from visual representations, on the one hand, and text, on the

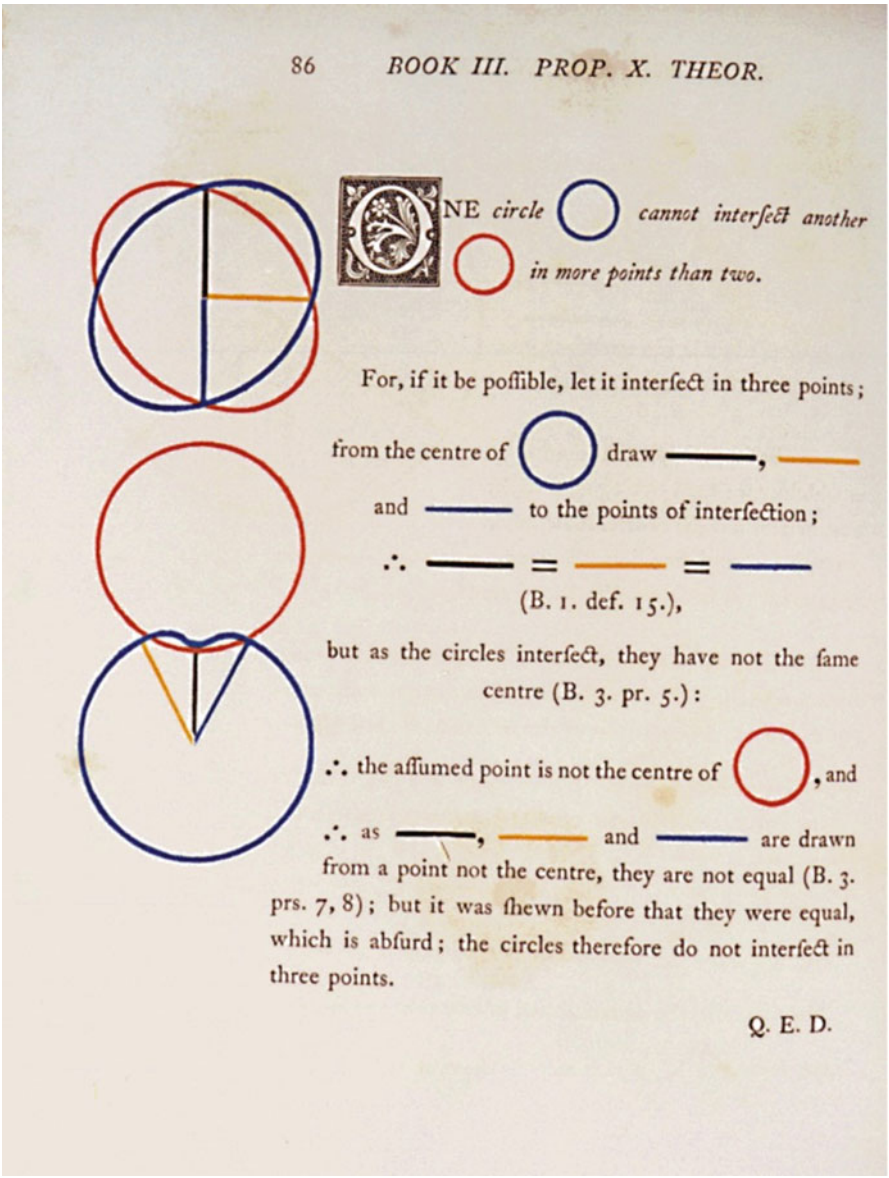


Fig. 2 Proposition X

other. *Exact* attributions are features such as metric information, usually given in the text, while *co-exact* attributions are topological details pertaining directly to the diagram. To import this distinction into the traditional discourse of Euclidean proofs, diagrams are used to infer co-exact information. Thus, in every act of geometrical

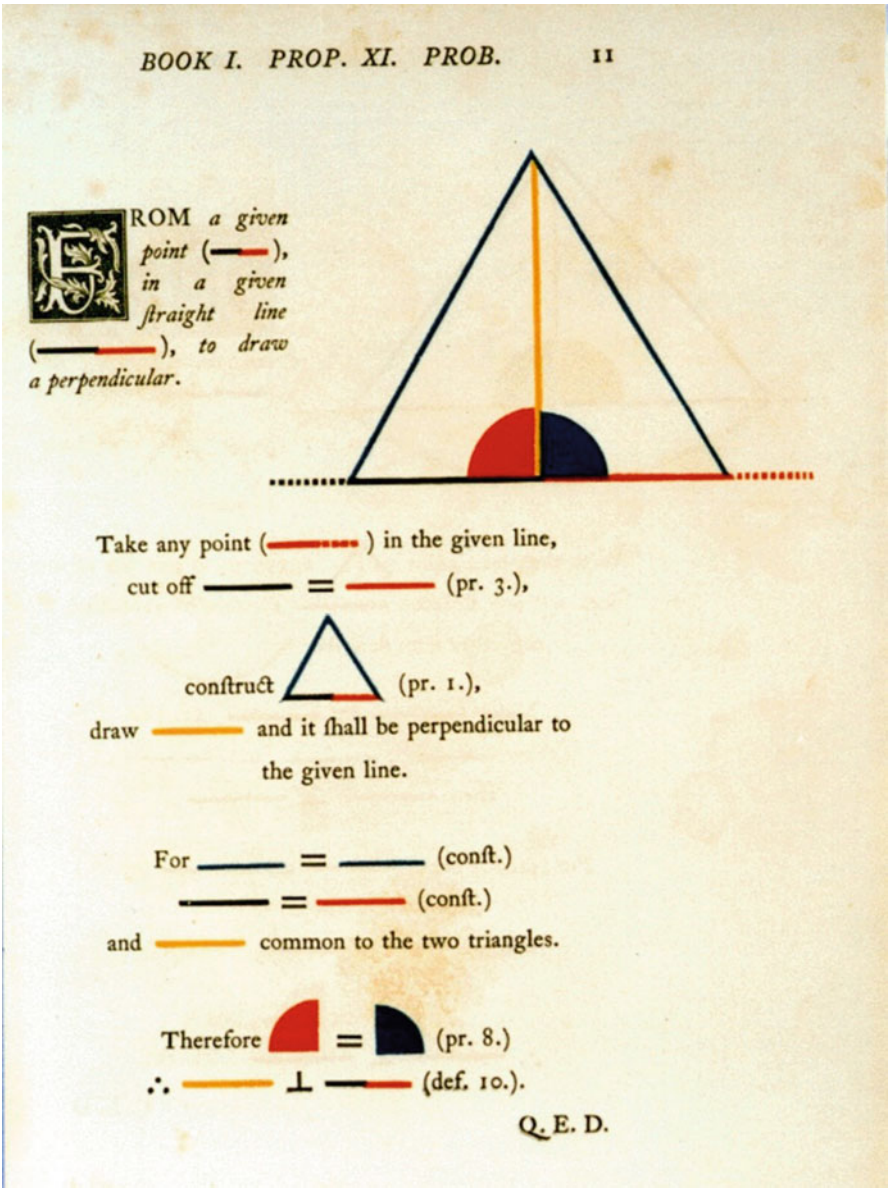

Fig. 3 Proposition XI

manipulation, co-exact aspects remain stable while exact aspects are amenable to change.

The above is especially clear in Byrne's diagrams, particularly on account of the absence of letters and (by and large) text. As Manders notes, Euclidian diagrams

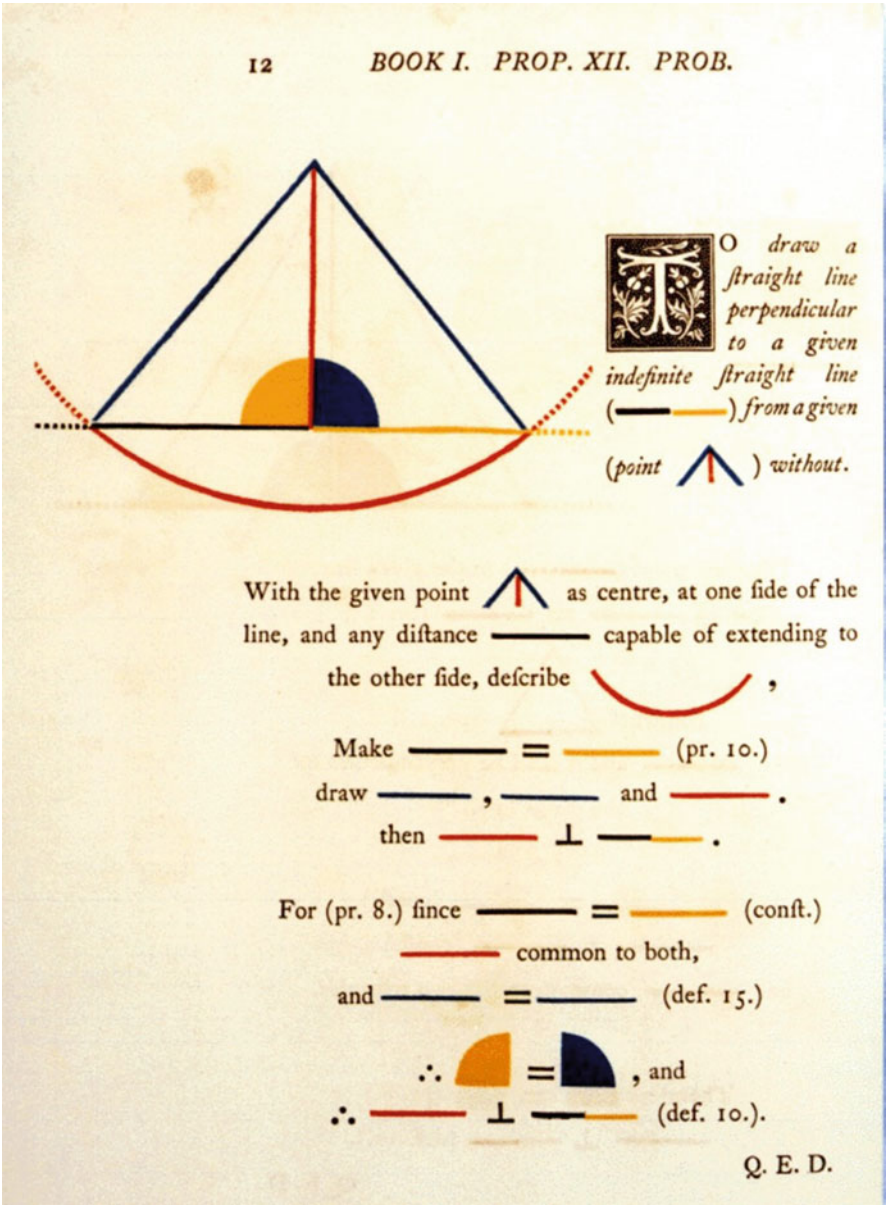

Fig. 4 Proposition XII

were designed to provide inferences about co-exact features. Thus, when we look at Byrne's Proposition 1, the problem of the existence of the point of intersection between two circles is something that incorporates a co-exact attribution, which we are able to infer without issues, namely by "seeing" how the two circular

constructions have been built. In this sense, Byrne's quasi-absolute reliance on visual representations provides the perfect model for avoiding "diagram fallacies," which, as Manders points out:

> Typical alleged 'fallacies of diagram use' rest on taking it for granted that an – to the eye apparently realized but false – exact condition would be read off from a diagram; but the practice never allows an exact condition to be read off from the diagram. Typical 'gaps in Euclid' involve reading off some explicit co-exact feature from a diagram; and this is permissible [...] (Manders 2010).

The very nature of Byrne's special graphical representations of the proposition (and of all the other Euclidean propositions), whereby both diagrams *and* text are symbolized by color-coded visual representations, actually force participants to focus on co-exact conditions. It further compels the reader to reason *in* the diagram, given the diagrammatic nature of the proof's steps. By following Byrne's version of Euclid's proofs, we can actually "see" the stability of Euclid's geometry and its proofs, as provided by the stability of co-exact conditions.

Therefore, for Byrne, what is largely a pedagogical expedient becomes a very efficient way (more so than traditional lettered diagrams) of representing the main features of the Greek archetype, thereby remaining faithful to the original purpose and use of diagrams and diagrammatic reasoning.

In a very brief book review of Byrne's book *The Young Geometrician*, published on the British journal *Atheneum* on July 1866, it is said, probably quite ironically, that "there is always something ingenious about Mr. Byrne's notions." This was the feeling at that time also for his version of *Euclid's Elements*. However, the recent literature on diagrams and diagrammatic reasoning shows how the "ingenious" color proofs used by Byrne cannot just be relegated to the domain of mathematical oddities. In fact, they possess the necessary features of representational cognitive tools and, accordingly, they efficiently allow theoretical and practical reasoning in the diagrams.

Abstract

Even if, since many thousands of years, humans were fascinated by symmetry, which is reflected in many preserved ornaments on buildings, paintings, pottery, etc., the mathematical study of symmetrical patterns is just a few hundred years old. In fact, until the nineteenth century, when it received an impulse from crystallography, no systematical approaches were developed. In this chapter, we follow the history of (Euclidean) symmetry from its first appearances and connections with art, over geometric classifications by nineteenth-century crystallographers, the coalescence of this crystallographic-geometrical approach with theory of groups in the second part of the nineteenth century, until various twentieth-century generalizations to symmetry groups in higher dimensions, magnetic, and colored groups.

1 Introduction

Once upon a time, the oldest known temple was built (Fig. 1). It features several symmetrical aspects in alignments and shapes found in its remains (Haklay and Gopher 2020). Highly symmetrical ornaments have been preserved from Paleolithic and Neolithic times, for example, friezes (Fig. 2) exhibiting all seven symmetry types ("frieze groups") can be found already in the Magdalenian period (ca. 12,000–10,000 BCE) (Jablan 2002). These are just some of the many pieces of evidence that since the earliest of times humans have been fascinated by symmetry.

The word *symmetry* itself is of ancient Greek origin: *συμμετρια*, originally referring to harmony of proportions (Weyl 1952). Ancient Greek art is well known for its symmetrical features, and the Greek sculptor Polykleitos (fifth century BCE) wrote on proportions, in particular the "ideal" ones for a human body. Through history, symmetry became to be associated with beauty and regularity, as numerous famous examples in art and architecture history confirm. In some cases, one might

conjecture that, at least on a subconscious level, attempts were made to systematically explore and design different symmetry *arrangements*, and not only different symmetrical figures themselves. The most studied of such examples are from the medieval Islamic period. The Islamic art is famous for its decorative patterns (Fig. 3). Even if the question if all the 17 possible "wallpaper groups," i.e., possible symmetry arrangements in two-dimensional periodic tilings, are represented in the palace of Alhambra in Granada, modern Spain, is not settled (Grünbaum 2006; Grünbaum et al. 1986; Rønning 2009), the Islamic art provides an abundance of examples of various types of symmetry in the plane, which are nowadays described mathematically by two-dimensional point groups, frieze groups, and wallpaper groups (Jablan 2002; Laigo et al. 2014; Weyl 1952). Indications of attempts of classification by symmetry types can also be found in ethnographic history, e.g., in traditional Hungarian needlework (Hargittai and Lengyel 1985).

As for many other scientific fields and branches, the roots of the systematic research of symmetry arrangements can be traced back to the period of Renaissance. A particularly well-known example is Johannes Kepler's attempt to explain the outer symmetry of snow crystals by inner symmetry (Kepler 1611). Kepler's

booklet is also often considered to mark the beginning of mathematical crystallography, which became the main motor for the development of symmetry group theory (Shafranovskii 1975).

There were two main directions developed in crystallography in the seventeenth and eighteenth centuries. One was the study of the external shape of the crystals (Fig. 4), including the measurements of the geometric features of naturally occurring crystals, leading to the *law of constant angles* (the First law of crystallography) discovered in 1669 by Nils Steensen (Nicolaus Steno, 1638–1686) and rediscovered in 1772 by Jean-Baptiste Louis Romé de l'Isle (1736–1790) and Arnould Carangeot (1742–1806). This eventually led to the analysis of symmetries of (three-dimensional) geometric figures. The other were the speculations on the internal structure of the crystals, generally by assuming periodic arrays of constituents (usually, in line with Kepler, presumed to be spheres). The two directions coalesced in the work of René Just Haüy (1743–1822), who proposed that internal structure of crystals comprised a periodic assembly of polyhedra, and derived the various shapes of the crystals, as well as the values of the observed interfacial angles (Burke 1966; Kubbinga 2012; Lalena 2006; Lima-de-Faria 1990; Molčanov and Stilinović 2014; Schuh 2007).

Even if the classifications of types of symmetry arrangements in one to three dimensions required only elementary geometry, they were not fully explored before the nineteenth century. In particular, the emergence of group theory simplified the formulation of the results, as well as the enumeration of different symmetry arrangements. There were several lines of mathematical thought that culminated in the creation of theory of groups, the most important one being the search for solutions in radicals for algebraic equations of degree 5 and higher. The algebraic solutions for linear equations, as well as quadratic ones, were in essence known to ancient

Babylonians and Egyptians, but for the first time fully described in Al-Khwarizmi's book *Al-Kitāb al-mukhtaṣar fī ḥisāb al-jabr wal-muqābala* (ca. 825 AD; from its title, the term *algebra* was derived). Solutions in radicals for algebraic equations of degree 3 and 4 were found by the sixteenth-century Italian mathematicians Scipione del Ferro, Niccolò Fontana Tartaglia, Girolamo Cardano, and Lodovico Ferrari. In the second half of the eighteenth century, French mathematicians Joseph-Louis Lagrange and Alexandre-Théophile Vandermonde were researching this topic and tried to find the solutions for equations of higher degrees by analyzing *why* solutions in radicals exist for degrees up to 4. They noted that for degrees 1 to 4, the coefficients in the equations are expressible as symmetric functions of the solutions, i.e., invariant with respect to permutations of solutions. Also, rational functions of the coefficients are symmetric, while the formulas for solutions in radicals are not, which suggests that the root functions are the ones "breaking" the symmetry. This approach via permutations was adopted by other mathematicians, who began to investigate properties of permutations themselves. In particular, the Italian mathematician Paolo Ruffini, around 1800, discovered several properties of sets now known as permutation groups. Ruffini was the first mathematician to claim that fifth-degree equations are in general not solvable in radicals; however, his proofs were incomplete, and the first full proof was given in 1824 by the Norwegian mathematician Niels Henrik Abel. His French contemporary, Évariste Galois, in turn investigated a more general question: Given an algebraic equation of order 5 or higher, how can one determine if that particular equation is solvable in radicals or not? His research marks the establishment of the theory of groups (of permutations). However, even if he developed his results in the period 1828–1832, they only became known after 1846, when Joseph Liouville posthumously published Galois'. Two years before, 1844, Augustin-Louis Cauchy, who was almost surely familiar with at least a part of Galois' work, published a text on *systémes des substitutions conjuguées*, a term for permutation groups which was used for several decades later. Still, it was not until the 1860s and the works of Camille Jordan, Arthur Cayley, and others that the mathematics community fully recognized the importance and power of the theory of groups. Jordan's papers used the term *groups*, which was adopted by subsequent mathematicians, and Cayley was the first who defined and studied abstract groups (Brückler 2017; Kleiner 1986; Van der Waerden 1985).

Meanwhile, other scientists successfully classified some of the symmetry arrangements, and after Jordan's and Cayley's popularization of the theory of groups, these were re-formulated, re-proven, and extended in group theory terms – symmetry group theory emerged. In this chapter, the main moments and results from this development are presented. The aim is to present a history of discovery of various types of symmetry groups as well as the history of their classifications in various dimensions. This survey is suitable not only for specialists and, in most part, is not formal, but a familiarity with basic group theory and Euclidean geometry, on the level presented, e.g., in Chapter 2 of Artin (1991) and the first three chapters of Ryan (1986), is of advantage. However, the most important definitions shall be stated and suitable explanations given as needed.

It has to be emphasized here that in this survey only *Euclidean* symmetry groups, i.e., only symmetries which are isometries (distance-preserving mappings) with

respect to the Euclidean metric, are considered. Thus, for the purposes of the present text, the following definition is used:

Definition 1 A *symmetry group* is a subgroup of the isometry group $E(n)$ of a Euclidean space E of dimension n. A symmetry group is the symmetry group of a set of points F in E if it contains all isometries of the ambient Euclidean space under which F is invariant (these are called symmetries of F).

Since most of the early history of symmetry group theory was motivated by crystallography, and since atoms and ions in crystals cannot be separated by infinitesimal distances, most of this text is restricted to *discrete* symmetry groups (Artin 1991; Brückler 2019; Burckhardt 1988), i.e., symmetry groups with the property that there exists a positive number ε such that:

- The translation vectors of all non-trivial translations in the group (if any) are longer than ε.
- The rotation angles of all non-trivial (both proper and improper) rotations in the group are greater than ε.

For the purposes of this survey, an orthogonal transformation is an isometry possessing a fixed point; for a more formal approach, see e.g., Artin (1991). From general Euclidean geometry, it is well known that every isometry, i.e., symmetry, can be described as a composition of an orthogonal transformation with a translation. This was proven for movements of rigid bodies (i.e., isometries preserving chirality) by Leonhard Euler in 1758. Somewhat later, in 1840, Olinde Rodrigues improved this result by showing that the mentioned translation can be taken to be in the direction of the rotation axis (Van der Waerden 1985, p. 120).

Consequently, symmetry groups can be classified into two basic types:

Definition 2 A *point group* is a symmetry group with the property that all its elements possess at least one common fixed point (i.e., it is a symmetry group containing only orthogonal transformations). A *space group* is a symmetry group containing non-trivial translations.

To be noted here is that since bounded objects cannot possess non-trivial translational symmetries (i.e., translational symmetries which are not the identity transformation), symmetry groups of bounded sets of points are always point groups. Also, point groups in n-dimensional Euclidean spaces are always subgroups of the orthogonal group $O(n)$, which is the subgroup of $E(n)$ consisting of all orthogonal transformations. On the other hand, if a geometric pattern also possesses non-trivial translational symmetry, then it cannot be bounded. The most prominent examples of periodical patterns in nature are (idealized) crystal structures. This is the motivation for defining *crystallographic groups* as a type of space groups which are both discrete and cocompact (Vince 1997). Alternatively, n-dimensional crystallographic groups can be defined as groups containing a normal, torsion-free (i.e., the only

group element of infinite order is the identity), maximal Abelian subgroup of rank n and a finite index (Cid and Schulz 2001). However, for the purposes of this survey, it is sufficient to say that a discrete space group is a crystallographic group if it is the symmetry group of an object (e.g., idealized crystal structure) in n-dimensional Euclidean space that contains translational symmetries in n linearly independent directions, i.e., of a periodic object in n-dimensional Euclidean space. Besides crystallographic groups, in the course of this exposition (discrete) space groups, which describe objects possessing translational symmetry in less than n linearly independent directions (subperiodic objects), as well as some generalizations of the notion (known as magnetic and color groups), shall also be discussed.

2 Point Groups

The first systematic determination of possible symmetries with a fixed point, in modern terms described by point groups, has been attributed to **Leonardo da Vinci** (1452–1519): "Leonardo da Vinci engaged in systematically determining the possible symmetries of a central building and how to attach chapels and niches without destroying the symmetry of the nucleus. In abstract modern terminology, his result is essentially our table of the possible finite groups of rotations (proper and improper) in two dimensions" (Weyl 1952, p.66). According to Weyl (1952), Leonardo has discovered that bounded plane figures either possess only rotational symmetries (with a common center) or both rotational symmetries around a center and line (mirror) reflections about axes passing through the common center of rotations (see Fig. 5). Thus, he noted that all symmetries of a bounded plane figure have (at least) one common fixed point. Bounded plane figures are usually known as *rosettes*; a circle would technically fit the definition of a rosette, but it is usually exempted from

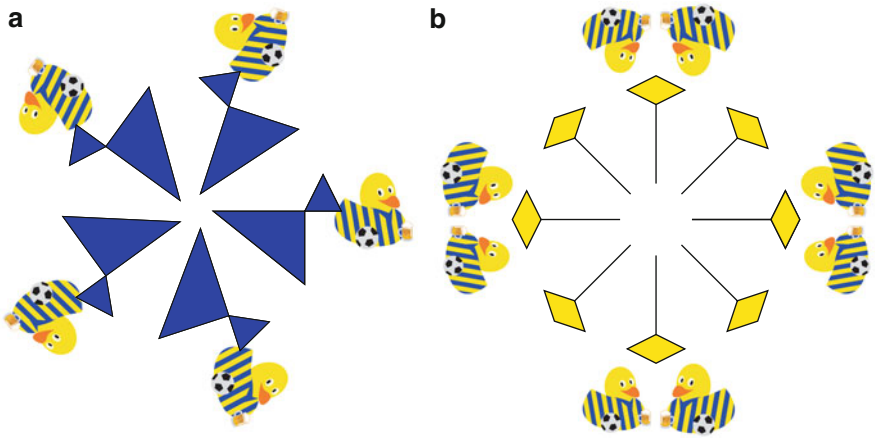

Fig. 5 Rosettes with symmetry groups C_5 (**a**) and D_4 (**b**)

it, since the symmetry group of a circle is the full orthogonal group $O(2)$ (Anglin and Lambek 1995), consisting of all rotations of the plane about a fixed point (the center of the circle) and reflections about any axis through that fixed point. More precisely, it is usually assumed that a rosette is a bounded two-dimensional figure with a discrete symmetry group (Sibley 2015). Thus, in modern terms, the discovery of the following theorem is attributed to Leonardo:

Theorem 1 (Leonardo's Theorem) The symmetry group of a rosette is either C_n or D_n, with n being a positive integer.

In Theorem 1, the symbol C_n is used to denote the *cyclic group* of order n, generated by a rotation with a rotation angle of $360°/n$ (a so-called n-fold rotation). The cyclic group C_1 is also known as the *trivial group*, and it is the symmetry group of all objects that are considered asymmetric in everyday language (mathematically speaking, it only possesses the trivial symmetry, which can be described as a rotation for $360° = 360°/1$ about an arbitrary axis). The symbol D_n is used to denote *dihedral groups* of order $2n$, generated by an n-fold rotation R and a reflection R' about a line through the center of R (in the three-dimensional case, R' is a twofold rotation about an axis intersecting the axis of R). Thus, D_1 is the symmetry group of rosettes possessing only one mirror symmetry, while in three dimensions, D_1 is the same as C_2. Here, as in the rest of the chapter, the *Schoenflies notation* for symmetry groups is used; other common notations are the Hermann-Mauguin notation and Conway's orbifold notation (Conway et al. 2008; Hahn 2005).

In crystallography, it is common to classify crystals into crystal classes. All crystals having the same point group belong to the same crystal class, which can be generalized into:

Definition 3 A *symmetry class* is the collection of all (bounded) objects having the same symmetry (point) group.

In other words, symmetry classes are equivalence classes with respect to "having the same point symmetry group" as an equivalence relation. Classes are usually denoted by the same symbol as the corresponding point groups. Due to Leonardo's systematic explorations of geometric shapes with different symmetries (Reynolds 2008), it might be more appropriate to say that he discovered that the possible symmetry classes of rosettes are C_n and D_n.

Leonardo's contribution apparently remained the only systematic attempt of classifying symmetry types for several centuries. In the beginning of the nineteenth century, even mathematicians did not consider (geometric) symmetry further than mirror-symmetry (Scholz 1989). In the eighteenth century, the definition of symmetry still resembled the ancient Greek one; for example, in Diderot's and d'Alemberts *Encyclopédie* one can read: "SYMMETRY (Architect.) is the relation, the proportion and the regularity of parts that are necessary to compose a nice whole [...]" (Kubbinga 2012, p. 7). The first mathematical definition of mirror symmetry was given by the French mathematician **Adrien-Marie Legendre** (1752–1833), who in

his *Géométrie* (1794) considered only this type of symmetry: "I will call two polyhedra symmetric polyhedra which, having a common base, are constructed similarly such that one is above the plane of this base and the other is below it, with the condition that the summits of the corresponding solid angles are located at equal distances from the plane of the base, on the same line perpendicular to this plane"[1] (Burckhardt 1988, p. 14; Hon 2005, p. 288).

It was crystallography which directed the attention to other types of symmetry of polyhedra and its systematic exploration. The regular (macroscopic) shapes of crystals (Fig. 4) have attracted attention since the antiquity, however the importance of crystal shapes – and thus a need to study their symmetry – has not been widely recognized until the late eighteenth century. In particularly, the idea of symmetry of crystals, although vaguely present, required almost a century to fully "crystallize."

The first to suggest that the shapes of the crystals might be an important feature (and a basis for a classification) of minerals was the Swiss physician and naturalist Moritz Anton Kappeler (or Mauritius Antonius Cappeler, 1685–1769) in his 1723 treatise *Prodromus crystallographiae de crystallis improprie* sic *dictis commentarium* (which also provides the first appearance of the word *crystallographia* = crystallography) (Lima-de-Faria 1990). However, he was only observing the crystal shape in most general terms (e.g., rounded, pyramidal, prismatic, polyhedral, dendritic, ...). Half a century later, Abraham Gottlob Werner (1749–1817) described crystal shapes as derived from six "primary" forms (icosahedron, dodecahedron, prism, pyramid, table, and lens), later adding also cube as the seventh. He also had a vague idea that certain forms were related (by symmetry) – e.g., cube and "perfect double tetragonal pyramid" (i.e., the regular octahedron) – as certain minerals may crystallize in both forms as well as a sequence of intermediary forms. This idea was further developed by Jean-Baptiste Louis Romé de l'Isle (1736–1790) who, basing his hypothesis on much closer observation of crystal forms as well as measurements of interfacial angles, defined the regular tetrahedron, cube, regular octahedron, rhombohedron, rhombic octahedron, and trigonal dodecahedron as the basic forms. From these, he derived further ca. 450 forms, which can be achieved by truncation of vertices or edges of the primitive (or subsequently derived secondary) forms, as possible shapes of crystals. When performing these truncations, he generally preserved some or all of the symmetry of the original form (Fig. 6), showing he had intuited the symmetry of different forms, although he never expressed it explicitly (Burke 1966; Capeller 1723; Romé de l'Isle 1783; Werner 1774).

Based on his description of the inner structure of crystals, R. J. Haüy in 1801 noted that not all five Platonic solids are possible as forms of crystals, but just the regular tetrahedron, hexahedron (cube), and octahedron. He also noted that rotational symmetry of order 5 is not possible in crystals (Burckhardt 1988, p. 18–19). In 1815, he

[1] *J'appelerai polyèdres symétriques deux polyèdres qui, ayant une base commune, sont construits semblablement, l'un au-dessus du plan de celte base, l'autre au-dessous avec celte condition que les sommets des angles solides homologues soient situes a egales distances du plan de la base, sur une meme droite perpendiculaire à ce plan.*

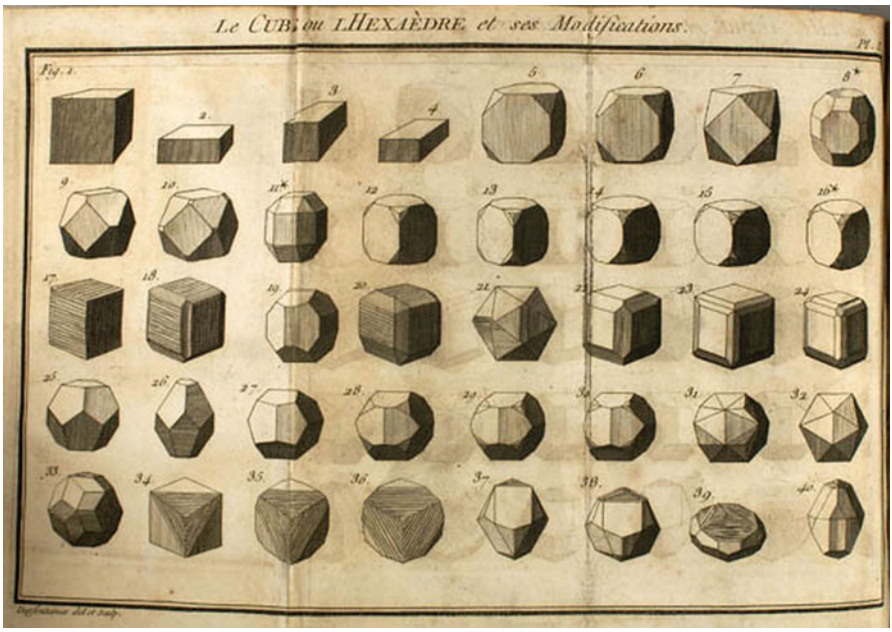

Fig. 6 Table from Romé de l'Isle's *Cristallographie* (1783) depicting various truncations of a cube leading to a series of different forms. Picture courtesy of Virtual museum of the history of mineralogy (https://mineralogy.eu/index.html)

published a series of memoirs concerning what he called the "law of symmetry" (*loi de symmétrie*), which postulated the idea of rotational symmetry in crystals, however without developing it in much detail. Also, he generally considered only a single (vertical) axis of rotation, which made it difficult to explain the observed crystal forms with additional (horizontal) axes of rotation (Haüy 1815). Haüy is also credited with the discovery (1784) of the crystallographic *law of rational indices* (the Second law of crystallography). In mathematical terms, this law says that if a face of the crystal is chosen to lie in the plane with equation $x + y + z = 1$ (thus implicitly defining the coordinate system), all intercepts of all other face planes of the same crystal always have rational coordinates. At Haüy's time, this law was conjectured and supported by observations of macroscopic crystals, but it has later been proven from the periodicity of the inner structure of crystals (Rogers 1912).

The actual classification of (not only) crystal symmetry begins with the so-called German school of crystallography: "The Germans more particularly assessed the outward geometrical appearance of the crystal, just as it presents itself to the observer. From 1815 to 1830 various attempts aiming at an exhaustive classification of the crystalline forms using this key concept had already been reported." (Kubbinga 2012, p. 13). The German mineralogist **Christian Samuel Weiss** (1780–1856), who visited Haüy in 1807/8, did not accept Haüy's molecular model of crystal structure, but argued that the macroscopic form of the crystal is determined

by directional forces leading to anisotropic crystal growth rates and therefore a polyhedral form – the form as well as the forces describable by means of a system of non-coplanar axes (Burke 1966). Building on the (at that time still not proven) fact that crystals cannot exhibit axes of rotational symmetry other than 1, 2, 3, 4, and 6, in 1815, he discussed their possible positions relative to one another and concluded that there are 4 types of possible configurations of axes (7, including sub-types): regular or isometric – modern cubic; four-tier or monodimetric – modern tetragonal; two-tier or trimetric – modern triclinic, monoclinic, and orthorhombic; six-tier or monotrimetric – modern hexagonal and trigonal (Burckhardt 1988; Burke 1966). In 1822, Friedrich Mohs (1773–1839), apparently unaware of Weiss's contribution, arrived also at seven types of configurations, avoiding some errors committed by Weiss, thus defining the modern seven *crystal systems* (Burke 1966; Scholz 1989). The symmetries of the seven configurations of the axes (being also the highest possible symmetries of the crystals belonging to corresponding crystal systems) later became known as *holoedries* (Burckhardt 1988, p. 31–32). After the periodicity of crystal structure was confirmed by X-ray diffraction in 1912, this was found to be equivalent to the modern group-theoretical definition of holoedries (Souvignier 2003; Streitwolf 1967):

Definition 4 A *lattice* in Euclidean space is the set of all points with integer coordinates with respect to a chosen – in general, skew – coordinate system. The *holoedry* is the group of all symmetries of the lattice which fix the origin (also known as the point group of the lattice). A *crystal system* is the set of all crystal structures with the same *holoedry*.

The names of the 7 crystal systems and the corresponding holoedries are given in Table 1.

In the 1820s, it was realized that there "are limits as to the geometry of crystals, and that a rigorously strict deduction of the distinct possibilities in terms of symmetry was a feasible enterprise" (Kubbinga 2012, p. 13). The German physicist, geographer, and crystallographer **Moritz Ludwig Frankenheim** (1801–1869) in 1826 departed from the law of rational indices for crystals and its consequence, the impossibility of rotational symmetries other than those of orders 1, 2, 3, 4, or 6. Using Weiss's classification of crystal axial systems into four types/seven subtypes,

Table 1 The 7 crystal systems and the corresponding holoedries

Crystal system	Holoedry
Triclinic	C_i (the symmetry group of a general skew four-sided prism)
Monoclinic	C_{2h} (the symmetry group of a skew rectangular prism)
Orthorhombic	D_{2h} (the symmetry group of a general cuboid)
Trigonal	D_{3d} (the symmetry group of a trigonal trapezohedron)
Hexagonal	D_{6h} (the symmetry group of a regular hexagonal upright prism)
Tetragonal	D_{4h} (the symmetry group of a square upright prism which is not a cube)
Cubic	O_h (the group of all symmetries of a regular octahedron or cube)

and analyzing which arrangements of lesser symmetry are possible for each, he arrived at 32 crystal classes. In fact, he essentially determined the 32 crystallographic point groups as subgroups of the seven holoedries (Burckhardt 1988, p. 34–39; Frankenheim 1826). However, Frankenheim's contribution remained generally unknown at the time, was rediscovered only ca. 150 years later, and therefore had no influence on the further developments of symmetry theory in the nineteenth century. For this reason, the first proof of the existence of exactly 32 crystal classes (crystallographic point groups) is usually attributed to the German physician and mineralogist **Johann Friedrich Christian Hessel** (1796–1872). Hessel's work also remained unnoticed for ca. 60 years, until L. Sohncke drew attention to it (Burckhardt 1988; Coxeter 1948; Cromwell 1997; Scholz 1989).

Hessel, who was familiar with Weiss's and Haüy's work, described the systematic derivation of possible symmetries of (macroscopic) crystals, and more general solids, in his more than 300-page-long essay *Krystall*, published in the 1830 edition of *Gehler's physikalisches Wörterbuch* (Scholz 1989). He described (macroscopic) crystal shapes as polyhedral and commented on the insufficiency of mathematical symmetry theory at that time: "A scientific knowledge of the forms of the crystals that satisfies all requirements presupposes that one is familiar with the general principles which the theory of shapes must follow when investigating the various possible shapes. However, since these principles are not yet clearly expressed in works on pure mathematics, and since the general theory of shapes in the extent it is now available is still a young science, it has to first be developed here, before continuing to its application to crystal shapes"[2] (Hessel 1830, p. 1034).

Thus, Hessel develops a systematical study of symmetries of two- and three-dimensional (bounded) figures. Besides mirror symmetry, he also describes p-fold rotational symmetry, explicitly allowing rotational symmetry of infinite order ($p = \infty$), see (Hessel 1830, p. 1045). First, he studies mirror and rotational symmetries of (bounded) plane figures. By studying the possibilities of rotating the figure itself or its mirror image into positions that coincide with the original, Hessel arguments that the second is only possible if the figure itself is mirror-symmetric and continues with the proof that every plane figure is either *1fach pgliedrig* (exhibits only p-fold rotational symmetry), or it is *2fach pgliedrig* (also exhibits mirror symmetry). In other words, in this part (Hessel 1830, pp. 1040–1043), Hessel has proven Leonardo's theorem (including circular symmetry), and this is apparently the earliest published proof of it. Hessel showed even more: For a chosen line in the plane of the figure (intersecting the p-fold rotational axis in the midpoint), in the first case one obtains p equivalent positions of that line (each two neighboring ones separated by an angle of $360°/p$), and

[2] *Eine wissenschaftliche Kenntniss von den Formen der Krystalle, die allen Anforderungen genügt, setzt voraus, dass man mit den allgemeinen Principien vertraut sey, welche die Gestaltenlehre bei Untersuchungen der verschiedenen möglichen Gestalten überhaupt zu befolgen hat. Da diese Principien jedoch in Werken über reine Mathematik noch nicht so bestimmt aus gesprochen sind, indem die allgemeine Gestaltenlehre in der Ausdehnung, wie sie jetzt vorliegt, eine noch jugendliche Wissenschaft ist, so muß sie hier erst entwickelt werden, um so dann die Anwendung derselben auf die Krystallgestalt folgen zu lassen.*

in the second case $2p$ equivalent positions line (each two neighboring ones separated by an angle of $360°/(2p)$). In group-theoretic terms, at that time unknown to Hessel (as noted in the introduction, Galois developed the foundations of group theory in the period 1828–1832, but it was not publicly known at that time, and besides, these foundations only considered groups of permutations), he has proven that the cyclic groups C_p are of order p, and that the dihedral groups D_p are of order $2p$.

Hessel then continues to study symmetries of solids. Here, he notes the possibility of a polyhedron possessing more than one rotational axis of symmetry and introduces names for rotational axes of various orders, including a systematic investigation of possibilities of rotations into mirror-symmetric positions. In other words, he considered both proper and improper rotations, where *improper rotations* in three-dimensional space are defined as the composition of a rotation with a mirror symmetry (reflection on a plane). In particular, mirror symmetries are examples of improper rotations of order 1. Hessel distinguishes classes of solids depending on if they possess a principal axis of symmetry (*Hauptaxe*) or not: A principal axis of symmetry, according to Hessel's definition, is a rotational axis that has no symmetrically equivalent positions for the same solid. An example of a solid with a principal axis would be a regular hexagonal prism, while a cube is an example of a solid without it. By systematically investigating the possibilities, Hessel enumerates (describes) symmetry types – de facto point groups – of solids with a p-fold principal axis. Again, he explicitly mentions the case of $p = \infty$ and the possibility of conical and cylindrical symmetry.

He then continues with the more abstract classification of the axial systems (possible configurations of rotational axes as symmetry axes of solids) and describes the forms (*Gestalten*) which correspond to each of the axial systems with a principal axis. To achieve this, he arrives at many geometric results on possible polyhedral shapes, or in crystallographic terms, Hessel developed another important notion in crystallography, the crystal forms. The description of this theory is not directly connected to our topic, and the interested readers are referred either to the original text (Hessel 1830) or the more modern exposition (Nelson 2011). Then Hessel continues to *hauptaxenlose Strahlensysteme*, axial systems without a principal axis. Developing his systematic theory, he geometrically proves several results about the possible orders and angles between rotational axes in such systems, e.g., that the highest possible order of a rotational axis in an axial system without a principal axis cannot be higher than 5 (Hessel 1830, p. 1116). Even if Hessel's approach is – from a modern perspective – cumbersome, and involves no group theory, he successfully and geometrically proved (the geometric equivalent of) the following generalization of Leonardo's theorem to three dimensions:

Theorem 2 (Hessel's Theorem) The only possible point groups of bounded sets of points in three-dimensional Euclidean space are:

1. With the principal axis:
   - C_n (contain only symmetries, which are rotations about one axis)
   - D_n *(only symmetries are rotations about one principal axis of order n and about n horizontal twofold axes)*

- *C_{nh} (like C_n with additionally one horizontal plane of reflection)*
- *C_{nv} (like C_n with additionally n planes of reflection containing the principal axis)*
- *D_{nh} (like C_{nv} with an additional horizontal plane of reflection)*
- *D_{nd} (like D_n with additional planes of reflection containing the principal axis and bisecting the angles between neighboring horizontal twofold axes)*[3]
- *S_{2n} (like C_n, but the principal axis is an improper one; not to be confused with the symmetric group of all permutations of a set with 2n elements, which has the same notation)*
- *Symmetry groups of a circular cylinder ($D_{\infty h}$) and circular cone ($C_{\infty v}$)*

2. Without the principal axis:
   - *T, O, I (groups consisting only of rotational symmetries of a regular tetrahedron, octahedron, or icosahedron)*
   - *T_d, O_h, I_h (groups of all symmetries of a regular tetrahedron, octahedron, or icosahedron)*
   - *T_h (like O_h, but with fourfold axes replaced by twofold ones)*
   - *Symmetry group of a sphere (K_h)*

   These point groups are illustrated in Fig. 7 by examples of solids in the corresponding symmetry classes.

Equivalently and more concisely, Hessel's theorem states that all finite subgroups of O (Artin 1991) are subgroups of one of the following four types of groups: D_{nh}, T_d, O_h, I_h (Sibley 2015, p. 290). The modern, group-theoretical proof of Hessel's theorem can be found, e.g., in Grove (1997).

Apparently unaware of Hessel, Auguste Bravais (more famous for his classification of plane and space lattice, see next section) also obtained the classification of polyhedral symmetries (i.e., Hessel's theorem) in 1849. In his two 1849 papers (Bravais 1849a, b), he studied symmetries of polyhedra, departing from Legendre's definition of (mirror) symmetry, adding his own definitions of central and rotational symmetry, and proving many classical geometrical results on symmetry, for example, that every rotational symmetry of a polyhedron is of integer order, i.e., that its angle is commensurable with 360° (Bravais 1849b, p. 141–142). In group theoretical terms, Bravais' results describe the properties of elements of point groups and their compositions.

In the second part of his essay (Hessel 1830), Hessel returned specifically to the study of crystals to arrive at the result he is most famous for: There are only 32 crystallographic point groups (crystal classes) in three-dimensional space. He proved this by combining his previous results on general symmetries of polyhedra and axial systems with arguments about directions of forces acting on crystal planes and the known macroscopic forms of crystals of his time. In this way, he arrived at

[3] Some of the groups listed above are not only isomorphic, but the same. For example, $C_{1h} = C_{1v}$ and $D_{1h} = C_{2v}$.

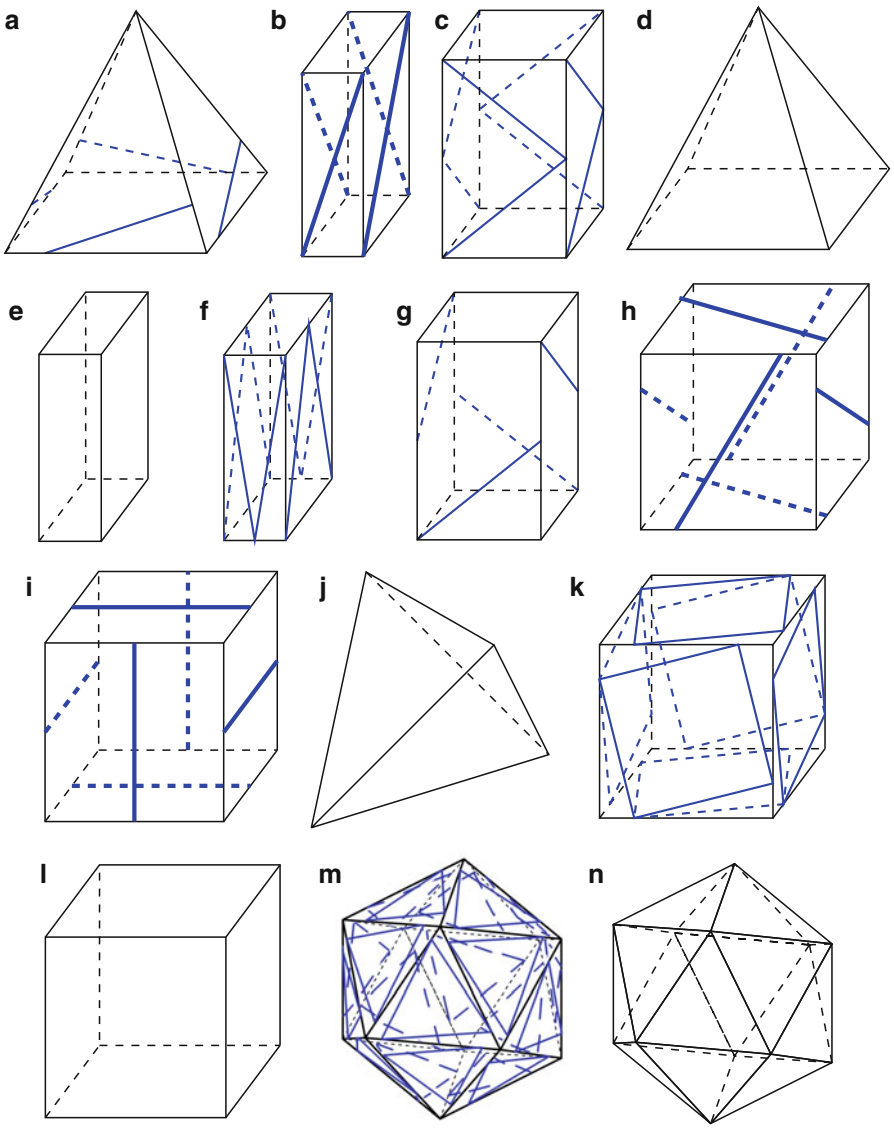

Fig. 7 Examples of solids with and without decoration demonstrating 14 basic types of three-dimensional point groups: (**a**) C_n (with $n = 4$), (**b**) D_n (with $n = 2$), (**c**) C_{nh} (with $n = 4$), (**d**) C_{nv} (with $n = 4$), (**e**) D_{nh} (with $n = 2$), (**f**) D_{nd} (with $n = 2$), (**g**) S_{2n} (with $n = 2$), (**h**) T, (**i**) T_h, (**j**) T_d, (**k**) O, (**l**) O_h, (**m**) I, n) I_h

the conclusion that not all the classes (point groups) from his theorem are possible for crystals and finally determined the possible crystal classes (Burckhardt 1988; Hessel 1830). Barlow refers to Hessel as the first to discover the 32 crystal classes – obviously Frankenheim's results were unknown to Barlow – highlighting the fact

that Hessel "treats crystal symmetry purely as a matter of similarity of position with respect to one another of lines and planes which obey Haüy's law of rational indices" (Barlow 1901, p. 2). In other words, Hessel's arguments lack the formal mathematical background, since his correct geometrical arguments depend on the inner structure of crystals, which implies the impossibility of rotational axes of orders other than 1, 2, 3, 4, and 6 (and the law of rational indices).

Definition 5 A point group (in two- or three-dimensional Euclidean space) is called a *crystallographic point group* if it does not contain (proper nor improper) rotations of orders other than 1, 2, 3, 4, and 6.

For example, of all the possible two-dimensional point groups from Leonardo's theorem, only 10 (C_1, C_2, C_3, C_4, C_6, D_1, D_2, D_3, D_4, D_6) are crystallographic. Independently of Hessel, Frankenheim, and Bravais, the Finnish-born Russian mineralogist **Axel Gadolin** (1828–1893) published his study, which included his proof of the existence of exactly 32 crystal classes, in 1869 in Russian (and 1871 in French). Like Hessel and Frankenheim, he based his argument for the impossibility of symmetries of orders 5 or higher than 6 on the law of rational indices and studied the possible combination of rotational axes and other symmetry elements to arrive at the result (Barlow 1901; Burckhardt 1988; Saurel 1911; Whitlock 1934):

Theorem 3 (Frankenheim-Hessel-Bravais-Gadolin) There exist exactly 32 crystallographic point groups (i.e., crystal classes, as illustrated in Fig. 8):

- 11 consisting only of rotations: C_1, C_2, C_3, C_4, C_6, D_2, D_3, D_4, D_6, T, O;
- 21 also including central or mirror symmetries: C_{1h} (often denoted C_s), C_{2h}, C_{3h}, C_{4h}, C_{6h}, C_{2v}, C_{3v}, C_{4v}, C_{6v}, D_{2h}, D_{3h}, D_{4h}, D_{6h}, D_{2d}, D_{3d}, S_2 (usually denoted by C_i), S_4, S_6 (usually denoted by C_{3i}), T_d, T_h, O_h.

As already mentioned, parallelly to the described developments in crystallography, group theory emerged, initially as the study of groups of permutations related to solutions of algebraic equations. Its importance and generality first began to be noted in the second half of the nineteenth century. Felix Klein used it in 1872 for "bringing order to geometry" (Kleiner 1986, p. 198). During the 1870s Sophus Lie, Henri Poincaré (and Felix Klein) introduced connections of group theory with analysis, and also Arthur Cayley's 1854 introduction of abstract groups began to have influence in the mathematical community (Brückler 2017; Kleiner 1986). However, for the present chapter, the most important line of thought, which enabled the reformulation of the described results on symmetry classes in group-theoretical terms and provided foundations for further classifications of symmetry patterns, began with one of many contributions to group theory by the French mathematician **Camille Jordan** (1838–1922). He was the first to study "groups of movements" (or in modern terms, symmetry groups) in his two-part study titled *Mémoire sur les groupes de mouvements* (1868/69). Jordan considered movements of space and his work was inspired by Bravais' *Etudes cristallographiques*. He defined groups of movements as follows: *The group formed by the movements having this*

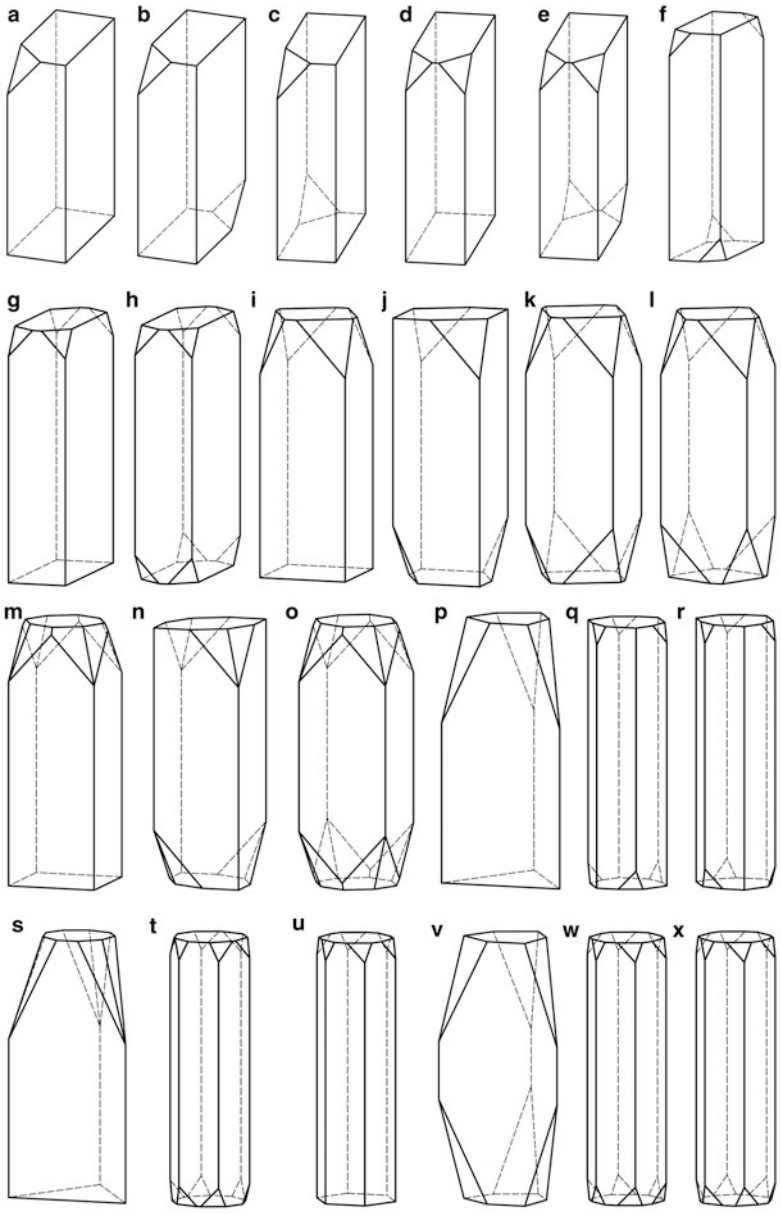

Fig. 8 Examples of polyhedra belonging to each of the 32 crystal classes: 1. Triclinic system (**a**) C_1, (**b**) C_i; 2. Monoclinic system: (**c**) C_2, (**d**) C_s, (**e**) C_{2h}; 3. Orthorhombic system: (**f**) D_2, (**g**) C_{2v}, (**h**) D_{2h}; 4. Tetragonal system: (**i**) C_4, (**j**) S_4, (**k**) C_{4h}, (**l**) D_4, (**m**) C_{4v}, (**n**) D_{2d}, (**o**) D_{4h}; 5. Trigonal system: (**p**) C_3, (**q**) C_{3i}, (**r**) D_3, (**s**) C_{3v}, (**t**) D_{3d}; 6. Hexagonal system: (**u**) C_6, (**v**) C_{3h}, (**w**) C_{6h}, (**x**) D_6, (**y**) C_{6v}, (**z**) D_{3h}, (**aa**) D_{6h}; 7. Cubic system: (**bb**) T, (**cc**) T_h, (**dd**) O, (**ee**) T_d, (**ff**) O_h. Pictures courtesy of Darko Tibljaš, generated by software Kristall2000 (Schilling 2019)

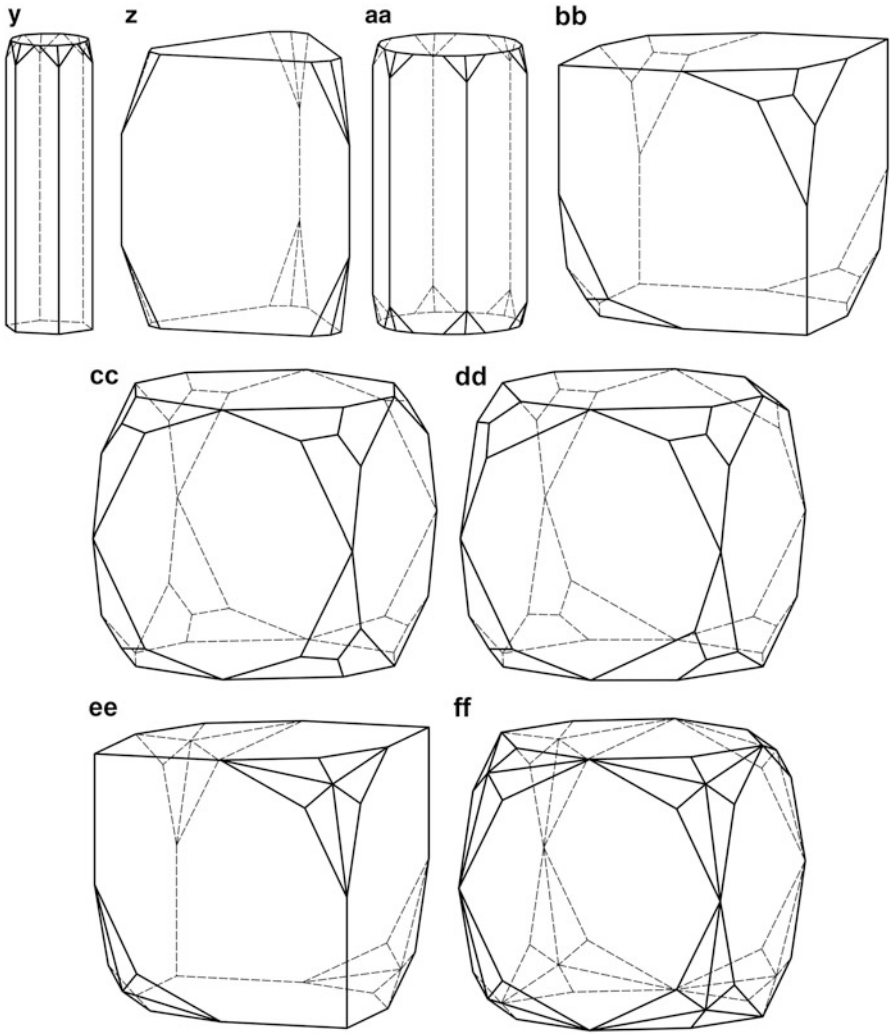

Fig. 8 (continued)

characteristic property that if M' and M" are any two movements forming part of this group, M'M" will also be part of it[4] (Jordan 1869, p. 168). Then he set out to enumerate all possible groups of movements. To achieve this, he first determined all (discrete *and* continuous) translation groups in three-dimensional space and in total obtains 10 types of topologically closed groups of translations. Then he found all

[4] *Le groupe forme par les mouvements cher de cette propriete earacteristique, quo si M' et M" sont deux mouvements quelconques faisant partie de ce groupe, M'M" en fera partie.*

possible groups of rotations in three-dimensional space: the discrete groups of type C_n, D_n, T, O, I, the two continuous rotation groups (all rotations about a fixed point or about a fixed axis); and finally the group consisting of all rotations about an axis *and* all "full turns" about axes perpendicular to the first one. In modern terms, Jordan determined all subgroups of the special orthogonal group SO (Artin 1991); these are often called *chiral point groups* (Jordan 1869; Kubbinga 2012; Van der Waerden 1985). As defined in the introduction, point groups are subgroups of orthogonal groups $O(n)$, and the name orthogonal group has apparently also been used first by Jordan a year later (Jordan 1870). Thus, it seems appropriate to say that Camille Jordan is *the* father of symmetry group theory.

By the beginning of the twentieth century, all of this became common knowledge in the crystallographic and mathematical community, as discernible, e.g., from the paper (Barlow 1901). Barlow begins his paper by emphasizing that no study of crystal symmetry can be complete without considering their internal structure and says: "it is somewhat remarkable that the important work of deducing the existence of 32 classes of crystal symmetry from first principles *has been based on crystal form and not on internal structure*" (Barlow 1901, p. 2). After criticizing the deficiencies of such proofs, in particular Gadolin's method, he explicitly bases his further considerations on Jordan's work. Barlow's starting point is the following "Fundamental definition. Homogeneity of structure consists in a likeness of ultimate parts or molecules of a body, both as to their nature and their relative arrangement, of the following kind: Corresponding to every mathematical point in the mass are found evenly distributed at finite intervals a number of points whose relation to the ultimate structure, regarded as of unlimited extent, is the same as that of the point selected" (Barlow 1901, p. 5). It is clear that Barlow's homogeneity is what is nowadays called periodicity. He then proves the existence of exactly 32 crystal classes (i.e., crystallographic point groups) combining arguments of Sohncke and Gadolin with mathematical formality of (geometric) arguments based on the periodic inner structure. Barlow does not explicitly use group theory techniques in his proofs, but his reference to Jordan and several formulations of partial results on "groups of movements" clearly show that he was well acquainted with the relation between symmetries (of crystals) and the corresponding groups.

Even if Barlow's criticism of Hessel's and Gadolin's arguments is well justified, it relates only to the reduction of all three-dimensional point groups to the ones relevant for crystallography. Hessel's theorem and its proof, even if formulated purely geometrically, is correct and only its original formulation (and the style of arguments, not their content itself) separates it from the modern group-theoretic one, so it is fully appropriate to say that Hessel was the first to prove it.

In the beginning of the twenty-first century, the English mathematician **John Horton Conway** (1937–2020) proved Hessel's theorem in an apparently different, but equivalent setting. Conway considers *spherical symmetry groups*, discrete symmetry groups of patterns on spheres and arrives at the same 14 types of (discrete) symmetry groups as Hessel (Conway et al. 2008). The equivalence of these two approaches is best explained by the following quote from (Belcastro and Yackel 2011, p. 151): "[. . .] if we had a tiling on a sphere made of soft clay, we could then flatten each tile (perhaps by smacking it with a pan) and make our previously tiled

sphere have a surface with flat sides [. . .]. If we then also straightened out the edges, the resulting object would be called a polyhedron. [. . .] Conversely, we could inflate a polyhedron until it is projected onto a sphere." For all readers interested in handicraft and/or art, it might be of interest to mention here that the Japanese temari-balls provide a beautiful illustration of Conway's spherical symmetry, i.e., three-dimensional point groups (Belcastro and Yackel 2011; Yackel 2012).

Before moving on to other dimensions than 2 and 3, reflection groups should be mentioned. These are point symmetry groups generated by reflections. While in dimensions up to 3, the usual notion of mirror symmetry is equivalent to reflection, it is customary to define reflections as a special type of isometries in arbitrary dimension:

Definition 6 A *hyperplane* in an n-dimensional Euclidean space E is any $(n-1)$-dimensional affine subspace of E. A *reflection* on a hyperplane Π is a non-trivial isometry of E for which the set of fixed points is Π. A *reflection group* is a discrete subgroup of the orthogonal group $O(n)$ generated by a set of reflections on hyperplanes in the n-dimensional Euclidean space.

Even if the motivation for considering reflection groups is most naturally described by kaleidoscopes (Fig. 9) and the corresponding symmetries of the

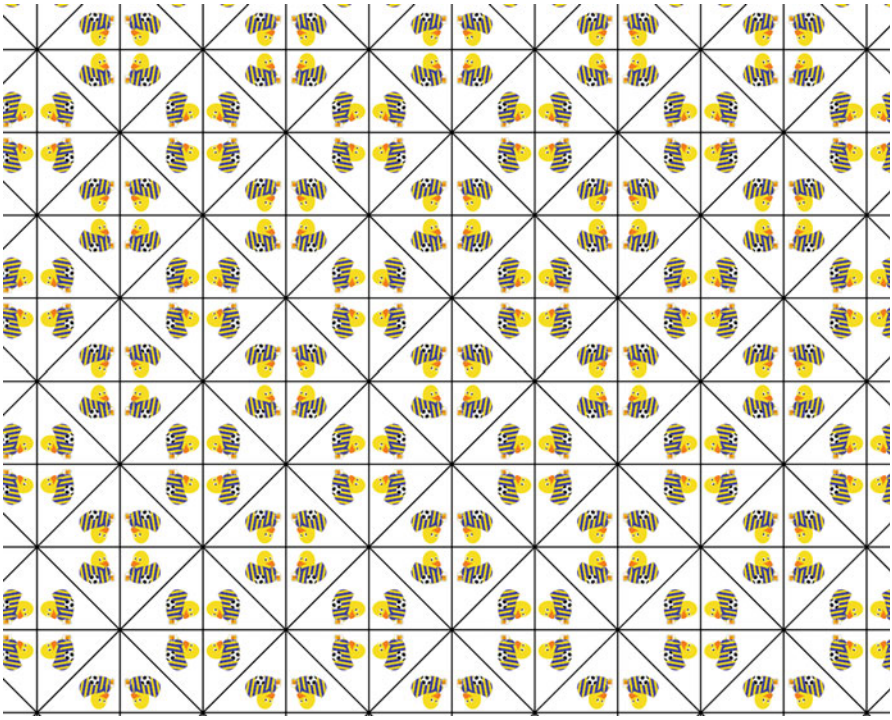

Fig. 9 Example of kaleidoscopic symmetry in the plane

plane, their separate study historically arose partly from the described line of investigation of polyhedral symmetries, partly from the research on Lie groups (in arbitrary dimensions) by W. Killing, E. Cartan, and H. Weyl. It was **Harold Scott MacDonald Coxeter** (1907–2003) who first classified reflection groups in arbitrary dimension, and introduced their abstraction, which is now known as Coxeter groups (Conway et al. 2008; Coxeter 1934, 1935; Goodman 2004).

Coxeter's studies were not the first to consider point symmetries in higher dimensions. He himself refers to an 1889 paper by the French mathematician **Édouard Jean-Baptiste Goursat** (1858–1936), who considered symmetry operations in four-dimensional space (Conway and Smith 2003; Coxeter 1934; Goursat 1889; Hurley 1951; Van der Waerden 1985). A few years before Coxeter's introduction of reflection groups, W. Threlfall and H. Seifert published the first enumeration of all four-dimensional point groups (Threlfall and Seifert 1931; Van der Waerden 1985). However, "Every group does appear in Seifert and Threlfall's list, but appears an uncertain number of times, since the equivalences between the groups that depend on parameters are not completely listed"(Conway and Smith 2003, p. 48). In 1949, C. Hermann provided the foundation for listing all crystallographic orthogonal transformations in arbitrary finite dimensions (Hermann 1949), and soon the first paper containing the enumeration of crystallographic point groups in dimension 4 followed (Hurley 1951). Here Hurley, departing from Goursat's results, deduced the 24 point-symmetry operations in four-dimensional space (MacKay and Pawley 1962). Using periodicity as the defining characteristic of crystal structure, i.e., determining crystallographic point groups in four-dimensional space as holoedries (see next section for crystallographic restriction in higher dimensions), Hurley found 222 crystallographic point groups in dimension 4. This was corrected in 1967, obtaining the final number of 227 crystal classes in four-dimensional space (Hurley et al. 1967). Conway and Smith (2003) finally described all point groups in four-dimensional space, i.e., all discrete subgroups of O (Bamberg et al. 2003). Starting from the general result that for an n-dimensional Euclidean space, every orthogonal transformation acting on it can be described as a composition of at most n mirror symmetries (reflections), they obtained a characterization of the elements in O (Bamberg et al. 2003) and classified all its subgroups to obtain the four-dimensional equivalent of Leonardo's and Hessel's theorem. In total, they obtained 71 types of discrete point groups in dimension 4 (Conway and Smith 2003, p. 44–47). In order to enumerate crystallographic (not only point) groups in higher dimensions, various algorithms were developed in the late twentieth and early twenty-first centuries, and the numbers of crystallographic point groups (geometric crystal classes) in dimensions 5 and 6 have been found to be 955 and 7103, respectively (Downward 2011; Plesken 1981; Plesken and Schulz 2000; Veysseyre and Veysseyre 2002; Veysseyre et al. 2002).

During the twentieth century, the approach to symmetry groups shifted even more toward abstract group-theoretic, and lists of crystallographic point groups are now understood simply as sets of representatives for the **Q**-classes of space groups: The point group P corresponding to a space group G can be defined as (isomorphic to) the quotient group G/T (T being the translational subgroup of G). Point groups can always be taken (represented) as finite subgroups of GL(n, **Z**), since every point

symmetry of an n-dimensional lattice is an invertible linear operator, and every invertible linear operator acting on an n-dimensional space can be, with respect to any chosen basis of the space, represented by an invertible square matrix of order n. If the basis is chosen to consist of n non-coplanar vectors connecting a fixed lattice point O (the origin) to n of its nearest neighbors, the matrix entries will be integers, i.e., the matrix will be an element of GL(n, **Z**). Two space groups are **Q**-equivalent if the corresponding point groups are conjugate in GL(n, **Q**). Besides the numbers of **Q**-classes (also called geometric crystal classes) the numbers of **Z**-classes (also known as arithmetical crystal classes) are known in dimensions up to 6 too (Brown et al. 1978; Plesken and Schulz 2000; Schwarzenberger 1984).

Finally, a short note on point groups in dimension 1. The only symmetry groups of bounded parts of a straight line are quite obviously C_1 and D_1, exemplified by the following two linear patterns:— - and –. The fact appears to be quite trivial, and there seems to be no reference as to who first explicitly noted it; implicitly, it was surely known to the mathematicians and crystallographers of the nineteenth century, and probably also much earlier.

3 Space Groups in Three Dimensions

Space groups describe the symmetries of periodic and subperiodic objects. In Fig. 10, the difference between periodicity and subperiodicity is illustrated by an example of a *wallpaper* (periodic object in the plane) and a *frieze* (subperiodic object in the plane). More formally:

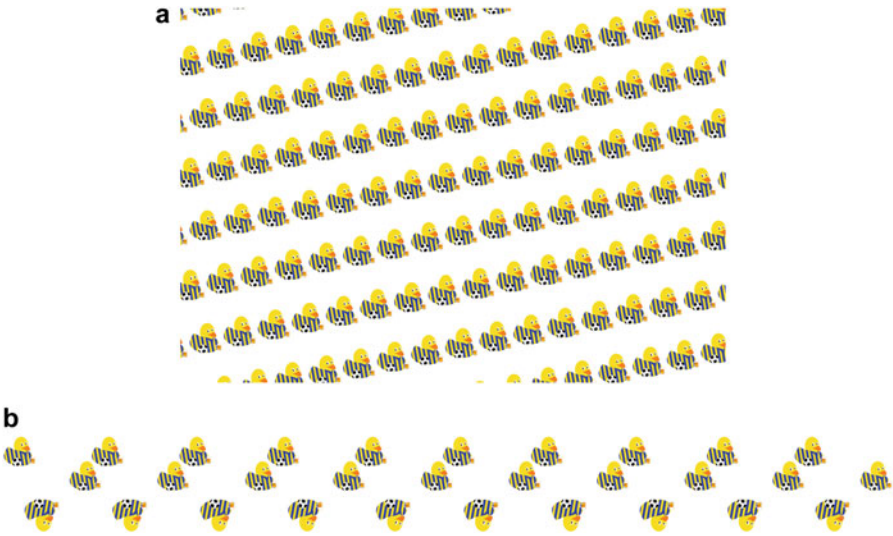

Fig. 10 Bounded clippings from a wallpaper (**a**) and a frieze (**b**) – a periodic and a subperiodic object in two-dimensional Euclidean space

Definition 7 A subset C of an n-dimensional Euclidean space is said to be *periodic* if there exists a basis B of the corresponding vector space such that translations for all basis vectors are symmetries of C, and it is said to be *subperiodic* if translations for at least 1 and at most n–1 basis vectors are its symmetries.

It is important to note that if C is periodic, then the basis B spans a parallelotope (this is the generalization of parallelograms and parallelepipeds to arbitrary finite dimension), which is usually called the *unit cell* of C. This unit cell is compact, thus the definition of a crystallographic space group as a discrete and cocompact space group is equivalent to saying it is the symmetry group of a periodic set. The fundamental models of periodic sets are lattices, since every periodic set can be described by superimposition (de facto, convolution) of the unit cell with the lattice (in a coordinate system with origin in one of the vertices of the unit cell and coordinate axes defined by B). In the following, the term "space group" is used when speaking of crystallographic space groups, i.e., symmetry groups of periodic objects. When speaking of space groups of subperiodic objects, the term "subperiodic space group" shall be used. These are discrete too, but not cocompact.

The early history of space groups is related to periodic plane tessellations (tilings). It is well-known, and often attributed to the Pythagoreans, that there exist only three regular tilings of the plane – with squares, isosceles triangles, and regular hexagons (Anglin and Lambek 1995). The oldest preserved proof of this fact appears to be Johannes Kepler's proof in his *Harmonice Mundi* (1619) (Burckhardt 1988; Brückler 2017; Grünbaum and Shephard 1987; Kepler 1619). This is a special case of the fundamental property of periodic objects in the background of the derivation of the space groups and known as the *crystallographic restriction*. The classical crystallographic restriction is a theorem which states that periodic objects in three-dimensional space cannot possess rotational axes of orders other than (1,) 2, 3, 4, or 6. Due to the laws of crystal growth, this property is also valid for macroscopic crystal shapes. As mentioned in the previous section, both Frankenheim and Hessel implicitly used it when they derived the existence of exactly 32 crystal classes, i.e., crystallographic point groups, even if explicitly their arguments were based on its consequence, the law of rational indices (Bamberg et al. 2003; Sibley 2015). The usual, simple geometric proof of the crystallographic restriction is generally attributed to W. Barlow (Barlow 1901, p. 17; Coxeter 1969, pp. 60–61), and it is equally valid for two-dimensional periodic objects. This, however, was not the first published mathematical proof of the crystallographic restriction: A. M. Schoenflies gave a proof already in 1891 (Schoenflies 1891), but it was lengthy and rather complicated.

The classification of lattices as models of periodic structures is the first step toward the determination of all space groups. The first to attempt a classification of space lattices was M. L. Frankenheim in 1835 and 1842. He arrived at 15 types of lattices, one too many – his error was that in the monoclinic system he counted one type of lattice twice. This error is not present anymore in Frankenheim's 1856 text, *Die Anordnung der Moleküle im Krystalle* (Burckhardt 1988, p. 48–51). Thus, the first full classification is attributed to the one who, in 1850, mathematically

rigorously achieved it both for dimensions 2 and 3: the French physicist **Auguste Bravais** (1811–1863). He was the first to systematically and purely mathematically investigated lattices. His famous 1850 essay *Mémoire sur les systèmes formés par des points distribués régulièrement sur un plan ou dans l'espace* contained a detailed formal mathematical proof of the existence of exactly 5 plane (Fig. 11) and 14 space lattice types, which are now known as *Bravais lattices* in his honor. Apparently, even if Bravais was familiar with results from the French and German schools of crystallography, he was not yet familiar with group theory, and his proofs use a combination of geometric and linear algebra arguments (Bravais 1850; Burckhardt 1988).

From the modern point of view, the definition of Bravais lattices is more abstract (Streitwolf 1967, p. 45):

Definition 8 Let T be the translational subgroup of a space group of a periodic object C, i.e., the subgroup consisting of all translational symmetries of C. If all translational vectors of translations from T are taken to have a common initial point O, then the set of all terminal points of all these vectors is the *Bravais lattice* of C.

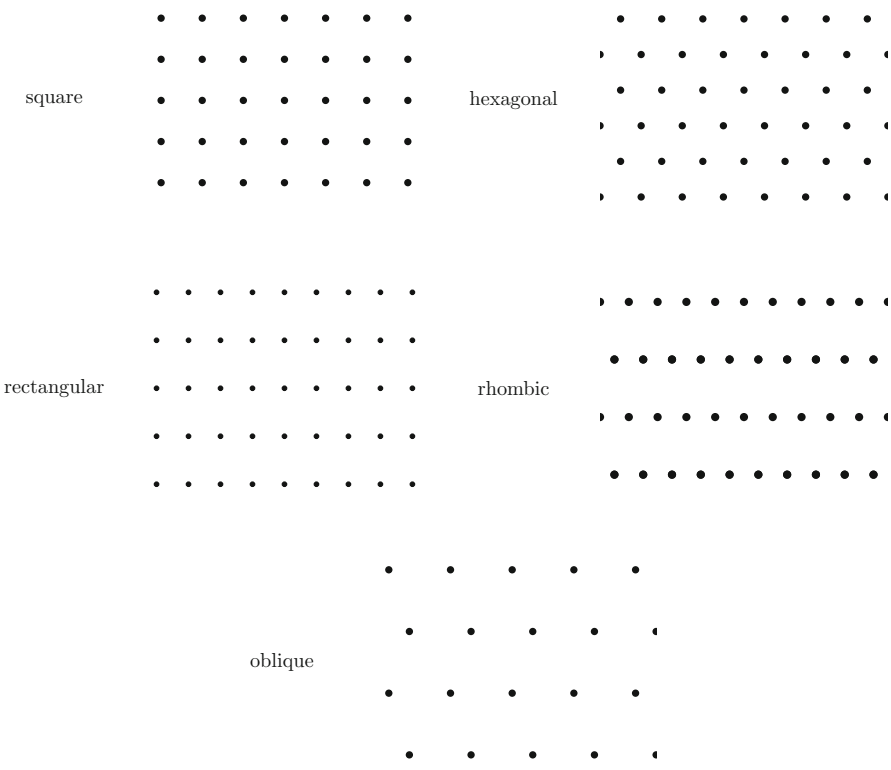

Fig. 11 Clippings of the 5 Bravais lattices in the plane

In even more modern approaches, the notion of Bravais lattice has become more abstract and gave rise to the definition of *Bravais groups*, see e.g., Souvignier (2003).

Bravais's writings influenced C. Jordan (Schwarzenberger 1984), who – as already described – introduced groups of movements, i.e., symmetry groups, in 1869. Jordan's work was very influential and soon became known in the crystallographic community. After determining all rotational (chiral) point groups in three-dimensional space, Jordan attempted to combine rotations and translations in order to determine all possible (chiral) groups of movements, but his enumeration was incomplete. Boisen and Gibbs (1976, p. 145) attribute the first group-theoretical classifications of crystal symmetry to Minnigerode (1884), Schoenflies (1891), and Weber (1896). However, an earlier usage of group theory in crystallography was due to German mathematician **Leonard Sohncke** (1842–1897), who first noted the incompleteness of Jordan's enumeration. In his major work *Entwickelung einer Theorie der Kristallstruktur* (1879), resulting from his studies from 1867 onward, Sohncke used group theory (as he calls it, *Jordan'sche Methode*) and obtained 66 chiral space groups in space, i.e., space groups in three-dimensional space containing only rigid motions: rotations, translations, and their compositions (Sohncke 1879). These are now known as *Sohncke groups*. He later found that he had counted one twice, so there are 65 of them (Burckhardt 1988; Van der Waerden 1985). Sohncke's classification was a herald of the soon-to-follow complete classification and enumeration of space groups in three dimensions, which was successfully completed independently by A. M. Schoenflies and E. S. Fyodorov.

The German mathematician **Arthur Moritz Schoenflies** (1853–1928), in his first works (1886/1887), re-proved many of the already mentioned results, including Sohncke's, but his proofs much more clearly emphasize the role of group theory. For Schoenflies, crystal classes are point groups (*Hilfsgruppen*), and he determined translations compatible with each of them. In the next years, he devoted himself to the determination of all *erweiterte Gruppen*, i.e., space groups which also include mirror-symmetries and were not considered by Jordan and Sohncke. By 1890, he determined the number of space groups in total to be, erroneously, 236. He also noted that each of these can be obtained by building up from one of the 32 *Hilfsgruppen*. Schoenflies's approach from these studies somewhat differed from the final one, as presented in his famous textbook *Kristallsysteme und Kristallstructur* (1891). He explicitly refered to Hessel, Bravais, and Sohncke in the preface, and after a quite complete introduction to the symmetry group theory of his time, he first gave the first fully group-theoretical deduction of all crystallographic point groups. Schoenflies divided them into groups of first kind (rotational groups) and groups of second kind (all the others, these he obtained from the groups of the first sort by systematically adding central and mirror symmetries and rotoinversions, i.e., compositions of rotations with central symmetry). He also proved that in each group of the second kind, the numbers of orientation-preserving and orientation-inverting elements are the same, and that the orientation-inverting elements can be obtained by composing just one of them with all the rotations in the group. All point groups are divided into seven crystal systems before, in the second part of his textbook, he systematically determined all the – now correctly – 230 three-dimensional space

groups, in each of the crystal systems: 2 in the triclinic system, 13 in the monoclinic system, 59 in the orthorhombic system, 68 in the tetragonal system, 25 in the trigonal system, 27 in the hexagonal system, and 26 in the cubic system. In the last chapter, Schoenflies finally proved the crystallographic restriction theorem (which was in the beginning just stated as a consequence of the law of rational indices) and the law of rational indices from the presupposed periodic structure of crystal, thus fully completing the arguments (Burckhardt 1967, 1988; Schoenflies 1891).

The Russian mineralogist and crystallographer **Yevgraf Stepanovich Fyodorov** (also often transliterated as Evgraf Fedorov, 1853–1919) was also familiar with Sohncke's classification of chiral space groups, and began his own researches in that direction already in 1881. During the 1880s, he developed his *Симметрия правилъных систем фигур* (*Simmetriya pravilnykh sistem figur*), which was published in 1890/1 with a follow-up containing corrections (Fyodorov 1890, 1891). His method arose from considerations of plane and space tessellations, and was developed independently of Schoenflies. However, from 1889 up to 1908, they communicated by letters. This correspondence was initiated by Schoenflies, who sent two of his publications to Fyodorov, but Fyodorov's 1890 classification of "regular systems of points" (periodic tilings) by symmetry was achieved independently and was more complete than Schoenflies's publication from the same year. Even if also based on group theory and departing from symmetry classes, his approach is different than Schoenflies's. Fyodorov classifies space groups as symmorphic, hemisymmorphic, and asymmorphic: "The systems themselves are classified into three groups: 1) The symmorphic systems are those whose elementary figures belong to the same kind of symmetry as the systems themselves. 2) The hemisymmorphic systems are to be understood as two analogous symmorphic systems, which together form a regular double (not symmorphic) system. 3) All the rest are asymmorphic systems. From these definitions follows that each figure in a symmorphic systems possesses a point in which all the symmetry elements of the system intersect, that in the analogous point of a figure in a hemisymmorphic system only elements of rigid symmetries (i.e. symmetry of the 1st kind) intersect, and that such points are missing in figures of asymmorphic sytems" (Fyodorov quote translated from its German translation: Burckhardt 1967, p. 235). By mid-October 1890, he arrived at the number of 228 "regular systems of points" (space groups), which he corrected in November 1890, after correspondence with Schoenflies, to 230 (Burckhardt 1967, 1971, 1988; Nespolo et al. 2018).

Thus, in 1891, the first two independent, fully group theoretical classifications of symmetry groups were published:

Theorem 4 (Fyodorov-Schoenflies) The number of crystallographic space groups in three-dimensional space is 230.

Some authors add the British crystallographer **William Barlow** (1845–1934) to the list of three originators of Theorem 4, since in 1894 he published his own (predominantly geometric) proof of it (Barlow 1894). In response to criticism, he responded that he had no access to Fydorov's and Schoenflies's papers (Burckhardt

1967; Lalena 2007; Whitlock 1934). By the beginning of the twentieth century, group theory became generally used in studies on symmetries of crystals, as is exemplified, e.g., by the textbook *Mathematical Crystallography and the Theory of Groups of Movements* (Hilton 1963), originally published in 1903, which more or less follows the exposition of (Schoenflies 1891). In fact, for a long time, it was the only book presenting Schoenflies's, Fydorov's, and Barlow's theory in English, since Schoenflies and Barlow published their results in German, and Fyodorov in Russian (Lalena 2007).

Finally, it should be noted that in literature, the number of space groups is often given as 219, and not as 230. Namely, from the point of view of abstract algebra, space groups describing two enantiomorphic periodic objects have the same group structure, and even their elements are the same (possibly differing only in the direction of a screw rotation). This approach, in which two space groups are equivalent if they are isomorphic, results in only 219 types of three-dimensional space groups, named *affine* (*classes of*) *space groups* (Nespolo et al. 2018). Of those 219, 11 are chiral (can appear in two enantiomorphic "copies"), and since in the physical world (including crystallography, chemistry and physics, and even art) the handedness is a relevant characteristic, it is common to state the number as 230 in most texts dealing with the history or application of space group symmetry.

4 Space Groups in Lower and Higher Dimensions

After such an intense period of studies of three-dimensional symmetry groups, it is no wonder that ideas of generalizations appeared. As noted in the section on point groups, toward the end of the nineteenth century, mathematicians – namely, Goursat – first considered symmetries in four-dimensional space. Among the famous 23 problems posed in 1900 by **David Hilbert** (1862–1943), one is directly related to generalization of symmetry group theory to other dimensions: In the first part of his 18th problem, Hilbert comments that Fyodorov and Schoenflies have shown that there are only finitely many symmetry groups with a "finite fundamental region" (i.e., crystallographic space groups) for the three-dimensional Euclidean space and asks if the same is true for every n-dimensional Euclidean space (Hilbert 1900). That the answer is "yes" was proven 10 years later by the German mathematician **Ludwig Bieberbach** (1886–1982). Bieberbach first proved that for a symmetry group, having a "finite domain" (which in modern terms would be a compact fundamental domain, i.e., a unit cell as described above) is equivalent to not containing "infinitesimal operations" (i.e., to being discrete). Further, he proved various other results, in particular that n-dimensional crystallographic groups contain translations in n linearly independent directions. Finally, he showed that for every finite dimension n, there exist only finitely many (up to isomorphism) different discrete subgroups of $E(n)$, the group of all isometries of the n-dimensional Euclidean space (Bieberbach 1910). This theorem is the reason that space groups for spaces of dimensions higher than 3 are sometimes referred to as *Bieberbach groups*; more commonly, this term is reserved only for torsion-free crystallographic groups (Cid and Shulz 2001). A year

later, another German mathematician, **Ferdinand Georg Frobenius** (1849–1917), noted that instead of proving the finiteness of the classes up to isomorphism, it would be more adequate to classify crystallographic groups according to "affine equivalence" and proved the corresponding variant of Bieberbach's theorem. Again, a year later, Bieberbach showed that for crystallographic groups, "affine equivalence" is the same as isomorphism and thus finalized the proof of the following theorem (Burckhardt 1988; Vince 1997; Zassenhaus 1948):

Theorem 5 (Bieberbach-Frobenius' Theorem) The number of classes of affine equivalence of crystallographic space groups in $E(n)$ is finite for every positive integer n.

In particular, Bieberbach's and Frobenius's results showed that crystallographic space groups G contain a normal, torsion-free, maximal Abelian subgroup T (the translational subgroup) of rank n and finite index, and that the corresponding point group $P = G/T$ is isomorphic to a finite subgroup of GL(n, $\mathbf{Z}$). On the basis of this insight, H. Zassenhaus in 1948 developed a fully algebraic group-theoretical algorithm for classification of space groups in arbitrary dimensions, more precisely, an algorithm for calculating the set of representatives of their isomorphism classes (Cid and Schulz 2001; Streitwolf 1967; Zassenhaus 1948).

Zassenhaus exemplified his algorithm by showing that there are 17 space groups in dimension 2, a result proven before by geometrical methods. Namely, in the 1920s, space groups with one- and two-dimensional periodicity also caught the interest of mathematicians. The two-dimensional analog of crystal structures, i.e., two-dimensional periodic objects in the plane, are known as wallpapers, and the corresponding two-dimensional space groups are known as *wallpaper groups*. Even if the depiction of (clippings of) wallpapers is common in the long history of art, their classification according to symmetry was only proven along with its three-dimensional counterpart. Their symmetries were first studied by Sohncke in 1874, who erroneously determined that the total number of wallpaper groups was 13 (Burckhardt 1988; Sohncke 1874). Fyodorov, along with his classification of three-dimensional space groups, published the correct classification of 17 wallpaper groups (1891), but this remained mostly unknown for some time. Thus, the first classification is usually attributed to **György (George) Pólya** (1887–1985), who published an independent proof in 1924 which soon became widely known (Burckhardt 1988; Pólya 1924; Speiser 1927).

Toward the end of his article, Pólya writes (Pólya 1924, p. 282): "A particularly easy problem is the following: to count all possible symmetry structures of a bordure (ribbon, frieze); there are seven of them."[5] These are now known as seven *frieze groups* (see Fig. 12), with frieze being the standard term for subperiodic patterns in the plane, i.e., objects in Euclidean space of dimension 2 possessing translational

[5] *Eine besonders einfache Aufgabe ist die folgende: es sind alle verschiedenen Strukturen der Symmetrie einer Bordüre (Band, Fries) aufzuzählen; es gibt deren sieben.*

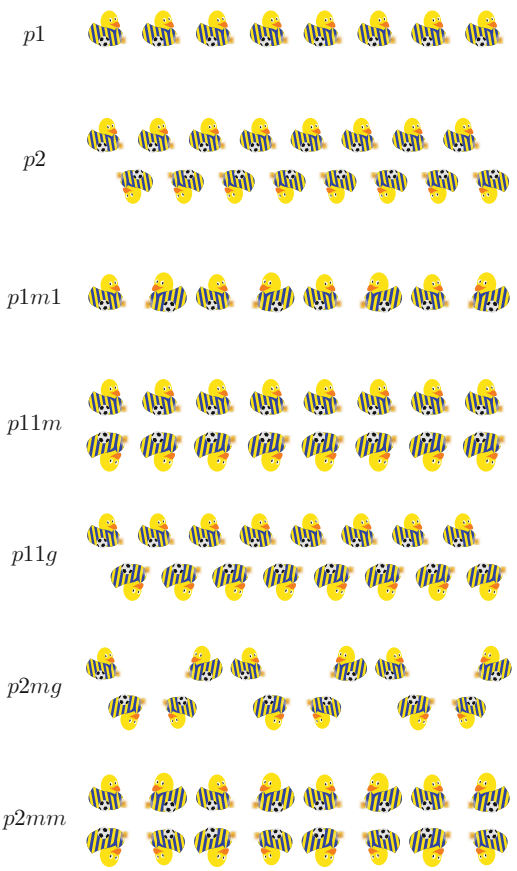

Fig. 12 Clippings from examples of seven frieze classes

symmetry in only one direction. A full proof of this fact was given by Swiss crystallographer **Paul Niggli** (1888–1953) in the same issue of the *Zeitschrift für Kristallographie* (Niggli 1924). According to (Burckhardt 1988, p. 141), in the period 1920–1923, A. M. Günzburg independently proved that there are seven frieze groups and 17 wallpaper groups, but he only published his results in 1929. Last, but not least, it is worth mentioning that Conway et al. (2008) arrive at the seven frieze groups as spherical symmetry groups by wrapping the friezes around a sphere.

To summarize the last two paragraphs:

Theorem 6 (Fyodorov-Pólya-Niggli) There exist 17 fully periodic and seven subperiodic space groups in dimension 2.

The three-dimensional equivalent of frieze groups, i.e., subperiodic space groups of objects in three-dimensional space with translational symmetry in only one direction, are known as *rod groups*. They were first, incompletely, studied in one

of the first influential textbooks on (finite) group theory, *Die Theorie der Gruppen von endlicher Ordnung, mit Anwendungen auf algebraische Zahlen und Gleichungen sowie auf die Kristallographie,* by the Swiss mathematician **Andreas Speiser** (1885–1970), which appeared in four editions. The sixth and seventh chapters in its second edition (Speiser 1927) are devoted to "Symmetries of ornaments" and "Crystal classes" and contain quite modern presentations of the mentioned results, and more. Besides giving the classification of frieze and wallpaper groups, Speiser considers friezes as reliefs, and by differentiating between mirror-symmetric copies with respect to the plane of the frieze, he arrived at an additional 24 space groups for "two-sided friezes," i.e., in total 31 frieze groups – 7 "one-sided" plus 24 "two-sided" (Burckhardt 1988; Speiser 1927). The full classification of rod groups was achieved in 1929, without reference to Speiser, but with reference to Niggli, by the German physicist and crystallographer **Carl Heinrich Hermann** (1898–1961): He showed that the number of rod groups, which he called chain groups (*Kettengruppen*), is 75 (Hermann 1929).

In general, space groups containing translations in only one direction (space groups of mono-periodic objects) are known as *line groups* (Damjanović and Milošević 2010). Even if, since antiquity, ornaments belonging to the class of friezes and all seven types of frieze symmetry were present in art (Jablan 2002), as described above, their mathematical classification did not happen until the twentieth century. Also, it is quite obvious that periodic "ornaments" on a line either have no other symmetry besides translation (e.g., — - - - - — - - - - — - - - -) or additionally possess mirror symmetries (e.g., – – – –), i.e., there are only two one-dimensional space (line) groups. As in the case of point groups in dimension 1, this seems to have been considered too trivial to merit a specific proof, and when mentioned in literature, it is stated without a specific reference, see e.g., Schwarzenberger (1984).

In three-dimensional space, one can also consider subperiodic space groups of biperiodic objects, i.e., of objects possessing translational symmetry in two (but not three) linearly independent directions. These are known as *layer groups* and were first classified in 1929 along with rod groups by C. H. Hermann, who called them net groups (*Netzgruppen*) and showed that there are 80 of them by systematically combining elements of symmetry. In the same year, the result was independently obtained by the Swiss crystallographer **Leonhard Weber** (1883–1968), who deduced them as special cases of Niggli's 1919 classification of space groups, which was based on the division of space groups into 73 *arithmetic crystal classes* (these are classes corresponding to the Fyodorov's 73 symmorphic space group types, usually defined as equivalence classes of ordered pairs of translational and point groups of periodic objects). Weber also noted that 17 of the 80 layer groups correspond to cases when the plane containing the pattern is itself a mirror-plane, i.e., there are 17 layer groups that correspond to "transparent" patterns, analogously to Speiser's "two-sided" friezes (Burckhardt 1988; Hermann 1929; Alexander and Hermann 1929; Heesch 1929; Nespolo et al. 2018; Pabst 1962; Schwarzenberger 1984; Weber 1929).

The study of space groups was also extended to higher dimensions. The above-mentioned Bieberbach's and Frobenius's results from the 1910s were the first step

toward a classification of n-dimensional crystallographic groups. A second important step is a suitable generalization of the crystallographic restriction, but that needed a few more decades. In general, for spaces of dimension n, the crystallographic restriction, i.e., the set of possible orders of rotational symmetry of an n-dimensional lattice, can be formulated as follows (Bamberg et al. 2003):

Definition 9 The *general crystallographic restriction* for dimension n (CR_n) is the set of all positive integers m for which an invertible matrix A of order with integer entries exists such that $A^m = I_n$ (the identity matrix of order n) and m is the smallest such integer.

The group-theoretical background of the definition is the following. For an element g in a group $(G,\cdot)$, the order of g, Ord(g), is defined as the smallest positive integer m such than $g^m = e$ (the identity element in the group), if such m exists (otherwise $\mathrm{Ord}(g) = \infty$ by definition). Thus:

$$CR_n = \{m \in \mathbf{N} : \exists A \in GL(n, \mathbf{Z})\ Ord(A) = m\}.$$

The classical crystallographic restriction can now be written in the form $CR_2 = CR_3 = \{1, 2, 3, 4, 6\}$. Also, quite obviously $CR_1 = \{1, 2\}$. The generalized crystallographic restriction was first studied in (Hermann 1949), even the first study of orders of invertible integer matrices was given in (Vaidyanathaswamy 1928). By extension of the number-theoretical method described by H. Hiller (Hiller 1985), who is one of several authors who independently discovered CR_n, one gets an efficient algorithm to compute $CR_n \setminus CR_{n-1}$, the additional possible orders when increasing the dimension for 1, for any n (Bamberg et al. 2003). Thus, it is known how to determine the values of CR_n for arbitrary n, and Table 2 contains the values for dimensions up to 11.

Even if such studies seem to be of purely abstract, mathematical interest, it has proven not to be so. The discovery of quasi-periodic crystals (usually referred to simply as *quasicrystals*) by Dan Schechtman and his colleagues in 1982, displaying many properties similar to crystals, but exhibiting "forbidden" axes of symmetry (e.g., of order 5) resulted in studies of possible models (Lifshitz 1996; Schechtmann et al. 1984). In the cases known to date, the exhibited rotational symmetry in

Table 2 The crystallographic restriction values for dimensions 1 to 11

N	CR_n
1	1, 2
2, 3	1, 2, 3, 4, 6

10, 11	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14, 15, 16, 18, 20, 21, 22, 24, 28, 30, 35, 36, 40, 42, 45, 48, 56, 60, 70, 72, 84, 90, 120

quasicrystals is either consistent with CR_3, or of one of the orders 5, 8, 10, or 12, consistent with CR_4 (Steurer 2018). A particularly often-used model is to describe quasiperiodic structures as projections of periodic ones from higher-dimensional spaces to dimension 3. Thus, for the description of currently known quasicrystals, space groups in spaces of higher dimensions than 6 do not seem necessary, but if, for example, a quasicrystal with rotational symmetry of order 11 would be discovered, the corresponding periodic model would (see Table 2) require a space of dimension at least 10 (Souvignier 2006; Stilinović and Brückler 2012).

In 1949, Hermann studied the possible elements of space groups for an arbitrary dimension (Hermann 1949), and by the turn of the centuries, a variety of results for dimensions up to 6 were proven (Janssen et al. 1999; Janssen et al. 2002). The final enumeration of four-dimensional space groups was achieved in the 1970s (with a small error) by H. Brown, R. Bulow, J. Neubüser, H. Wondratschek, and H. Zassenhaus. In that enumeration, one of the 4894 four-dimensional space groups was doubly counted, and this error was corrected in 2002. The error was related to the already mentioned distinction between chiral and achiral symmetry groups: Just as in three dimensions 11 of the 230 space groups appear as two enantiomorphic pairs each, and the total count is 219 if one does not distinguish enantiomorphic pairs, in dimension 4 there are 111 chiral groups, i.e., the total count is 4783 if one does not distinguish enantiomorphic pairs (Brown et al. 1978; Conway and Smith 2003; Neubüser et al. 2002).

The direct approach based on CR_n, however, seems unfeasible for higher dimensions since the number of space groups increases rapidly. To this effect, the original Zassenhaus algorithm was further refined, and then implemented by J. Opgenorth, W. Plesken, T. Schulz, and others as the CARAT (Crystallographic Algorithms and Tables) package in 2000 (Cid and Schulz 2001; Lehrstuhl B für Mathematik Aachen 2023; Opgenorth et al. 1998; Plesken and Schulz 2000). Using it, Plesken and Schulz arrived at 222,018 space groups in dimension 5, and 28,927,922 in dimension 6 (both not counting enantiomorphic pairs as different); the number for dimension 6 has later been corrected to 28,927,915 (Lehrstuhl B für Mathematik Aachen 2023). The distinction between enantiomorphic pairs was published by Souvignier in 2003, who arrived – correctly – at 79 chiral among the 222,018 five-dimensional space groups (making the total 222,097), and – erroneously due to old data from CARAT – at 7052 in dimension 6 (Souvignier 2003). The correct number of chiral space groups in dimension 6 is apparently still unknown at the present time, as are the numbers of space groups in higher dimensions.

5 Color Symmetry Groups

Besides the more abstract types of symmetries and symmetry groups in non-Euclidean spaces, which are outside the scope of this chapter, another type of Euclidean symmetry groups has been studied extensively during the last 100 years. Their study dates back to the papers written in 1929 and 1930 by German mathematician **Heinrich Heesch**

(1906–1985). His research began by investigating layer groups, inspired by Speiser's results, and he noted that the "two-sided" ("transparent") friezes and wallpapers can be interpreted as "normal" ones, but allowing coloring in two colors. Motivated by the idea of generalizations to higher-dimensional spaces, he writes (Heesch 1930a, p. 326): "This is the problem of extending the 17 Niggli's two-dimensional plane groups to the 80 three-dimensional ones, just as it is here about building up from the 230 three-dimensional R3 groups into four dimension."[6] Heesch begins with explaining that the step from 17 wallpaper to 80 layer groups can be achieved if we add a third coordinate to the plane of the ornament, but only use the sign (plus or minus) of that coordinate to discern between the mirror-symmetric copies, and comments that this can be viewed as being colored in two colors. He refers to Weber for the coloring representation, and to Speiser and Hermann for other ornamental representations of the additional coordinate. Furthermore, Heesch added a possible physical interpretation with positive and negative ions arranged in lattice points, thus essentially prophetically announcing future applications. Heesch successfully enumerated all three-dimensional "black-and-white" symmetry classes and arrived at now 122 "black-and-white" point groups in space, divided into the 7 usual crystal systems. These were rediscovered as part of Hurley's derivation of all crystallographic point groups in dimension 4 (Burckhardt 1988; Heesch 1930a; Hurley 1951; MacKay and Pawley 1963; Schwarzenberger 1984; Wills 2017; Zamorzaev 1988). In the follow-up paper (Heesch 1930b), Heesch also considered continuous and semidiscontinuous (meaning, continuous in some, discrete in other directions) symmetries, referring to the mentioned paper by C. Jordan and the paper (Shubnikov 1930), in which the future "father" of anti-symmetry, A. V. Shubnikov, first illustrated Speiser's 31 two-sided frieze groups. Belov later noted that the derivation of these groups becomes easier if instead of being monocolored and two-sided, the friezes are considered to be one-sided and two-colored (Belov 1956; Pabst 1962).

At Heesch's time, the idea did not seem to have possible applications, but – as often with mathematical theories – it has proven otherwise two decades later. It was the Soviet mathematician **Alexei Vasilievich Shubnikov** (1887–1970) who in 1951 brought the "black-and-white" symmetry groups into prominence for crystallography in his monograph *Симметрия и антисимметрия конечных фигур* (*Simmetriya i antisimmetria konechnykh figur*) (Bradley and Cracknell 1972; Shubnikov 1951). He developed the concept of *anti-symmetry* "as a tool to understand the spatial anisotropy of a crystal's physical properties, following in the direction laid by Curie" (Wills 2017, p. 152). According to Shubnikov, for a three-dimensional periodic structure an additional, two-valued (black/white, +/−, parallel/anti-parallel magnetic moment, . . .) coordinate is considered in every point, and the anti-symmetry operation is defined as changing the value of this coordinate in all points. He re-derived Heesch's result and showed that there are 32 "colorless" point groups (i.e., the usual crystallographic ones), 32 "grey" point groups (here every

[6] *Es ist dies das Problem der Erweiterung der 17 Nigglischen zweidimensionalen Ebenengruppen zu den 80 dreidimensionalen, so, wie es sich jetzt darum handelt, die 230 dreidimensionalen R3-Gruppen zur Gesamtheit der vierdimensionalen auszubauen.*

symmetry operation occurs both with and without antisymmetry, i.e., they are invariant under antisymmetry), and 58 "black and white" point groups (where some anti-symmetry operations are combined with some symmetry operations), in total 122 (Wills 2017; Zamorzaev 1988). Later, Shubnikov also extended the Hessel's list of point groups in dimension 3 by considering "limiting symmetry groups," i.e., two-colored point groups of objects possessing rotational axes of infinite order. The colorless version is often called *Curie limiting groups*, as it was Pierre Curie who first investigated them (Curie 1894; Shubnikov 1988a). There are seven Curie limiting groups (Fig. 13), which arise as limits of the point groups from Hessel's theorem: C_∞ (the symmetry group of a circular cone rotating in one direction), D_∞ (the symmetry group of a twisted circular cylinder), $C_{\infty h}$ (the symmetry group of a rotating cylinder), $C_{\infty v}$ (the symmetry group of a cone at rest), $D_{\infty h}$ (symmetry group of a cylinder at rest), $K_h = O$ (the symmetry group of a sphere), and $K = SO$ (symmetry group of a sphere without planes of reflection, i.e., such that all its diameters are twisted in the same direction) (Artin 1991; Curie 1894; Shubnikov 1988a). By adding the antisymmetry feature, Shubnikov arrived in 1988 to 14 *limiting antisymmetry point groups*, more precisely to seven gray and seven black-and-white ones. Together with the seven Curie groups, it makes 21 two-colored limiting point groups (Krishnamurty and Gopalakrishnamurty 1969; Palistrant 2005; Shubnikov 1988a, 1988b).

Shubnikov's (and Heesch's) ideas were extended to space groups by Soviet mathematician, **Alexander Mihailovich Zamorzaev** (1927–1997), in his PhD thesis in 1953, who found in total 1651 "generalized Fyodorov groups," divided into four classes – colorless, gray, black and white point groups with colorless Bravais lattices, and black and white point groups with black and white Bravais lattices (Burckhardt 1988; Litvin 2016; Wills 2017). They were also enumerated by Belov, Neronova, and

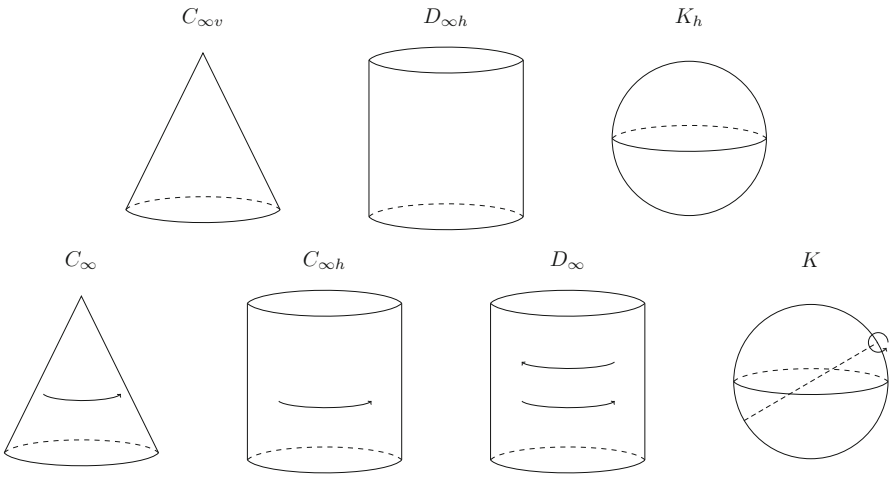

Fig. 13 Examples of solids belonging to symmetry classes of the seven Curie limiting groups (arrows indicate directions of rotations or twists)

Smirnova in 1957 and by Opechowski and Guccione in 1965. These groups became known as *Shubnikov groups* (so they were called, e.g., by Zamorzaev) or *magnetic space groups*, but also as *Heesch groups*, *Opechowski-Guccione groups, dichromatic, 2-color* or *black-and-white groups*. Shubnikov, on the other hand, called them *type III groups* (Ш is the Russian letter with pronunciation "sh"), and as Ш was often typeset as III in later works, the three subtypes became known as type I (colorless), type II (gray), and type III (black-and-white) groups (Bradley and Cracknell 1972; Lifshitz 2005; Wills 2017). The term magnetic groups was used by B. A. Tavger and V. M. Zaitsev, who described the magnetic structure of MnO, using antisymmetry as an operation that reverses atomic magnetic moments or electron spins (Wills 2017). Tavger and Zaitsev also tabulated the magnetic point groups, while the 1651 magnetic space groups (230 colorless, 230 gray, and 1191 black and white) were derived by a different method than Zamorzaev's by Belov, Neronova, and Smirnova in 1955, who called them Shubnikov groups (Bradley and Cracknell 1972; Burckhardt 1988; Tavger and Zaitsev 1956; Senechal 1988; Wills 2017; Zamorzaev 1988). The study of magnetic space groups has more recently been extended to higher dimensions too, and related to quasicrystals (Lifshitz 2005).

Another development, this time directly from art, simultaneously inspired the interest in color symmetry groups. It was the work of Dutch artist **Maurits Cornelis Escher** (1898–1972), whose many depictions of periodic tessellations of the plane started to be subject to mathematical analysis at the time. In particular, his usage of color symmetry attracted attention during the 1960s, and its value as teaching aids became recognized in the crystallographic community too (Senechal 1983, 1988). Soon the ideas were generalized to more than two colors, to multiple antisymmetry, to *P*-symmetry, to spin groups (with spins viewed as classical axial vectors which are free to rotate in all directions), and to arbitrary dimensions.

The first ideas on extensions of the described antisymmetry to a more general, multiple one, were considered by Shubnikov already in 1944 (but not mentioned in his 1951 monograph). They were further developed by Zamorzaev and others in the 1970s, and "the theory of simple and multiple antisymmetry is actually completed, the only thing left is to develop new methodical techniques for the purpose of its further incorporation into natural sciences" (Zamorzaev 1988, p. 558), such as S. V. Jablan's method of generating groups of simple and multiple symmetry types using his "antisymmetry characteristic" (Jablan 1986). Also, in the 1970s, the idea of spin groups was studied by Litvin, Opechowski, and others (Lifshitz 2005), while Zamorzaev and his group in about the same time generalized both antisymmetry and color symmetry to *P*-symmetry (Jablan 1994; Lungu 2002).

One of the first attempts of considering more than two colors appeared already in 1956, when N. V. Belov and T. N. Tarhova published a paper on "Groups of color symmetry." The definition was fully clarified, and the subject was theoretically founded in 1961 in a short paper called *Farbgruppen* by B. L. van der Waerden and J. J. Burckhardt (Jablan 2007; Schwarzenberger 1984; Van der Waerden and Burckhardt 1961; Zamorzaev 1988). Their definition is essentially the following:

Definition 10 Let S be a discrete set of points (or more general motifs), where each point $x \in S$ has an additional property ("color") $f(x)$ from a finite set F, i.e., a *coloring* $f: S \to F$ is given. We speak of a *colored set* S_F. The *color symmetry group* of S_F is the group of all ordered pairs (T, P), where T is an element of the symmetry group G of S and P a permutation of F, such that $fT = Pf$.

Van der Waerden's and Burckhardt's paper became the basis of much of the further research in the field (Senechal 1983). By now, the research of color symmetry groups is a rich field of study. Besides the fully periodic color groups in various dimensions, subperiodic have been studied as well, and applications in the study of quasicrystals have been discovered too (Lifshitz 1997; Litvin 2005; Palistrant 2000; Palistrant and Jablan 1994; Souvignier 2006).

6 Conclusion

Even if the oldest evidence of human interest in symmetry are related to art, and even if Euclidean geometry was already highly developed in Ancient Greece, the mathematical study of symmetrical patterns arose less from artistic interests or purely mathematical considerations: It was in most part inspired by the development of crystallography at the end of the eighteenth and the beginning of the nineteenth centuries. When the initially purely geometric approaches were integrated with the simultaneously, but independently, developed branch of group theory, the study of symmetry groups emerged. At first serving the purpose of classifying crystals according to symmetry, at the beginning of the twentieth century, it began a life of its own. Many aspects of this were described in the text above, others were omitted.

Of the omitted ones, two deserve a special mention. The scope of this exposition was limited to symmetry in Euclidean spaces, but symmetry group research was also, in the second half of the twentieth century, extended to non-Euclidean spaces (Wilkie 1966). Also, one of the most important applications of symmetry groups is in theoretical physics. Its beginnings date to Pierre Curie and his "symmetry principle," introduced in 1894 and related to the mentioned discovery of limiting groups. Curie says: "The elements of the symmetry of the causes are to be found in the effects they produce"[7] (Curie 1894, p. 394). A crucial moment regarding applications of symmetry group theory in physics was Emmy Noether's first theorem (1915/1918), which established the connection between symmetries of physical systems and the conservation laws. Readers interested in the history of this line of impact of symmetry group theory are kindly referred to (Kosmann-Schwarzbach 2018).

In the beginning, there were friezes (on temples and otherwise), which exemplify human age-old fascination by symmetry. Now, at the end of this time-travel through the history of Euclidean symmetry groups, there are quasicrystals, for which many facts – on symmetry and more – are yet to be discovered.

Abstract

In this essay we give a general picture about the evolution of Grothendieck's ideas regarding the notion of space. Starting with his fundamental work in algebraic geometry, where he introduces schemes and toposes as generalizations of classical notions of spaces, passing through tame topology and ending with the formulation of a geometry of forms, we show how the ideas of Grothendieck evolved from pure mathematical considerations to physical and philosophical questions about the nature and structure of space and its mathematical models.

Keywords

Schemes · Toposes · Tame spaces · Geometry of forms · Grothendieck

1 Introduction

Alexander Grothendieck is one of most influential mathematicians of the last century and it is not difficult to argue that is one of the most influential through the history of mathematics. The reach and depth of Grothendieck's work have been extensively discussed in many places, see for instance (Cartier 2001; Lochak and Schneps 1997; Zalamea 2019) and the bibliography therein. Our goal is more modest since we do not pretend to cover fully Grothendieck's ideas but just focus on a specific, but central part of his work, namely the notion space (Since this text is thought for a general audience including mathematicians, philosophers, philosophers of mathematics, and, in general, anyone interested in the history and philosophy of the notion of space in the grothendieckean work, we will avoid the technicalities and will privilege a conceptual approach.).

It is very clear, even in a superficial reading of Grothendieck's work, that the search of an adequate definition of the notion of space is a leitmotif for Grothendieck, from the very beginning of his mathematical career when he was interested in nuclear spaces to the last mathematical reflections in the 1980s when he tried to develop a geometry of forms as a new foundations for topology and the physical space (It is known that during his retirement in Lasserre since 1991 until his death, Grothendieck wrote extensively about different topics and it would be plausible to think that one of these topics was the notion of space. However, this is a mere speculation, so for the purpose of this text, we do not take into account that period.), passing through his monumental work in algebraic geometry.

The question *What is a space?* has been one of the main questions the human being has asked since the ancient times. Many philosophers, natural philosophers (We will use the expression *natural philosopher* as it was understood in seventeenth and eighteenth century.), and mathematicians have tried to give an answer (There is no point to make an extensive list of the people who have been interested in the problem of the space but this list should include people like Plato, Aristotle, Archimedes, Leibniz, Newton, Riemann, and Einstein, just to mention some outstanding examples. Clearly Grothendieck follows this line.) and even though we have now a better understanding of the problem we are still far from a definitive answer. The question is hard since it involves not only mathematics but also physics and philosophy. This was cleverly noted by Grothendieck in the 1980s (Of course, Grothendieck was not the first one who notes this. However, we want to emphasize that Grothendieck realized the importance of philosophy and physics as complements of the mathematical approach to the notion of space, since traditionally the studies on Grothendieck's work have not paid attention to this aspect. On the contrary, it is usually believed that Grothendieck was not interested at all in the physical and philosophical aspects of the notion of space, and this is partially true, if we only focus on Grothendieck's ideas before the 1980s. Nevertheless, his mind changed a lot, regarding physical and philosophical issues, and this is one of the points we want to discuss in this essay.) and we will return to this point later in this text.

In fact, in (Grothendieck n.d.) Grothendieck writes about the notion of space:

> "*'La notion d' 'espace' est sans doute une des plus anciennes en mathématique. Elle est si fondamentale dans notre appréhension 'géométrique' du monde, qu'elle est restée plus ou moins tacite pendant plus de deux millénaires. C'est au cours du siècle écoulé seulement que cette notion a fini, progressivement, par se détacher de l'emprise tyrannique de la perception immédiate (d'un seul et même 'espace' qui nous entoure), et de sa théorisation traditionnelle ('euclidienne'), pour acquérir son autonomie et sa dynamique propres. De nos jours, elle fait partie des quelques notions les plus universellement et les plus couramment utilisées en mathématique, familière sans doute à tout mathématicien sans exception. Notion protiforme d'ailleurs s'il en fut, aux cents et mille visages, selon le type de structures qu'on incorpore à ces espaces, depuis les plus riches de toutes (telles les vénérables structures 'euclidiennes', ou les structures 'affines' et 'projectives', ou encore les structures 'algébriques' des 'variétés' de même nom, qui les généralisent et qui assouplissent) jusqu'aux plus dépouillées: celles où tout élément d'information 'quantitatif' quel qu'il soit semble disparu sans retour, et où ne subsistent plus que la quintessence qualitative de la notion de 'proximité' ou de celle de 'limite', et la version la plus élusive de l'intuition de la forme (dit 'topologique').*"

Following Deligne (Deligne 2020) we can think of a space as something for which *localization* makes sense. In this approach the key word is *localization*. Thus, the question *What is a space?* might be replaced by *What does localization mean?*. Along this essay we will try to show how Grothendieck approached this question. The basic idea of localization, the one Deligne had in mind, is exemplified by the following situation (This example is due to Deligne who wrote it to the author in (Deligne 2020).): Let X be a topological space. In order to define a continuous function $f: X \to \mathbb{R}$, it suffices to define it on open subsets $\mathcal{U}_i$ covering X and to check the agreement on two by two intersections. This way the notion of continuous function is defined by localization on X.

In the example above there are two important points that play an important role in the grothendieckean notion of space. The first one is the absence of points, replaced by another thing, in the example by open sets, and the second one is that those open sets cover the whole thing. It has been remarked in other places (see Cartier 2001) how problematic the notion of point could be in order to understand what a space is. One of the main features in the several generalizations Grothendieck proposes for the notion of space is that for Grothendieck the space is not made by points. Points are just marks that can be put on the space but not its fundamental elements. On the other hand, the idea of covering is essential in order to understand the relation between the local and the global aspects of the space and it also will be important in the discussion between the continuum and the discrete in Grothendieck's geometry of forms as we will see later.

1.1 A Brief Biographical Note

We will give a very short review of Grothendieck's life. More detailed accounts can be found in (Cartier 2001; Jackson 2004; Scharlau 2010; Zalamea 2019) (We include

this brief note in order to give the reader an idea of Grothendieck's particular life and shed light on how his personality as mathematician, and more general as human being, was formed.). Alexander Grothendieck was born in Berlin on March 28, 1928 to Alexander Schapiro and Hanka Grothendieck, both were active political militants. Due to the activities of his parents, Grothendieck lived nearby Hamburg (The years in Hamburg had a big impression in Grothendieck. We were informed by Winfried Scharlau (Scharlau 2020) that Grothendieck visited Hamburg around 2006. He knew this by some local people that informed him on the visit. In some sense, it seems that Grothendieck was recollecting his own steps.) under the tutelage of the family of a protestant priest until 1939 when he met his family (Grothendieck's parents took part in the Spanish Civil War enrolled in the anarchist militias.). However, his father was taken prisoner in the concentration camp Le Vernet and then deported to Auschwitz where he died and Alexander and his mother were sent to the camp Rieucros. This compromise of his parents with political issues was very influential in Grothendieck's point of view, both mathematical and nonmathematical.

From 1945 to 1948 Grothendieck studied mathematics at Montpellier. In Récoltes et Semailles (Grothendieck n.d.) he recollects the years in Montpellier and how in solitude developed a measure theory close to the one developed by Lebesgue many years ago. This episode marked his life as mathematician. As Grothendieck wrote (see Grothendieck n.d.) thanks to this he learnt the importance of solitude in the work of a mathematician. A solitude that accompanied him his whole life beyond mathematics.

In 1949 Grothendieck arrived to Paris to Cartan's seminar at the École normale supérieure. This was an important turn on Grothendieck's mathematical education, since he moved from the border (Montpellier) to the center of French mathematics (Paris). In Paris and Nancy, where he wrote his doctoral dissertation under Jean Dieudonné and Laurent Schwartz, Grothendieck could show his enormous mathematical talent. After this, he spent time as postdoctoral researcher in Sao Paulo and Kansas.

During his time in Kansas in 1955 Grothendieck's work took an important turn since he left analysis and started a new mathematical road in (algebraic) geometry. It is in this stay when he wrote the main ideas of his work in abelian categories (This work is known as *Tôhoku* because of the journal where it was published.) and also he started to work in his version of the Riemann–Roch theorem. Thus, his monumental reconstruction of algebraic geometry started and, even more, his quest of an adequate definition of the notion of space really started in an explicit way.

Since 1958 until 1970 Grothendieck occupied a position at IHES. With Dieudonné as his scribe, Grothendieck wrote the giant treatise *Elements of Algebraic Geometry* (EGA) and ran his celebrated *Seminar of Algebraic Geometry* (SGA). Grothendieck was positioned as the main expert in algebraic geometry in the world and won the Fields medal in 1966 for his fundamental work. During this time he introduced many important concepts (schemes and toposes among others) in order to carry out his program of providing a vast generalization of the notion of space.

Despite the success of his seminar and the fruitful years at the IHES, Grothendieck resigned his position in 1970 arguing ethical reasons because the founding the IHES

was receiving from the military agency (This is the universal accepted reason on Grothendieck's resignation to the IHES. However, some authors (see (Ruelle 2007), for instance) believe that there could be deeper reasons behind Grothendieck's demission.). After being involved in ecological activities in the group *Survivre et vivre* he moved back to Montpellier and took one position as professor. It is argued that Grothendieck left mathematics after his departing of IHES since he ceased any mathematical publication but this is far from being true. Certainly Grothendieck abandoned the establishment but this does not mean that he abandoned mathematics. In fact, many important Grothendieck's ideas were developed during the late 1970s and the beginning of the 1980s when he was in Montpellier.

In order to have an idea of Grothendieck's mathematical interests during the 1980s, it is good to see (Grothendieck 1997). This influential text (It is known the story on how Voevodsky, being a student in Moscow, started to learn French just to read Grothendieck's Esquisse. Certainly this reading was very important in Voevodsky's career.) contains the main ideas of Grothendieck after his reconstruction of the algebraic geometry. There we can find discussions about moduli spaces of Riemann surfaces and the Teichmüller tower, tame topology (another approach to a generalization of the notion of space), children drawings, and anabelian geometry. This text condensed many of the mathematical thoughts written in manuscripts that widely circulated between the mathematical community.

It is interesting to note, however, that some ideas concerning the geometry of forms that will be important for us, in the sense that they constitute an important grothendieckean approach to the notion of space and its relations with physics and philosophy, written in an relatively unknown manuscript (Grothendieck 1986), are not discussed at the Esquisse. These ideas were really important for Grothendieck as we can see from this extract of a letter sent to Tsuji on July fourth 1986:

> "*Excusez-moi d'avoir laissé passer quelques jours avant de répondre à votre lettre précédente - depuis près d'un mois je suis lancé sur un nouveau thème mathématique. Des nouveaux fondements de la topologie, dans un esprit très différent de celui de la topologie générale - j'ai envie d'appeler cette nouvelle topologie 'géométrie des formes' ou 'analysis situs', et il est bien possible que ce sera là le premier texte mathématique que je publierai, après mon départ de 1970 (et avant les divers textes prévus, que j'annonce dans l'introduction à Récoltes et Semailles).*"

Aside from the mathematical texts, Grothendieck wrote in the 1980s other general texts of great interest. His long text Récoltes et Semailles is a jewel in the whole sense of the word. There Grothendieck not only explored his past as mathematician but also discussed the intricate aspects of mathematical creativity and the ethics of a mathematician. In La clef des songes, Grothendieck analyzed his dreams and arrived to a personal discovering of God.

In 1991 Grothendieck decided to move to Lasserre and only kept contact with few people. During this time he wrote extensive texts about different topics, but it is still a mystery the exact content of the thousands of pages he wrote in his isolation. He passed away on November 13, 2014, at Saint-Girons, leaving behind him a big legacy for the future generations.

2 A Walk Around Algebraic Geometry

In this section we will discuss two generalizations of the notion of space that Grothendieck proposed as part of his program of reconstruction of algebraic geometry. Those generalizations are the notion of scheme and topos. These two concepts are central in Grothendieck's work, and particularly relevant if one wants to understand Grothendieck's idea of space. In (Grothendieck n.d.) Grothendieck examined his more important contributions in mathematics and regarding toposes and schemes he writes:

> "*Parmi ces thèmes, le plus vaste par sa portée me paraît être celui des topos, qui fournit l'idée d'une synthèse de la géométrie algébrique, de la topologie et de l'arithmétique. Le plus vaste par l'étendue des developpements auxquels il a donné lieu dès à present, est le thème des schémas. C'est lui qui fournit le cadre 'par excellence' de huit autres parmi ces thèmes envisagés, en même temps qu'il fournit la notion centrale pour un renouvellement de fond en comble de la géométrie algébrique, et du langage algébrico-géométrique.*"

It is clear from this quote the unifying role played by schemes and toposes inside Grothendieck's mathematical vision. Thus, these two concepts allow to study not only topological or geometric aspects of the space but also algebraic and arithmetic ones. Here, we would like to emphasize that from the very beginning Grothendieck's idea of space involve a particular entity of arithmetic and geometric nature. That is what Zalamea (2019) calls the space-number (In (Cruz Morales Submitted) we associate Zalamea's idea of the space-number to the idea of form in Grothendieck. We will go back to this point later in this text, since it is important in this discussion about the notion of space.) in analogy with the space-time in physics. We agree with Zalamea's interpretation, so we believe we need to understand Grothendieck's idea of space in terms of his idea of merging arithmetic and topology/geometry (This is a manifestation of the duality discrete/continuum. When we discuss Grothendieck's ideas of the space coming from his work in the 1980s, this dichotomy will be clearer. Now, it is interesting to notice that some mixed discrete/continuum structure for the space is present in Grothendieck's first works in algebraic geometry, at least in an implicit way, and it will be more relevant when Grothendieck tries to think in the physical space.). Therefore, schemes and toposes can be seen as the first instances of the space-number that Grothendieck had in mind.

2.1 Schemes: Generalizing Algebraic Varieties

In his ICM talk in 1958 (Grothendieck 1958) Grothendieck introduced his vast program of generalization of algebraic geometry that took him the next decade. During his years at the IHES he dedicated his life (Grothendieck's capacity of work is legendary. It is said that he could spend until 12 h of continuous work.) to develop these ideas. One of the central notion he introduced is the notion of scheme and for us this is important since it is his first generalization of the notion of space.

As it is discussed in (Deligne 1998; Zalamea 2019) Grothendieck's intrepid idea is to accept that for every commutative ring A (with unit) it is possible to define an affine scheme $X = \mathrm{Spec}(A)$. What is needed here is to define the structure sheaf $\widetilde{A}$. In this case, the structure sheaf is the sheaf of rings over X with a basis of open sets $\{x \in X : f(x) = [f]_x \neq 0\}$ with $f \in A$ and with fibers the local rings A_x with $x \in X$. Thus, considering a ringed space, i.e., a pair $(X, \mathcal{O}_X)$ with X a topological space and $\mathcal{O}_X$ a sheaf of rings over X, we say that it is an affine scheme if it is isomorphic to $\left(\mathrm{Spec}(A), \widetilde{A}\right)$. A general scheme is defined by gluing affine schemes.

Note that in the definition above the points of a scheme are not relevant. The important thing is that a scheme is an object where we can make *localization*, in the sense we discussed before. Thus, a scheme is a space of algebraic geometric nature that generalizes the notion of algebraic variety. Indeed, Grothendieck characterized the notion of scheme as a metamorphosis of the notion of algebraic variety (see Grothendieck n.d.). The use of the word metamorphosis is interesting, since it suggests a natural transformation (Naturalness is important for Grothendieck. In his view, mathematical concepts must be natural, in contrast to artificial and intricate constructions.) from the notion of algebraic variety to that of scheme.

About naturalness of the notion of scheme, Grothendieck wrote in (Grothendieck n.d.).

> "*La notion de schéma est la plus naturelle, la plus 'évident' imaginable, pour englober en une notion unique la série infinie de notions de 'variété' (algébrique) qu'on maniait précédemment.*"

And also in the same text adds

> "*L'idée même de schéma est d'une simplicité enfantine - si simple, si humble, que personne avant moi n'avait songe à se pencher si bas. Si 'bébête' même, pour tout dire, que pendant des années encore et en dépit de l'évidence, pour beaucoup de mes savants collègues, ça faisait vraiment 'pas sérieux'! Il m'a fallu d'ailleurs des mois de travail serré et solitaire, pour me convaincre dans mon coin que 'ça marchai' bel et bien.*"

It is clear that the notion of scheme is for Grothendieck the natural way in which the notion of algebraic variety should evolve, but also he noticed that the notion was always there, but it was needed to have the right eyes (his eyes in this case) to see it. Grothendieck was interested in capturing in one notion the multitude of varieties that arise when we work over prime characteristics. Again, the dichotomy discrete/continuum is present here. This is the fundamental aporia associated to the notion of space and Grothendieck started to struggling with it by introducing the idea of scheme. However, the notion of space is richer than that of algebraic variety and Grothendieck knew that.

2.2 Toposes: Spaces Without Points

At this point we have just discussed a restricted idea of space since we have considered only those spaces that are algebraic varieties and look at their

metamorphosis in the idea of scheme. However, for Grothendieck the space is something more general and, in this sense, the notion of scheme is not enough to capture the subtleties of space. Thus, it is necessary to go beyond algebraic geometry and entering in the realm of topology. The right notion to start doing that is the notion of topos.

In order to understand what a topos is we need to start with the idea of site. Here we will follow the description in (Zalamea 2019). Let us consider a category $\mathcal{C}$ and let us define a topology on it. For any object X of $\mathcal{C}$ it is possible to define a set of sieves $J(X)$ (A sieve can be identified with subobjects of the dual category.) satisfying some axioms, namely:

1. For any object $X \in \mathcal{C}$, any sieve $R \in J(X)$ and any morphism $f : Y \to X \in \mathcal{C}$, the sieve $R \times_X Y$ is in $J(Y)$.
2. For any sieves of X, R, and R', if $R \in J(X)$ and for any $Y \to R$, $R' \times_X Y \in J(Y)$, then $R' \in J(X)$.
3. For any object X of $\mathbb{C}$, $X \in J(X)$.

A category $\mathcal{C}$ endowed with a topology that satisfies 1, 2, and 3 is called a site. We focus on the idea of site since it allows us to illustrate Deligne's point that a space is something where localization makes sense. However, a site is just the first germ in the generalization of topological spaces that Grothendieck had in mind. Then, what is needed to be considered is a sheaf over a site.

Thus, a topos (In this text, we use the word topos in order to refer Grothendieck topos. There is a more general definition of topos (elementary topos) due to Lawvere but we do not consider it here.) is the category of all sheaves on a site. Therefore, a topos can be seen as a generalized space. Like schemes that can be seen as a metamorphosis of the idea of algebraic variety, a topos can be seen as a metamorphosis of the idea of topological space. Again, the word metamorphosis is quite accurate, since it allows to see how toposes arise as a natural deformation of the classical idea of topological space (We will see later that this metamorphosis does not stop in the notion of topos and will take another forms in terms of moderate topology and geometry of the forms.).

Grothendieck introduced the idea in order to deal with cohomology theories in algebraic geometry, and in particular, toposes play an important role in Grothendieck's approach to Weil conjectures. This way, toposes also arise as an important objects in problems of arithmetic nature. Again, it is possible to see that for Grothendieck the notion of space is something beyond purely geometric/topological considerations and it is central in whole mathematics. In (Grothendieck n.d.), Grothendieck points out:

> "*Celle de topos constitue une extension insoupçonnée, pour mieux dire, une métamorphose de la notion d'espace. Par là, elle porte la promesse d'un renouvellement semblable de la topologie, et au delà de celle-ci, de la géométrie. Dès à présent d'ailleurs, elle a joué un rôle crucial dans l'essor de la géométrie nouvelle (surtout à travers les thèmes cohomologiques ℓ-adique et cristallin qui en sont issus, et à travers eux, dans la démonstration des conjectures de Weil).*"

In the same text Grothendieck adds:

> "*C'est le thème du topos, et non celui des schémas, qui est ce 'lit', ou cette 'rivière profonde', où viennent s'épouser la géométrie et l'algèbre, la topologie et l'arithmétique, la logique mathématique et la théorie des catégories, le monde du continu et celui des structures 'discontinues' ou 'discrètes'. Si le thème des schémas est comme le coeur de la géométrie nouvelle, le thème du topos en est l'enveloppe, ou la demeure. Il est ce que j'ai con'çu de plus vaste, pour saisir avec finesse, par un même langage riche an résonances géométriques, une 'essence' commune à des situations des plus éloignées les unes des autres, provenant de telle région ou de telle autre du vaste univers des choses mathématiques*."

From the last quote it is very clear that for Grothendieck the notion of space, with its avatar in the notion of topos, is ubiquitous and central in mathematics (The notion of topos is, in certain sense, marginal in mathematics nowadays. However, recent works of Alain Connes and his collaborators (see (Connes and Consani 2014), as an example) have brought new life to the idea of topos and we believe this concept will play a central role in major mathematical problems like the Riemann hypothesis, for instance.) and adequate device to study in a unified way arithmetic and geometry, a place where discrete and continuous structures can live together in harmony.

So far, we have seen a generalization of the notion of space running in two steps. First one corresponding to the notion of scheme and the second one corresponding to the notion of topos. This two-steps generalization occurs inside the domain of algebraic geometry which was the main object of Grothendieck's reflections between 1958 and 1970. Thus, starting with the natural spaces in algebraic geometry, i.e., algebraic varieties, Grothendieck tried to find an archetypical structure for the space in the notion of topos. However, as we will see below the notion of topos does not constitute the final step in Grothendieck's thoughts related to the notion of space. There are other aspects to be considered and the idea of going beyond the notion of topos will dominate Grothendieck's work during the 1980s.

3 Searching for New Foundations: Tame Topology

Around the middle of the 1980s Grothendieck wrote an interesting text (Grothendieck 1997) detailing several research programs he was thinking during the 1970s, after his retirement from the mathematical milieu, which he considered would play an important role in the future mathematical research. One of these programs concerns to the development of the so-called tame topology, a new foundations for topology. In Grothendieck's words (see Grothendieck 1997):

> "*I would like to say a few words now about some topological considerations which have made me understand the necessity of new foundations for 'geometric' topology, in a direction quite different from the notion of topos, and actually independent of the needs of so-called 'abstract' algebraic geometry (over general base field and rings). The problem I started from, which already began to intrigue me some fifteen years ago, was that of defining a theory of 'dévissage' for stratified structures, in order to rebuild them, via a canonical process, out of 'building blocks' canonically deduced from the original structure*."

Here, in this quote, we see how Grothendieck wanted to propose a new setting that goes beyond the idea of topos and, in fact, beyond algebraic geometry. As we have seen, the origin and the development of the notion of topos is linked to the development of algebraic geometry in the setting Grothendieck envisioned during the 1960s, so the notion of space developed during this period. Nevertheless, Grothendieck realized that in order to capture the essence of the space is necessary to considered a more general picture. Thus, with his idea of tame topology, the notion of space in Grothendieck started to be independent of the algebraic-geometric origin of Grothendieck's first approach.

Grothendieck chose an axiomatic approach in order to understand what a tame space could be. In his words:

> "*My approach toward possible foundations for a tame topology has been an axiomatic one. Rather than declaring (which would indeed be a perfectly sensible thing to do) that the desired 'tame spaces' are no other than (say) Hironaka's semianalytic spaces, and then developing in this context the toolbox of constructions and notions which are familiar from topology, supplemented with those which had not been developed up to now, for that very reason, I preferred to work on extracting which exactly, among the geometrical properties of the semianalytic sets in a space* $\mathbb{R}^n$*, make it possible to use these as local 'models' for a notion of 'tame space' (here semianalytic), and what (hopefully!) makes this notion flexible enough to use it effectively as the fundamental notion for a 'tame topology' which would express with ease the topological intuition of shapes*."

Even though, as Grothendieck wrote, a tame space is not a semianalytic space, it is illustrative, in order to understand the idea Grothendieck had in mind, to discuss a bit the notion of semianalytic set, since Grothendieck did not provide an explicit definition of tame space in (Grothendieck 1997).

Let M be a real analytic manifold and consider a subset X of M, the X is called semianalytic if each $a \in M$ has a neighborhood $\mathcal{U}$ such that $X \cap \mathcal{U} \in S(\mathcal{O}(\mathcal{U}))$, where $\mathcal{O}(\mathcal{U})$ denotes the ring of real analytic functions on $\mathcal{U}$ and $S(\mathcal{O}(\mathcal{U}))$ denotes the smallest family of subsets of $\mathcal{U}$ containing all $\{f(x) > 0\}, f \in \mathcal{O}(\mathcal{U})$, which is stable under finite intersections, finite unions, and complement.

Without a precise definition, but using the notion of semianalytic space as local model, it is possible to see that the new tame spaces fit in the general definition of space we have assumed following Deligne. However, there is an important point in the origin of the idea of tame spaces that it did not appear in the previous notions of scheme and topos. When Grothendieck formulated the idea of tame space he was thinking in a right framework to deal with the notion of geometrical shape. Thus, the main motivation here is to develop a notion of space that allows us to study the geometric properties of shapes (In the next section we will see that with the same motivation of understanding the elusive idea of form (being geometrical shapes just one instance of this archetypical notion), Grothendieck was beyond tame spaces and proposed the so-called geometry of forms.). This point is very clear from this quote (see Grothendieck 1958):

> "*After some ten years, I would now say, with hindsight, that 'general topology' was developed (during the thirties and forties) by analysts and in order to meet the needs of*

analysis, not for topology per se, i.e. the study of the topological properties of the various geometrical shapes. That the foundations of topology are inadequate is manifest from the very beginning, in the form of 'false problems' (at least from the point of view of the topological intuition of shapes) such as the 'invariance of domains', even if the solution to this problem by Brouwer led him to introduce new geometrical ideas."

Unlike the notion of scheme and topos, both central in algebraic geometry and widely known for mathematicians nowadays, the notion of tame space, and therefore tame topology, is marginal in mathematics. There are some developments in logic (van den Dries 1998) in relation to O-minimal structures, but besides this the idea of tame space is not that relevant (We consider that it would be a very interesting research program to try to develop Grothendieck's ideas in (Grothendieck 1997) related to tame topology. We think that this could open new geometric perspectives and new understanding of topological phenomena as Grothendieck envisioned.). However, in our study of the notion of space in Grothendieck is, in fact, very important, since it provides the first attempt of Grothendieck to formulate a theory of space with the clear motivation of providing a setting to study shapes as foundational objects for geometry/topology, as we already mentioned. In this sense, we believe that it is not possible to understand how the idea of space evolved in Grothendieck's work without passing through the discussion about tame topology. On the other hand, we will see that in order to tackle the problem of understanding shapes, this is not the final answer that Grothendieck wanted to provide.

It is important to remark that the notion of tame space does not pretend to generalize the idea of topological space (like toposes do) but provides a new understanding for it. In that sense, a tame space is a new form that the notion of space can take, it is new type of space. Thus, we can see that the notion of space is really protean for Grothendieck.

4 Towards a New Geometry of Forms

We saw in the last section how part of the motivation for developing a tame topology was to construct a right notion of space in order to deal with the various geometrical shapes. In fact, the notion of form (In (Cruz Morales Submitted) we have argued that there is an important difference between form and shape and we have discussed how the notion of form is more general than that of shape. In fact, Grothendieck himself chose to use the word form rather than shape, as we can see in a letter to Ronald Brown on June 17th, 1986:

"I've been very strongly involved with mathematics lately, working out another approach to 'topology' and 'form' (different from topological spaces, from topoi and from moderate spaces as proposed in Esquisse d'un Programme), just getting the basic language straight.") was one of the main subjects of Grothendieck's reflections in the 1980s, and in some sense tame topology was not enough for Grothendieck in order to provide a general setting for the notion of space if we want to study the geometric properties of forms. In this direction, Grothendieck

proposed a new approach for the foundations of topology. This is what he called geometry of forms. In a letter to Yamashita on July 9th, 1986, Grothendieck wrote:

"*I have been very intensely busy for about a month now, with writing down some altogether different foundations of 'topology', starting with the 'geometrical objects' or 'figures', rather than with a set of 'points' and some kind of notion of 'limit' or (equivalently) 'neighbourhoods'. Like the language of topoi (and unlike the so-called 'moderate space' theory foreshadowed in the Esquisse, still waiting for someone to take hold of the work in store), it is a kind of topology 'without points' - a direct approach to 'shape'. I do hope the language I have started developing will be appropriate for dealing with finite spaces, which come off very poorly in 'general topology' (even when working with non-Hausdorff spaces).*"

Grothendieck wrote a manuscript (Grothendieck 1986) about these ideas. The manuscript remained relatively unknown (except for a few mathematicians) until the online publication of Grothendieck's manuscripts by Université de Montpellier. However, since these were handwritten by Grothendieck, it is not easy to decipher its content. To the best of our knowledge the first places where there is an attempt to discuss the content of the manuscript are (Cruz Morales 2017, 2018) based on some correspondence of Grothendieck where he wrote about it. For the purpose of this essay, we consider that the ideas on the manuscript that we can extract from the correspondence are very important since they allow us to really understand how the notion of space was evolving in Grothendieck's work. We want to argue that a full understanding of the problem of space in Grothendieck is impossible without studying the manuscript or at least its main ideas. However, a deep study of the text is still a work in progress, but here we hope to give a good idea of what Grothendieck was thinking (Just to provide an idea of the text, we want to give the title of the different chapters of the manuscript.

Chap 1. On a Topology of the (Topological) Forms. Chap 2. Topological Realizations of Networks. Chap 3. Networks via Decompositions. Chap 4. Analysis Situs (First Attempt). Chap 5. Algebra of Figures. Chap 6. Analysis Situs (Second Attempt). Chap 7. Analysis Situs (Third Attempt). Chap 8. Analysis Situs (Fourth Attempt). Chap 9. Notes.

It is interesting to see how Grothendieck uses the expression analysis situs that evokes Leibniz and Poincaré. In a letter to Yamashita on September 16th, 1986, Grothendieck mentioned Poincaré conjecture in relation to the analysis situs he invented. It is still matter of study to understand the relation between Poincaré and Grothendieck (and also between Grothendieck's ideas and Leibniz' ideas), but we find illustrative this extract of the letter:

> "*I have been impressed, of course, by your second list of 'newest events'. I didn't even know about the solution of Poincaré's conjecture - comes just at the right time for me, to be able to justify within the framework of the 'geometry of forms' or 'analysis situs' I am developing in terms of extant 'general topology', a certain definition of 'regular figure' (the combinatorial substitute for 'variety') I had in mind*".
>
> Grothendieck refers the proof announced by Colin Rourke and Eduardo Rêgo. The proof turned out to be incorrect. However, some years after this, Gregory Perelman found a right proof for the conjecture. So it is tempting to ask: What is the relation between Poincaré conjecture and Grothendieck's geometry of forms?).

In the extract of the letter to Yamashita we have quoted there is one important point that we want to remark. Grothendieck pointed out that his new approach to the notion of space is closer to the idea of topos than the idea of tame space, in the sense that these new spaces are not made by points, but also because here he is looking for a direct approach to shapes. However, looking at the discussion in (Grothendieck 1958) concerning tame topology we can see that the motivation of Grothendieck was to understand the forms from a geometric point of view. Is there any contradiction here? We think the answer is no.

One thing is to be motivated by some idea and another thing is that this idea can be carried out by certain construction we propose. Our conjecture is that Grothendieck realized that his tame topology was not the right framework for the goal of understanding forms, taking forms in a very broad sense, and for this reason he saw the necessity of producing a new theory and that is what he expressed in the letter to Yamashita. Actually, Grothendieck explored different approaches during the years in order to understand what exactly a space is and the idea of tame space can be thought as one of them. Before his retirement at Lasserre in June 24th, 1991, Grothendieck wrote a letter to an unknown recipient (The unknown recipient is identified as A.Y. This letter and its relation with the manuscript about the geometry of forms have been discussed in (Cruz Morales 2017).):

> "*Il est vrai qu'us cours de dix dernières années, j'ai réfléchi ici et là à diverses extensions de la notion d'espace, en gardant à l'espirit la remarque pénétrante de Riemann. J'en parle dans quelques lettres à des amis physiciens ou 'relativistes'. Il ne doit pas être très difficile p. ex. de développer une sorte de calcul différentiel sur des 'variétés' qui seraient des ensembles finis (mais à cardinal 'très grand'), ou plus généralement discretes, visualisés comme format une sorte de 'réseau' trés serré de points dans una variété* C^{∞} *(p. ex. una variété riemannienne) - une sorte de géometrié différentielle 'floue', oú toutes les notions numériques son défines seulement 'à* ε *prés', pour un ordre d'approximation* ε *donné*."

This quote is particularly relevant. Three important points appear here that are not present in the reflections about the notion of space that Grothendieck proposed in his work in algebraic geometry and in tame topology. First of all, Grothendieck asks for the intrinsic structure of the space and its discrete or continuous structure. Of course, when he discussed about toposes the relation between the discrete and the continuum world was present, but in the sense on how toposes can put arithmetic and geometric phenomena together, but here the difference is that the discussion on the dichotomy continuum/discrete appears in a more foundational and structural way. Secondly, he was not only thinking of the mathematical space but also in the physical space. It is widely believed that Grothendieck was not interested in physics at all, but it seems that in his last period and regarding the problem of space he was interested in physics and, in fact, he had contact with some physicists and discussed with them his ideas. Finally, he recognize explicitly that some of his thoughts about the space came from Riemann. We will back to the

relation with Riemann later, so let us focus on the first and the second points we have mentioned.

What was the kind of space that Grothendieck had in mind? We can find a first answer in the letter to Yamashita on June 9th, 1986. There Grothendieck argued:

> "*As Riemann pointed out I believe, the mathematical continuum is a convenient fiction for dealing with physical phenomena, and the mathematics of infinity are just a way of approximating (by simplification through 'idealisation') an understanding of finite aggregates, whose structure seems too elusive or too hopelessly intricate for a more direct understanding (at least it has been so till now). Yet it may well be that we are approaching at present the point where the continuous models of the physical world fail to be adequate - but the physicists are so accustomed taking for granted the conceptual superstructure of 'continuous space' worked out by the Greeks and their successors up to Relativity and Quantum mechanics, and to confuse it with reality, that they may well never get aware of a widening gap between concepts and phenomena. This brings to my mind that not only the language of (so-called 'topological') shape is to be rethought from scratch, in order to be capable to account for 'shape' of finite spaces, but the same holds with vast sectors of geometry and analysis, if not all of it. Thus differential and integral calculus, differential equations and the like, differentiable or Riemannian varieties, the tensor calculus on it, etc - all this quite evidently (once you start thinking about it) should make and has to make sense within the framework of (say) finite aggregates as well. Just think, say, of* 10^{100} *or* 10^{1000} *points pretty densely located on the unit sphere or in the unit ball, a lot more than needed for exceeding by very far he accuracy of any conceivable physical measurement, so that no physicists nor anybody whosoever (except maybe God Himself) could ever possible distinguish between the ambient "continuous" space (granting it does have some kind of 'physical' existence, which I doubt) and this kind of network thought of as an 'approximation' (whereas in reality, the opposite seems to me more likely to be true: the continuum is the concept approximating the elusive finite - but very large - aggregate). This would mean rethinking too the notion of differentiability (say) and of differential, in wholly new terms, when 'passing to the limit' means now a finite process, namely passing to 'small' values of the parameter or parameters, where the rate of 'smallness' is precisely prescribed and should by all means not be exceeded, and where the 'margin of errors' admitted in the computation or definition of the 'differential' or 'derivative' is equally precisely prescribed, in keeping with the former prescription*."

Grothendieck was inclined for a discrete structure for the space and even he thought of the continuum as a convenient fiction. This is actually quite impressive. Nobody before Grothendieck proposed to think the continuum as an approximation to the discrete (In the letter Grothendieck attributes this idea to Riemann. However, it is not that clear that actually Riemann was thinking the continuum in this terms. We will back to this point later.). We find this idea very suggestive on its own (We discuss about this in (Cruz Morales 2017). Let us just mention that this idea is an inversion respect to the usual way of thinking the relation between the continuum and the discrete. Usually the continuum is seen approximate by the discrete via a saturation (limit) procedure. Grothendieck is proposing a radical, but we think very fruitful, change of perspective. It would be very interesting to explore in more detail this line of thought.). For Grothendieck, the continuous structure of the space can be thought as an artificial, but necessary and convenient, construction in order to understand its actual structure. However, the relation between the discrete and the

continuum is not that simple for Grothendieck. In fact, in (Grothendieck n.d.) he proposed that there could be three possibilities for the structure of the space. The space can be discrete, continuum, or mixed discrete/continuum structure. In Grothendieck's words:

> "*Les développements en mathématique des dernières décennies ont d'ailleurs montré une symbiose bien plus intime entre structures continues et discontinues, qu'un ne l'imaginait encore dans la première moitié de ce siècle. Toujours est-il que de trouver un modèle 'satisfaisant' (ou, au besoin, un ensemble de tels modèles, se 'raccordant' de fa'çon aussi satisfaisante que possible), que celui-ci soit 'continu', 'discret' ou de nature 'mixte' — un tel travail mettra en jeu sûrement une grande imagination conceptuelle, et un flair consommé pour appréhender et mettre à jour des structures mathématiques de type nouveau. Ce genre d'imagination ou de 'flair' me semble chose rare, non seulement parmi les physiciens (où Einstein et Schrödinger semblent avoirété parmi les rares exceptions), mais même parmi les mathématiciens (et là je parle en pleine connaissance de cause)*."

Again, it is clear that he was thinking not just in the mathematical space but also in the physical one. Unlike what he did in algebraic geometry and in tame topology, his new geometry of forms is not just a mathematical description of the space but it should be thought as a description useful for physical purposes. This is the reason, we believe, that the notion of form was so central in this new approach. A form has many manifestations in the world not only in mathematics, so any theory about the space focused on the idea of form should reflect those manifestations. We think Grothendieck had fully conscience about this.

4.1 Riemann's Heritage

An important point to analyze in Grothendieck's conception of the geometry of forms is Riemann's influence. Of course, Riemann has a big influence in the whole grothendieckean work, but in relation to the geometry of forms that influence is particularly interesting. In (Grothendieck n.d.) we find:

> "*Il doit y avoir déjà quinze ou vingt ans, en feuilletant le modeste volume constituant l'oeuvre complète de Riemann, j'avais été frappé par une remarque de lui 'en passant'. Il y fait observer qu'il se pourrait bien que la structure ultime de l'espace soit 'discrète', et que les représentations 'continues' que nous nous en faisons constituent peut-être une simplification (excessive peut-être, à la longue. . .) d'une réalité plus complexe; que pour l'esprit humain, 'le continu' était plus aisé à saisir que 'le discontinu', et qu'il nous sert, par suite, comme un 'approximation' pour appréhender le discontinu. C'est là une remarque d'une pénétration surprenante dans la bouche d'un mathématicien, à un moment où le modèle euclidien de l'espace physique n'avait jamais encore été mis en cause; au sens strictement logique, c'est plutôt le discontinu qui, traditionnellement, a servi comme mode d'approche technique vers le continu*."

Here Grothendieck again refers Riemann as the one who was the first in thinking the continuum as an approximation of the discrete, and in this sense the continuous structure of the space as an approximation of a more intricate discrete structure of it

(We already saw that Grothendieck also mentions Riemann in relation with this idea in his letter to Yamashita on June 9th, 1986.). What it is also important to consider is that Grothendieck pointed out that the relation between the continuum and the discrete can be determined by the fact that the continuum is easier to assimilate by the human mind (he uses the expression human spirit) than the discrete. This has deep philosophical implications in terms of the nature of space. The question is to some extent this idea is already in Riemann in the explicit way that Grothendieck is presenting it.

Riemmann's contribution started to be clarified in a letter to Yamashita on September 16th, 1986. There Grotehndieck wrote:

> "*When I wrote about the theory of mathematical continuum begin a kind of approximation and idealization of very large and complex discrete aggregates, I thought I was citing an idea of Riemann, from what I remembered from reading through his collected works, many years ago (presumably in his exposition of the idea of what is now called riemannian geometry). When I later looked for a precise reference in his work, I was rather surprised that I wasn't able to find it - and it seems you didn't find it either. So maybe, I found his idea only 'in between the lines' of his actual words*."

The "in between the lines" at the end is really remarkable. At the end of his Habilitation thesis (Riemann 1854), Riemann discussed about the possibility of a discrete structure for the space. That idea yielded a big impression on Grothendieck. After looking with more detail, he recognized that in an explicit way the idea is not in Riemann but he certainly believed that it can be extracted from what Riemann wrote. This is a risky implication. Thus, why does Grothendieck make that implication? We could find a partial answer again in the letter to Yamashita from September 16th:

> "*It would almost seem that there has been something like 'telepathic' communication (to give it a name) from Riemann's thought-world to mine. I am still convinced now, or rather, I well know, that I never discovered myself this idea (because this kind of discovery of some significant view, I mean the moment of such discovery, one never forgets I believe) but that I got it from Riemann, and with some surprise.*"

This passage is very beautiful. That "telepathic communication" between Grothendieck and Riemann, two of the biggest mathematical geniuses of all times, connected by their mathematical passion and the wish of understanding the notion of space, is one of the most remarkable examples of mathematical creativity. Despite of being separated by many years, both of them had the intention of unveiling the inner and deep structure of the space and they walked together going behind that goal. Thus, without doubt Grothedieck's ideas about the space, and in particular the geometry of forms he envisioned in the late 1980s, are Riemann's heritage.

5 The Notion of Space: Mathematics, Physics, and Philisophy

In the previous section we discussed how thanks to the formulation of his geometry of forms Grothendieck began interested in the relations between the physical and the mathematical space. It is also important to remark that in fact Grothedieck was

beyond mathematics and physics in his reflections and also consider the importance of philosophy in order to understand what a space is. This give us a new perspective about Grothedieck's thoughts in the late 1980s and also about his understanding of the notion of space as a whole. In particular, Grothendieck was interested in the role of mathematical models for the physical reality and the philosophical background of them. He thought that only putting together philosophy, physics, and mathematics we can find an adequate approach to the problem of space. Regarding this, in (Grothendieck n.d.) he wrote:

> "*Pour résumer, je prévois que le renouvellement attendu (s'il doit encore venir) viendra, plutôt d'un mathématicien dans l'âme, bien informé des grands problèmes de la physique, que d'un physicien, Mais surtout, il y faudra un homme ayant 'l'ouverture philosophique' pour saisir le noeud du problème. Celui-ci n'est nullement de nature technique, mais bien un problème fondamental de 'philosophie de la nature'.*"

And in a letter to AY on June 24th, 1991 he also pointed out:

> "*Je suspecte que les nouvelles structures à dégager seront beaucoup plus subtiles qu'un simple paraphrase de modèles continus connus en termes discretes. Et surtout, qu'avant toute tentaive de dégager des nouveaux modèles, présmés meilleurs que les anciens, il símpose de poursuivre une réflexion philosophico-mathématique très servie sur la notion même de 'modèle mathématique' de quelque aspect de la realité - sur son rôle, son utilité, et sus limites*."

It is beautiful to see how Grothendieck uses the expression natural philosophy. The problem of space is not just a mathematical, physical of philosophical one, it is a problem of natural philosophy in a very broad sense that includes mathematics, physics, and philosophy but also goes beyond them. This is evidence of how deep Grothendieck's thoughts about the space became. The philosophical side of Grothendieck's approach to the notion of space is, in general, unknown but for us it is very relevant and it should be studied in more detail. Here, we just mention this aspect to motivate the study and the debate about it.

Grothendieck pointed out that the problem of space is not only of technical nature. It is not enough to think of the problem in mathematical or physical terms. We also need a right conceptual approach and it is in this point where philosophy should enter. One of the aspects to be consider is how the mathematical models of the space that we can propose reflect the nature and the structure of the physical space and it is consistent philosophically. Of course, this is not an easy problem and Grothendieck had no answer. Again, the reflection on the role of mathematical models is of philosophical nature as Grothendieck saw (see Grothendieck n.d.):

> "*J'ai le sentiment que la r'eflexion fondamentale qui attend d'être entreprise, aura à se placer sur deux niveaux différents.*
> 1. *Une réflexion de nature 'philosophique', sur la notion même de 'modèle mathématique' pour une portion de la réalité. Depuis les succès de la théorie newtonienne, c'est devenu un axiome tacite du physicien qu'il existe un modèle mathématique (voire même, un modèle unique, ou 'le' modèle) pour exprimer la réalité physique de façon parfaite, sans 'd'ecollement' ni bavure. Ce consensus, qui fait loi depuis plus de deux siècles, est*

comme une sorte de vestige fossile de la vivante vision d'un Pythagore que 'Tout est nombre'. Peut-être est-ce là le nouveau 'cercle invisible', qui a remplacé les anciens cercles métaphysiques pour limiter l'Univers du physicien (alors que la race des 'philosophes de la nature' semble définitivement éteinte, supplantée haut-la-main par celle des ordinateurs). Pour peu qu'un veuille bien s'y arrêter ne fut-ce qu'un instant, il est bien clair pourtant que la validité de ce consensus-là n'a rien d'évident. Il y a même des raisons philosophiques très sérieuses, qui conduisent 'a le mettre en doute a priori, ou du moins,à prévoir à sa validité des limites très strictes. Ce serait le moment ou jamais de soumettre cet axiome à une critique serrée, et peut-être même, de 'd'emontrer', au delà de tout doute possible, qu'il n'est pas fondé: qu'il n'existe pas de modèle mathématique rigoureux unique, rendant compte de l'ensemble des phénomènes dits 'physiques' répertoriés jusqu'à présent.

Une fois cernée de façon satisfaisante la notion même de 'modèle mathematique', et celle de la 'validite' d'un tel modèle (dans la limite de telles 'marges d'erreur' admises dans les mesures faites), la question d'une 'théorie unitaire' ou tout au moins celle d'un 'modèle optimum' (en un sens à préciser) se trouvera enfin clairement posée. En même temps, on aura sans doute une idée plus claire aussi du degré d'arbitraire qui est attaché (par nécessité, peut-être) au choix d'un tel modèle.

2. *C'est apr'es une telle réflexion seulement, il me semble, que la question 'technique' de dégager un modèle explicite, plus satisfaisant que ses devanciers, prend tout son sens. Ce serait le moment alors, peut-être, de se dégager d'un deuxième axiome tacite du physicien, remontant à l'antiquité, lui, et profondément ancré dans notre mode de perception même de l'espace: c'est celui de la nature continue de l'espace et du temps (ou de l'espace-temps), du 'lieu' donc où se déroulent les 'phénomènes physiques*."

We include this extensive quote because it illustrates in Grothendieck's own words what we are trying to argue, i.e., that the technical description of the space only makes sense for Grothendieck after a conceptual approach. It took him around 40 years to reach this conclusion. This quote also shows the evolution of Grothendieck's ideas from his pure technical questions in his work in algebraic geometry to the more physical-philosophical questions in his geometry of forms. Thanks to this, it is very clear that notion of space is indeed a leitmotif in Grothedieck's mathematical life.

6 Conclusion

Along this essay we have shown how the idea of space in Grothedieck evolved from his generalization of the notion of (algebraic) variety via schemes to the formulation of a new approach for the foundations of topology in what he called geometry of forms, passing through the notion of topos and tame space. Of course, for Grothendieck the notion of variety and topological space (in the classical sense) were useful in mathematics but he realized of new situations where new ideas on space were needed. In particular, one of these situations is related to the notion of form and its role in topology and, in general, in mathematics.

Grothendieck wrote that there are three main areas of mathematical reflection, namely arithmetic (associated to the notion of integer numbers), analysis (associated to the notion of magnitude), and geometry (associated to the notion of form). From

the beginning he put the notion of form as belonging to the realm of geometry and more general topology, but even more, it is the central notion for geometry in the sense that geometry for him is the branch of mathematics in charge of studying the aspects of the universe, not just the mathematical universe of course, related to the form.

Following that line, for Grothendieck there are three different notions which are important from a mathematical point of view, namely number, magnitude, and form. In (Cruz Morales Submitted) we argue that number and magnitude are manifestations of a more general notion of form and in this sense number can be thought as an arithmetical form while magnitude can be thought as an analytic form. What Grothendieck called form should be interpreted as a geometrical form (or shape). What we have is a fundamental triad that gives the most important aspects to be considered in a mathematical approach to the notion of space, i.e., arithmetical, analytical, and geometrical aspects. We have argued that this was the quest of Grothendieck for more than 40 years.

On the other hand, as we have already mentioned before in this text, Zalamea's interpretation (Zalamea 2019) of the space-number in Grothendieck's work as analogue to the space-time in physics gives a nice way to understand Grothendieck's ideas. Zalamea proposes that we should think Grothendieck's work as an attempt to develop the notion of space-number as the conjunction of arithmetic and geometry in one entity. This analogy is very suggestive since, as we have shown, Grothendieck was interested in physical aspects of the space. For this reason, we find very plausible to think of his last works in terms of constructing a theory for a space-number. We think that this line of thought could be very helpful in order to understand the notion of space in Grothendieck and it is a future project try to follow it.

In (Bolzano 2004) Bolzano presents an idea of mathematics as a general theory of forms. In some sense Grothendieck's approach to the notion of space is a realization of Bolzano's idea, including physics and philosophy in the picture. We believe this should be a way to think of Grothendieck's contribution to the human knowledge. There are still many problems to be considered and many gaps to be filled in order to understand Grothendieck's ideas about the space. In this text we wanted to present a new perspective and contribute with some elements which, to the best of our knowledge, were not considered before in the literature. More than giving a definitive answer about the problem of space in Grothendieck's work we wanted to give a picture as complete as we could do it, in order to start the dialogue. A dialogue that follows Grothendieck's own advice will require a mathematical, physical, and philosophical way of thinking.

Acknowledgments The author wants to thank Fernando Zalamea for many illuminating discussions on Grothendieck's work over the years, his constant and warm support and having read a draft version of this essay. Of course, any mistake that remains is completely responsibility of the author. He also thanks Winfried Scharlau for providing him with Grothendieck's correspondence with Yamashita and Tsuji and for conversations on Grothendieck's life, and Yuri Manin for supporting the idea of writing this text. Finally, he thanks Pierre Deligne for many interesting emails and his patience in explaining his ideas.

Abstract

This is an exposition of the work of Herbert Busemann (1905–1994), seen as a return to the geometry of Ancient Greece. The importance of this work, its recognition, and its relation with other works are discussed.

1 Introduction

The twentieth century saw the spectacular development of several fields in mathematics: algebraic topology, low-dimensional manifolds, algebraic geometry, number theory, dynamical systems, mathematical physics, to name a few. Among these fields, there is one which, in my opinion, is not sufficiently emphasized: metric geometry. In writing this, I am thinking of the work of Herbert Busemann, whose collected papers have been published recently in Springer's Collected Works Series (Busemann 2018a, b). Busemann's work goes against the tide, and I think that it is still under-evaluated. This is why I would like to highlight it here.

The path opened up by Busemann is in a sense a return to Euclid's geometry. I will explain in what sense, and in fact this is the theme of the whole present chapter. Let me first give some indications on what I mean by this return.

To start with, I would like to make it clear that in this chapter, when I talk about Euclid's geometry, I am not necessarily referring to the propositions found in the *Elements*, but rather to a geometry inspired by them and which is close to them in several respects. To explain this, let me start by recalling that an important (maybe the most important) part of the geometric books of Euclid's *Elements* is an exploration of the properties of triangles. Likewise, a significant part of Busemann's geometry includes a study of the geometry of triangles on surfaces (which are not necessarily the Euclidean plane): such a surface may be the sphere, or the hyperbolic plane, or a convex surface embedded in three-space, or any other two-dimensional manifold. In particular, classical "non-Euclidean" geometry, as a study of properties of non-Euclidean triangles, is part of Euclid's geometry as I intend it here. For example, Menelaus' *Spherics*, which I discuss in another chapter of this Handbook (see the chapter ► "Menelaus' Spherics in Greek and Arabic Mathematics"), being a treatise on the intrinsic properties of spherical triangles, is an example of what I call Euclid's geometry. Higher-dimensional hyperbolic and spherical geometry, in particular the study of non-Euclidean polyhedra, which generalize triangles, are also part of this geometry.

The geometry developed by Busemann is defined axiomatically – with a few number of axioms: these include those of a metric space, to which are added some axioms on the existence of shortest lines joining pairs of points. Thus, the notion of distance between two points is one of the basic notions in that geometry. I recall incidentally that Euclid's *Elements* do not use the notion of distance between two points. From the philosophical point of view, this is important and needs a thorough discussion, but for what concerns us here, this is not an issue. Furthermore, in Busemann's geometry, considerations of differentiability are excluded. Thus, the methods of differential calculus are not part of it. Consequently, Riemannian geometry is not part of this geometry either.

Why call such a geometry "Euclidean"? Because it deals with problems similar to those raised by Euclid's *Elements* or motivated by them. I shall start by explaining this in the next section, using a significant example, namely, a work of Busemann arising from a question raised by Leibniz. At the same time, the result I am about to describe will show how non-Euclidean geometry naturally fits into this framework.

2 Leibniz, Busemann, and a Question of Euclidean Geometry

Leibniz addressed the question of defining a plane. His work on this subject is reproduced in his *Mathematical writings* (Leibniz 1849, p. 166). The problems raised by such a definition are presented and commented on by Busemann in his article *On Leibniz's definition of planes* (Busemann 1941) and are taken up again in his book *The geometry of geodesics* (Busemann 1955, p. 46). The question of the definition of a plane can be traced back to Euclid, although, as Busemann remarks, the definitions of surface and line that are given in the *Elements* are difficult to work with. We recall that Euclid, in Book I of the *Elements*, defines a *line* as something "that has length and no width," but the terms length and width are not defined there. Likewise, he defines a *plane* as something "that has only length and width." Busemann notes that ancient authors already found these definitions objectionable, and that it is not possible, within the framework of Euclidean geometry, to characterize, based only on these definitions, straight lines among curves, and planes among surfaces. Thus, one cannot give an answer to Leibniz's question based only on Euclid's *Elements*. Archimedes went further than Euclid. In *The sphere and the cylinder*, following a definition of straight line due to Heron, he introduced as an axiom the fact that the straight line is a shortest curve among all curves joining two points. He also developed a method for calculating lengths of curves. All this is recalled in the same passage by Leibniz, who considers that this cannot be used for a definition of a straight line, and proposes to define a straight line as the set of points fixed by the rotation of some body – which assumes that the notion of body precedes that of straight line, and which gives rise to other difficulties. I refer here to Couturat's comments on Leibniz's work, see Chap. IX, of his treatise *The logic of Leibniz* (Couturat 1901), titled *Geometric calculation*. Regarding Leibniz's question, Busemann writes in the introduction to his article (Busemann 1941):

> The well-known unsatisfactory Euclidean definitions of straight lines and planes have evoked early attempts to replace them by better ones. Leibniz proposed *to define a plane as the locus of points which have equal distances from two given points*, and the straight line as locus of points having equal distance from three given points. Since the idea of metric space or anything which could be substituted for it had not yet been developed, this attempt of Leibniz did not grow into a well-founded theory. The present note tries to give a critical investigation of the implications of Leibniz's definition from the point of view of metric spaces.

To address such a problem, and similar ones, Busemann introduced the axioms of a G-space (the letter G stands for "geodesic"). In fact, these axioms are already present in Busemann's doctoral thesis (defended in 1931), and they are the same ones he used throughout the rest of his works. This is the moment to introduce these axioms:

1. The space is equipped with a distance function $d(x, y)$.
2. Every bounded infinite set has an accumulation point. (Busemann calls a space satisfying this property *finitely compact*.)

3. For any distinct points x, z, there is a point y such that $d(x, y) + d(y, z) = d(x, z)$. (One says that *$y$ lies between x and z*.)
4. For every point p, there exists a positive real number ρ_p such that for any distinct points x, y in the ball of center p and radius ρ_p, there exists a point z such that y is between x and z. (This is a property of local extendability.)
5. (Uniqueness of extension of geodesics) For any distinct points x and y, if y is between x and z_1 and between x and z_2, and if $d(y, z_1) = d(y, z_2)$ then $z_1 = z_2$.

We note that it is not assumed here that the metric space is a manifold. In fact, it is an important open problem, which is presently solved only under some special extra hypotheses, to know whether a G-space is a manifold; see the reviews by Andreev (Andreev 2018) and Berestovskii (Berestovskii 2018a) who both made important contributions to this problem.

The notion of G-space is used extensively in many of Busemann's writings, e.g., in his 1942 book *Metric Methods in Finsler Spaces and in the Foundations of Geometry* (Busemann 1942), in his 1943 paper *On spaces in which points determine a geodesic* (Busemann 1943), and in his 1955 book *The geometry of geodesics* (Busemann 1955).

Busemann and B. B. Phadke (one of his former students) write in (Busemann and Phadke 1993, p. 190): "One of the most attractive features of G-space theory is that it maintains a strong connection with the foundations of geometry."

With the above axioms in the background, Busemann can address Leibniz's question of defining a plane. He calls a subset of a G-space "flat" if, equipped with the induced metric, it is a G-space. In his paper (Busemann 1941) and in his book (Busemann 1955), §§46 and 47, he considers Leibniz's question in the setting of G-spaces to which a single hypothesis is added; it concerns *bisectors*, that is, loci of points equidistant from two distinct points. The hypothesis says the following:

> *Any bisector contains with any two points at least one segment connecting them.*

Busemann calls this property *flatness* of the bisectors. It is obviously satisfied in the case of the classical geometries of constant curvature. He proves the converse:

> *The three classical spaces of constant curvature (Euclidean, spherical, and hyperbolic) are the only G-spaces in which all bisectors are flat.*

Thus, motivated by Leibniz's question, Busemann deduces a remarkable (probably the simplest) characterization of the three classical geometries. He writes in (Busemann 1955, p. 307), considering such a characterization of the classical spaces: "Besides being of considerable historical interest, these results form perhaps the most direct and conceptually simplest access to the elementary geometries, and they have many important applications."

In his book *The geometry of geodesics* (Busemann 1955, p. 310), Busemann shows that with a slight modification of the notion of flatness, one gets a *local* characterization of the three classical geometries. In fact, he gives a characterization

of spaces that are *locally* the above spaces of constant curvature, based on a "local bisector theorem," a criterion involving a property of small enough open balls; see Theorem 46.1 of (Busemann 1955). It is interesting that Busemann obtains the fact that the metric he ends up with is either the Euclidean, hyperbolic or spherical by establishing the trigonometric formulae for right triangles in such a space, see (Busemann 1955, p. 320). Busemann calls the *Helmholtz–Lie problem* the question of characterizing the three elementary geometries. From the above bisector theorem characterizing the three classical geometries, he deduces several corollaries, in particular, statements concerning motions and the Helmholtz–Lie problem, of which the following very general statement is given (Busemann 1955):

> *If in a G-space, for any four points a, a', b, c satisfying $d(a, b) = d(a', b)$ and $d(a, c) = d(a', c)$, there exists a motion leaving b and c fixed and carrying a to a', then the space is either locally Euclidean, hyperbolic or spherical.*

Another application of the bisector theorem is the fact, obtained in (Busemann 1955), see also (Busemann 1947), that in dimension two, the three elementary geometries are the only geometries in which the area of a triangle is expressible in terms of its sides. More precisely, Busemann proves the following:

> *If every point of a G-surface has a neighborhood in which a notion of area for triangles is defined and has the same value for all isometric triples, then the surface is locally Euclidean, hyperbolic or spherical.*

3 Busemann's Doctoral Dissertation

In one of his last papers, written with Phadke and titled *Novel results in the geometry of geodesics* (Busemann and Phadke 1993), Busemann recalls that he already introduced the axioms of a G-space (without the name) in his doctoral dissertation, defended in 1931. The history of this dissertation is interesting. The thesis supervisor was Richard Courant. Busemann declares in his autobiographical memoirs that he wrote his thesis "against" Courant. He recounts the following:[1]

> Officially, I took my degree with Courant. This was only "officially," in the sense that I was really inspired by [Pavel Sergueevitch] Aleksandrov, who visited Göttingen regularly. He gave me the idea of the subject of the thesis. I wrote it, but of course he could not be the official reviewer of my thesis, so he was my co-referee. I must say that my thesis was partly in protest against Courant. I went to Courant originally, he gave me something and it turned

[1] Unless otherwise stated, Busemann's quotations are taken from the recording of an interview with Constance Reid, presumably made on April 22, 1973 and kept at the library of the University of Göttingen. I would like to thank again Herbert Goenner for providing me with a copy of this interview. I presented this recording in more detail in the biography I wrote on Busemann, included in the first volume of his *Collected works* (Busemann 2018a, p. 3–12).

> out to be much easier than what he thought. I did it and it became a small paper,[2] but not enough for a thesis. Then he gave me something else, I did this too, but then Kolmogorov came to Göttingen, Courant showed it to him, and Kolmogorov said: "Oh, that's all very fine, but it's well known." So I became really mad, and I went away to Rome. I was angry with Courant, and wrote my thesis there, on my own.

According to the paper by Busemann and Phadke (Busemann and Phadke 1993, p. 181), Busemann became convinced of the importance of non-Riemannian metrics after he read the beginning of Minkowski's *Geometrie der Zahlen* in 1926. At the same time, he heard a course on point set topology and learned about Fréchet's concept of metric spaces.[3] We read in that paper:

> The older generation ridiculed the idea of using these spaces as a way to obtain results of higher differential geometry. But it turned out that a few simple axioms on distance suffice to obtain many nontrivial results of Riemannian geometry and, in addition, many which are quite inaccessible to the classical methods.

Busemann wrote his thesis by himself, while he was visiting Rome, and he sent his work to Courant. The latter responded in a letter dated August 8, 1930 that this "geometric work" is sufficient for a "reasonable" dissertation.[4] Let me say a few words about the results of the thesis.

The subject of Busemann's thesis is the axiomatic characterization of Minkowski spaces, that is, metric spaces that underlie finite-dimensional vector spaces equipped with a norm.

The paper *Über die Geometrien, in denen die "Kreise mit unendlichem Radius" die kürzeten Linien sind* (On the geometries where circles of infinite radius are the shortest lines) is extracted from that thesis. An English translation of this paper is contained in Vol. I of Busemann's *Selected Works* (Busemann 1932). Here, the term "circle of infinite radius" means a horocycle, that is, the limit of a family of circles passing through a given point and whose center tends to infinity along a geodesic. The notion of horocycle (and its higher-dimensional analog, horosphere) was first used in hyperbolic geometry and it plays a crucial role there. In Euclidean geometry, the limit of such a family of circles is a straight line. The main result that Busemann proves in the paper (Busemann 1932) is that a two-dimensional space where horocycles are straight lines is isometric to a Minkowski space.

The metric characterization of Minkowski spaces remained one of Busemann's main objects of study. I refer the interested reader to the survey titled *Busemann's work on the characterization of Minkowski geometries* (Papadopoulos 2018a) which appeared in the section containing preliminary essays of Volume II of Busemann's *Selected Works* (Busemann 2018b).

[2] Busemann talks here about his paper (Busemann 1930).

[3] The concept of metric space as we intend it today, was first introduced (without the name) by M. Fréchet in his thesis, defended in 1906 (Fréchet 1906).

[4] An English translation of Courant's report on Busemann's dissertation is contained in Volume II of Busemann's Selected Works.

In the next section, I will mention other problems considered by Busemann and results he obtained in metric geometry.

4 Classical Notions: Questions and Results

The questions and results I mention in this section may seem unrelated but they all pertain to classical geometry, and many of them date back to the time of Euclid. They are all topics on which Busemann worked. His methods of proof, making use only of elementary geometry, are often ingenious.

1. A distance characterization of the three classical geometries. Since we already talked about the characterization of the three constant curvature geometries, I start by giving another local distance characterization of these three geometries (Busemann 1955, p. 47):

   If every point in a G-space has a neighborhood in which every quadruple of point is isometric to a quadruple of points in a Euclidean, hyperbolic or spherical space (the choice of such a space may a priori *depend on the point), then the space is locally Euclidean, hyperbolic or spherical.*
2. A theory of spaces with prescribed geodesics, and in particular, a thorough study of Hilbert's Problem IV. Roughly speaking, this problem asks for a determination of all metrics on subsets of Euclidean space whose geodesics are the (Euclidean) straight lines. There are several papers by Busemann on this problem, e.g., (Busemann 1939; Busemann 1976), see also the survey (Papadopoulos 2014). Busemann was the main promoter of Hilbert's Problem IV, and his work acted as a catalyst to the solution of that problem that was given by A. V. Pogorelov in 1973. The latter writes in the introduction to his monograph *Hilbert's fourth problem* (Pogorelov 1979): "The occasion for the present investigation is a remarkable idea due to Herbert Busemann, which I learned from his report to the International Congress of Mathematicians at Moscow in 1966."
3. A theory of perpendicularity in G-spaces and conditions under which this relation is symmetric (Busemann 1961).
4. The question of convexity of metric spheres (that is, sets of points whose distance to a given point is constant) in G-spaces (Busemann and Phadke 1980; Busemann and Phadke 1983; Busemann and Phadke 1993).
5. A theory of parallelism. In the paper (Busemann and Phadke 1993, p. 190), Busemann and Phadke write: "It is hard to understand that the theory of parallels was almost completely neglected in the classical theory after Lobachevsky's discoveries. We now explain the concepts upon which a beautiful theory of parallels can be built in a very general setting." In his 1933 paper *On spaces with convex spheres and the parallel postulate* (Busemann 1933), under the assumption of convexity of metric spheres and the fact that the parallel postulate is satisfied, Busemann studied conditions under which a space can be mapped onto a Euclidean space such that the geodesics are mapped to straight lines. Here, the

fact that the *parallel postulate* holds means that if g is an arbitrary straight line (that is, a geodesic isometric to the real line) and P a point not on g, then for every sequence of points x_n on g converging to infinity, the line Px_n converges to a unique geodesic. Parallelism is also the subject of Chap. III of *The geometry of geodesics* (Busemann 1955), titled *Perpendiculars and parallels*, see also the papers (Busemann 1979; Busemann and Phadke 1993) and the survey (Busemann 1961). A theory of parallelism in spaces with nonpositive curvature is developed in (Busemann 1955, p. 248).

6. Angle bisectors in triangles. In his paper *Planes with analogs to Euclidean angular bisectors* (Busemann 1975), Busemann gives a characterization of Minkowski planes based on a property of angular bisectors of triangles, namely, the fact that an angle in a triangle divides the opposite side in the ratio of the adjacent sides.
7. A theory of length-preserving maps. Here, Busemann's original aim is to determine all locally finite length-preserving self-maps of the Euclidean, hyperbolic, and spherical spaces (Busemann 1964). The first example that he gives of a length-preserving map is folding a piece of Euclidean paper. Among the results he proves is that any finitely compact space with an intrinsic metric and a pairwise transitive group of motions that possesses a proper length-preserving map has constant curvature.
8. The question of existence of axes of motions, the theory of axial motions, translation distances, asymptotes to axes, and parallelism of axes, see (Busemann 1955, 1970, Busemann and Phadke 1993).
9. A theory of horospheres (which he calls limit spheres) (Busemann and Phadke 1993).
10. A theory of asymptotes, and the relation between asymptotes and limit spheres (Busemann 1933, 1955, 1961). The asymptoticity relation is in general neither symmetric nor transitive. Symmetry and transitivity hold in spaces which Busemann calls *straight Desarguesian* (Busemann 1955, p. 139).
11. A study of the properties of fundamental groups of compact spaces of negative curvature (Busemann 1961).
12. The introduction of a theory of timelike spaces: a metric setting for the theory of general relativity, see (Busemann 1967).

The next notions need special attention, and I include them in separate sections.

5 The Sign of the Curvature, Angle Excess, and Area of Triangles: Replacing Equalities by Inequalities

Busemann introduced a notion of sign of the curvature (negative, nonpositive, vanishing, nonnegative, and positive) in metric spaces. This theory is developed in his book *The geometry of geodesics* (Busemann 1955, p. 236 ff.) and in other works. It is a generalization of the notion of sign of the curvature in Riemannian manifolds in the sense that it coincides with this notion when the underlying space is a

Riemannian manifold. Let us recall the definitions. In fact, the theory works for a class of metric spaces that are more general than G-spaces: for most purposes it suffices that the space is *midpoint convex* in the sense that for any two points x and y, there exists a point z whose distances from x and from y are both equal to half of the distance from x to y. Such a point z (which is generally not unique) is called a *midpoint* of x and y. A G-space is a special case of a midpoint convex space. A midpoint convex space which is complete is geodesic (any two points can be joined by a geodesic).

Busemann says that a midpoint convex metric space (M, d) is *nonpositively curved* if for any three points a, b, c in M, if a' is a midpoint of a and c and b' a midpoint of b and c, then

$$d(a', b') \leq 1/2(d(a, b)).$$

There are variations of this definition, namely, the space is called *negatively curved, nonnegatively curved, or positively curved* if the above inequality is replaced by a strict inequality or by the reverse large or strict inequality respectively. If the inequality is replaced by an equality, the space is said to be *zero curved*. These notions are used today under the name *Busemann nonpositive (resp. nonnegative, positive, negative, zero) curvature*.

The inequality expressing negative, nonpositive, nonnegative, positive curvature replaces an equality valid in Euclidean geometry by an inequality. Obtaining theorems in curved spaces from analogous theorems in Euclidean geometry by replacing equalities by inequalities, is known since antiquity. This is highlighted in my article (▶ "Menelaus' Spherics in Greek and Arabic Mathematics, this handbook) on the work of Menelaus of Alexandria (2nd c. AD). One proposition of Menelaus' *Spherics* says that the sphere is negatively curved in the above sense (see Proposition 27 of (Rashed and Papadopoulos 2017)), but there many other propositions involving this notion. In the *Geometry of geodesics*, Busemann proves that a G-space has nonpositive curvature in the above sense if and only if every point has a neighborhood in which all the triangles of sides α, β, γ and angles A, B, C opposite to these sides satisfy the *cosine inequality*

$$\gamma^2 \geq \alpha^2 + \beta^2 - 2\alpha\beta \cos C,$$

that is, if the usual Euclidean cosine formula holds, but where the equality has been replaced by an inequality (this is Proposition 41.3 of (Busemann 1955)). In the same book, Busemann studies several other metric notions of curvature, see in particular Chap. 5. One of them uses the notion of angle excess of triangles in G-spaces, see (Busemann 1955, p. 279ff). He also gives several statements that make relations between the theory of parallels and that of angle excess. Let me recall here that the fact that the angle excess of a spherical triangle is positive is also a result of Menelaus, see (Rashed and Papadopoulos 2017, Proposition 12). In hyperbolic geometry, angle excess is negative; this was known to J. H. Lambert, for whom the existence of hyperbolic geometry was hypothetical, see §81 of his *Theory of*

parallels (Lambert 1766), in which he defines the area of a triangle in the hyperbolic plane as the *angle defect* of that triangle. Building a theory of angle excess in G-spaces is one of the themes of Chap. V of Busemann's *Geometry of geodesics* (Busemann 1955), titled *The influence of the sign of the curvature on geodesics*.

Talking about area, let me quote another result of Busemann giving a characterization of Minkowski spaces in terms of a property of areas of its triangles. This is Theorem 51.5 of (Busemann 1955). The theorem concerns G-spaces that are *straight*, that is, in which the property of local extendability in the axioms of a G-space is replaced by a global one. The result says that in a straight space, the fact that the area of any triangle ABC depends only on the distances BC and the distance from A to the segment BC is equivalent to the fact that the space is a Minkowski plane with symmetric perpendicularity.

6 Convexity Theory

Among the introductory essays included in Volume II of the *Selected Works*, there is one titled *Busemann and Feller on curvature properties of convex surfaces* (A'Campo Neuen and Papadopoulos 2018), written by Annette A'Campo and the author of the present chapter. It is a commentary on the paper *Krümmungseigenschaften konvexer Flächen* (Curvature properties of convex surfaces), written in 1935, by Busemann and Feller (Busemann and Feller 1936).

This work of Busemann and Feller is strongly influenced by Hilbert's vision of mathematics. Both Busemann and Feller obtained their PhD in Göttingen, which, in those times, was one of the two most important mathematical centers of the world (the other one being Paris). Although their thesis advisor was Courant, both Busemann and Feller were shaped by Hilbert's view on the foundations of geometry. Hilbert retired in 1930 but continued to give a course on the philosophy of mathematics. Feller obtained his PhD in 1927, and Busemann in 1931. Before talking about their work, let me say a few words on some work of Hilbert related to the same topic.

In 1932, together with Stephan Cohn-Vossen,[5] Hilbert published his remarkable book *Geometry and the Imagination*[6] (Hilbert and Cohn-Vossen 1932) which is based on Hilbert's lectures held in 1920/21. The book contains a chapter on the geometry of surfaces, but the point of view is purely geometric, unlike the one of Euler, Monge, and most of the other mathematicians who followed, who studied surfaces and curves using analytic geometry. The methods used in the chapter on differential geometry of Hilbert and Cohn-Vossen's book constitute a return to the methods of the Greeks. For instance, their description of the osculating circle at a point of a plane curve starts with: "We draw a circle through P_1 and two neighboring

[5] For a comprehensive review on Cohn-Vossen's work, we refer the reader to the article (Aleksandrov 1947) by A. D. Aleksandrov.

[6] The original German title is: Anschauliche Geometrie.

points on the curve. If we let the two neighboring points approach P_1, the corresponding circle converges to a limit position [...]. This limit circle is called the osculating circle at P_1." No differentiation is involved. The discussion then is generalized to space curves. The osculating plane of a space curve at a point is constructed as the limit of the plane through the tangent at P and a neighboring point that approaches P (Hilbert and Cohn-Vossen 1932, p. 158). After a study of intrinsic properties that characterize the sphere, Hilbert and Cohn-Vossen in (Hilbert and Cohn-Vossen 1932), §32 study convex surfaces sharing the same properties.

Between the work of Hilbert and Cohn-Vossen and that of Busemann and Feller on convexity, I mention the work of Bonnesen and Fenchel on the same topic. They wrote a book titled *Theorie der konvexen Körper* (The theory of convex bodies) which was published in 1934, the year Werner Fenchel, who also belonged to the Göttingen school, moved to Denmark. This book, which is one of the founding texts of modern convexity theory, is also written in the tradition of Hilbert's foundations of geometry. Section 17 starts with the following: "Far-reaching assertions can be made about the curvature relations of convex curves without making any assumption of differentiability" (Bonnesen and Fenchel 1934, p. 153). Indeed, the authors, in that section and the next one, develop a geometric theory of curvature of convex curves and surfaces without differentiability conditions.

Busemann's works on convexity is in the same style. His first published work on the subject is the joint paper (Busemann and Feller 1936) with Feller.[7] In this paper, the authors study curvature properties of convex surfaces in three-space. Notions like tangent line, tangent plane, osculating circle, radius of curvature, etc. are studied using their original geometrical meaning rather than differential calculus. Busemann and Feller prove that a convex surface has almost everywhere second-order derivatives. (It was only known before that such a surface is almost everywhere differentiable, cf. (Reidemester 1921).) Among the other results, they obtain that there is a well-defined nearest point projection of curves lying in the complement of a convex body bounded by a convex surface onto this convex surface which is length nonincreasing. They also study geodesics on convex surfaces. They describe their goal in the introduction as follows: "The aim of this paper is to develop the elements of differential geometry of convex surfaces without making the usual regularity assumptions. Hereby necessarily, purely geometric considerations often replace the usual analytic arguments."[8] They show that without any differentiability hypothesis, one can define a notion of curvature and obtain the analogs of the classical theorems of Euler, Meusnier, and others on the differential geometry of surfaces. Their arguments are synthetic. The theorems of Meusnier and Euler are recurrent in

[7] William Feller (1906–1970) studied in Göttingen, obtaining his PhD with Courant, like Busemann. Feller obtained his PhD in 1927, and Busemann in 1931. They both emigrated to the USA after the Nazis formed a coalition in Germany. They wrote seven joint papers, published between 1934 and 1945. The reader interested in this turbulent period of the history of Europe in relation with mathematics may refer to Feller and Busemann's biographies contained in their Selected Works editions, (Feller 2015, Vol. 1) and (Busemann 2018a).

[8] Cf. the English translation in (Busemann, 2018a, p. 235).

Busemann's work. In a paper he wrote 15 years later (Busemann 1950), Busemann introduced a new notion of curvature in Minkowski spaces, and to justify the relevance of this notion, he showed that analogs of the theorems of Meusnier and Euler hold in this new setting as well. The study of the differential geometry of curves and surfaces, based on the notion of tangent, normal, order of contact, etc. of plane curves finds its origin in the work of Archimedes and Apollonius (third and second centuries B.C.) and of other Greek geometers.

This work of Busemann and Feller was the beginning of a lifelong program conducted by Busemann on the study of convexity theory using a minimal amount of differential geometry or differential calculus. He worked later on various geometric aspects of this subject, including volume, Brunn–Minkowski theory and convexity in general metric spaces. The subject of convexity dates back to Greek antiquity. Busemann, in his study of convex curves in G-spaces in his book *The geometry of geodesics* (Busemann 1955, p. 154), after he proves that a convex simple closed curve in a two-dimensional G-space has a supporting line at each point, writes that "it is remarkable that an exact proof of this proposition in the plane was already given by Archimedes." On the notion of angle, tangents, and contact in Greek mathematics, I refer the reader to the remarkable editions by R. Rashed, (Rashed 2008, 2009a, b, 2010, 2015; Apollonius 2008).

In 1956, together with C. M. Petty, Busemann formulated a set of problems on convex bodies, in a paper titled *Problems on convex bodies* (Busemann and Petty 1956). Most of these problems are still open, see the commentary by D. Burago (Burago 2018) in Volume II of Busemann's *Selected Works*. The latter, in the conclusion to his article, writes that "[he believes] that this circle of problems posed by Busemann opened a can of worms, a new direction or perhaps even a new area of research which is likely to be very active for many years to come."

In 1958, Busemann published a book titled *Convex surfaces* (Busemann 1958). In the Introduction, he declares that his purpose is to present a subject, convex surfaces, which "during the past 25 years has experienced a striking and beautiful development, principally in Russia, but has remained largely unknown, at least in the USA." Indeed, the book is a tribute to the work of A. D. Aleksandrov. The following paragraph gives us some information on how Busemann presented his book project to the publisher:

A letter dated July 23, 1956, from the editor-in-chief of Interscience Publishers Inc., addressed to Busemann, starts with:[9] "It is with very special pleasure indeed that we learn from Dr. Stocker of your willingness to present in our Tracts series an account of important recent development of the work of certain Russian geometers." The letter refers to the work of A. D. Aleksandrov and the school he founded in Russia. I am not going to attempt any review of the results of Aleksandrov and his school because this would lead us much too far, but I shall mention some of this work later in this chapter. It is interesting to know that Busemann's book on convexity which was initially planned to be a review of the work of the Russian school on this subject, was eventually translated into Russian in 1964, see

[9]The letter is part of Courant's correspondence kept at the Elmer Holmes Bobst Library in New York. Carbon copies of the letter were sent to Courant and to Bers.

(Busemann 1958). The book contains several important results on convex bodies. Among these results, let me mention a proof of a theorem in convexity theory that was independently obtained by Busemann and Fenchel and Jessen (Fenchel and Jessen 1938), stating that if two convex bodies in Euclidean n-space have equal p-th order area measure (we shall not go into the definition here) for some p satisfying $1 \leq p \leq n - 1$, then the two bodies are the same up to a translation.

7 Busemann's Work Recognition

The recognition of Busemann's work came from the Soviet Union. In 1985, he was awarded the Lobachevsky Prize "for his innovative book *The Geometry of geodesics.*" The book was written 30 years before. The Lobachevsky Prize (or Lobachevsky medal, depending on the epoch and on the institution which delivered it), is still a prestigious prize. Its first recipients were Sophus Lie in 1897, Wilhelm Killing in 1900, and David Hilbert in 1903. A. D. Aleksandrov obtained it in 1951. The list of the more recent recipients includes Weyl, Pontryagin, H. Hopf, P. S. Alexandroff, Efimov, Kolmogorov, Hirzebruch, Arnold, Margulis, Gromov, and Chern.

Busemann's work was not appreciated for its true value in the West. In the three-volume set titled *A Century of Mathematics in America* (Duren et al. 1988) published in 1988 by the AMS, there is no mention of Busemann's work. In a letter to V. Pambuccian, dated November 26, 1989 and published in Volume II of Busemann's *Selected Works* (Busemann 2018b, p. 64), Busemann writes: "... Your complaint regarding the neglect of synthetic geometry in the USA is unfortunately justified. *The Geometry of Geodesics* (GG) and *Recent synthetic Differential Geometry* are still available, however for ridiculously high prices. . . . The absence of interest in the USA is recognizable from the very fact that every year there are approximately twice as many copies sold abroad than in the USA. And the factor two is probably lower than the real one, for three of my books were translated in Russian, and appeared in well-printed, large, very cheap editions, e.g., GG costs 1.88 rubles."

Busemann's work started to be recognized in the West only in the 1980s, when metric geometry was revived by M. Gromov, who introduced the methods of synthetic global geometry. In fact, metric geometry became fashionable in France after Gromov started giving courses on this topic in Paris at the end of the 1970s. His 1979 course was published in several editions, see (Gromov 1981). Igor Belegradek, in his *Math Reviews* review of the first English edition of this book (1991), writes that it is "one of the most influential books in geometry in the last twenty years." This coincided with the last years of Busemann's career. Gromov is an heir of the Russian school of metric geometry founded by A. D. Aleksandrov. I will talk about the latter in the next section.

8 On the Work of A. D. Aleksandrov

A. D. Aleksandrov founded an important school on metric geometry, with a large number of students and collaborators. Like Busemann, he was interested in the most basic notions of geometry. Classical problems of convexity, isoperimetry, and

isoepiphany, on which he and the school he founded were working, became at the forefront of research. For him, like for Busemann, classical synthetic geometry and the old geometric problems that originate in Greek Antiquity were more important than Riemannian geometry based on linear algebra and tensor calculus. In some sense, his work was a return to Euclid and Archimedes.

Like Busemann, Aleksandrov's interest abides in the most basic notions of geometry. Aleksandrov's work was perpetuated by his students and his student's students. Yurii Burago, Yurii Borisov, Ilya Backelman, Alexei Pogrelov, Victor Zalgaller, Grigorii Perelman, Yurii Reshetnyak, Anton Petrunin, and Valerii Berestovskii are among his descendents – there are many others. Aleksandrov was an invited speaker at the 1960 ICM, where he delivered a talk titled *Modern development of surface theory* (Aleksandrov 1960) in which he presented an outline of his work together with that of his students, including the metric condition of the boundedness of curvature of triangles in terms of angle excess leading to this metric definition of curvature, and a variety of notions and results obtained under the condition of bounded curvature, including a definition of area, a study of convexity, embedding problems, parallel translation, and several others. We saw that in the paper (Busemann and Feller 1936), Busemann and Feller proved that a convex surface in three-dimensional space has a second order differential at almost every point, and that the Dupin indicatrix has the usual form.

In 1939, A. D. Aleksandrov extended this result to an arbitrary convex hypersurface in n-dimensional Euclidean space. I refer the reader to Aleksandrov's book *Intrinsic geometry of convex surfaces* (Aleksandrov 2005), in which he provided proofs of the theorems of Euler, Meusnier, and Rodrigues in the general setting of convex surfaces, attributing these generalizations to Busemann and Feller. In the same book, he proved that any convex two-dimensional manifold is nonnegatively curved in the sense he introduced and which we recalled above, and that every nonnegatively curved two-dimensional manifold homeomorphic to the sphere is isometric to some convex surface.

We mentioned Busemann's work on "timelike spaces," which provides a geometric setting to general relativity. Aleksandrov with his students developed a similar theory, which they called *chronogeometry*, see the review in (Papadopoulos 2018c) and the references there.

The metric notions of curvature introduced by Aleksandrov and by Busemann turned out to be at the bases of very important developments in geometry, and the terms "Busemann geometry" and "Aleksandrov geometry" refer to these works. Two AMS Mathematics Subject Classification codes carry the names of Busemann and Aleksandrov geometries[10] and there is a multitude of theorems and research problems that rely on their intrinsic definitions of the sign of the curvature.

In (Kutateladze et al. 2012), Kutateladze, Novikov, and Reshetnyak write:

[10]These are: 53C70: Direct methods (G-spaces of Busemann, etc.) and 53C45: Global surface theory (convex surfaces la A. D. Aleksandrov).

> It would be impossible to understand Aleksandrov's philosophy without turning to the roots of the science he loved best. In 1981 he wrote: "The spirit of modern mathematics lies in the tendency to return to the Greeks." His favorite motto was: "Back to Euclid!" Geometry was a part of the culture of the ancient world.

They also write:

> Aleksandrov steered mathematics toward the synthetic geometry of the ancients in a much subtler way than is now recognized. What is meant is not just a transition from smooth local geometry to geometry in the large without restrictions on differentiability. By enriching differential geometry with the tools of functional analysis and measure theory, he strove to regain the grandeur of mathematics in the times of Euclid. And by synthesizing geometry with other branches of twentieth-century mathematics, he aspired to the ancient ideal of a unified science.

See also the article (Katateladze 2012) with the significant title *Aleksandrov of Ancient Hellas*. Likewise, Zalgaller, in his paper (Zalgaller 2012) writes about Alexandrov: "When talking about methodology, he often pronounced the slogan: 'Retreat to Euclid!', fighting for visual methods."

9 In Guise of a Conclusion

Since his doctoral dissertation and until the end of his life, Busemann used to formulate problems and work on them without relying on the trends that were fashionable in his time. In an article that appeared in the Los Angeles Times on June 14, 1985, (Dembart 1985), on the occasion of the attribution of the Lobachevsky Prize to Busemann, the author writes: "Few mathematicians ever make it into public consciousness, but Busemann has had a hard time even within his own field, in part, at least, because he never worked on trendy problems and never followed the crowd." The same journalist quotes Busemann saying: "If I have a merit, it is that I am not influenced by what other people do."

A geometry freed from the dominion of differential calculus kept growing since the last quarter of the twentieth century, reinvigorated in the works of Thurston whose methods constitute a return to the synthetic methods of non-Euclidean geometry, and of Gromov, closer in spirit to the Busemann and Aleksandrov approaches. Problems on area and volume, isoperimetry, and convexity, became catalyzers of a new trend of mathematical research.

Finally, I started this article by mentioning Leibniz. I would like to end it by mentioning another mathematician-philosopher, René Thom.

Thom was one of the main founders of modern topology. His work on cobordism, for which he was awarded the Fields medal in 1958, inaugurated the combination of the methods of differential topology with those of algebraic topology. He writes in (Thom 1991, p. 10) that in his youth, "[he] had a certain taste for Euclidean geometry which immediately attracted [him] very much." He kept this taste for Euclidean geometry – the "old Euclidean geometry," as he used to call it, with its constructions,

criteria for triangle equality, etc. all his life, even though, in the mathematical milieu in which he was to evolve, it was against the grain. Having disappeared from the school and university curricula. Euclidean geometry became a field not only unknown, but, what is worse, he said, poorly understood. He writes in (Thom 2004): "I have kept a preference for Euclidean geometry that my colleagues and fellow mathematicians do not forgive me."

Busemann's work is still poorly known and greatly underrated. I find no good reason for that, except that this work lacks publicity, which, it seems, Busemann himself was reluctant to do. In his letter to V. Pambuccian, dated November 26, 1989, which I quoted above, he writes: "The reason for the neglect of synthetic geometry appears to me to lie first in the fact that every professor cares about seeing his ideas live on via his students. To admit that his methods use to a large extent unnecessary hypotheses is inconvenient and is simply swept under the rug. In fact, I do not know, except for some of my students, anybody in the USA who has actually read GG."

Abstract

Mathematical logic is the study of reasoning about mathematical objects and the degree to which mathematical and scientific reasoning can be formalized and mechanized. Logic provides the foundations of mathematics and of theoretical computer science. Classical logic defined truth, developed the theory of infinite numbers, resolved paradoxes of naive set theory, defined what an algorithm is, and established that certain mathematical principles are independent from the rest of mathematics. Modern logic contributes to current developments in mathematics and its foundations, and continues to closely interact with various areas of mathematics. Essential and surprising connections are often found in order to solve big problems. To bring various resources into a single argument, common methods, uniform terminology, and concisely stated theorems are needed. This interaction of disciplines has not only led to new approaches and results but also to new areas of mathematical research, such as computable structure theory, reverse mathematics, and the emerging quantum computing theory.

1 Introduction

Mathematical logic is the study of mathematical and scientific reasoning and degree to which it can be formalized and made algorithmic. It also provides the foundations of mathematics. It studies the common language used in mathematics, how main mathematical objects are defined, and formalizes the laws of reasoning with these objects. Logic played a key role in developing the axiomatic systems for geometry, arithmetic, and analysis. It resolved foundational crisis of mathematics at the beginning of the twentieth century. This led to formalism championed by Hilbert. Hilbert's program for the foundations of mathematics involved formalization of classical mathematical theories based on consistent axiomatic systems, which are also complete. Work of Genzen, Gödel, Turing, Tarski, and others led to discovery of general phenomena about power and limitations of the axiomatic methods with deep mathematical and philosophical ramifications. In particular, Gödel's incompleteness theorem established that a consistent system with an algorithmic set of axioms, capable of expressing arithmetic, cannot be complete. Hence, there are statements that cannot be decided from the standard axioms, thus leading to nonstandard models of theories. A. Robinson developed precise model-theoretic machinery to extend the real numbers by infinite and infinitesimal numbers, allowing us to study calculus in the original framework of Newton and Leibniz.

Logic has been instrumental in solving some of the biggest mathematical problems, such as Hilbert's tenth problem and Dehn's word problem in combinatorial group theory. Hilbert's tenth problem asked whether there is an effective procedure to decide whether a given Diophantine equation has a solution in integers. Dehn's word problem was about groups presented by finitely many generators and relators and asked for an algorithm deciding whether two words in the generators represent the same element. Negative solutions to both problems were possible after decades of work by many mathematicians, but only after computability theory was established as an exact theory. Hilbert's tenth problem for rationals is currently one of the main open problems in mathematics. Computability theory also led to complexity theory in computer science where time and space resources for algorithms are taken into consideration. Complexity theory uses computable reductions to define the hardest problems within certain complexity classes. The question whether nondeterministic polynomial time algorithms can be simulated by deterministic polynomial time algorithms is one of the biggest open problems of our times.

Logic tries to explain essential phenomena of mathematical practice and to use these explanations to further contribute to mathematics. Set-theoretic developments in logic established that some principles mathematicians ordinarily use in their practice are neither provable nor refutable from the rest of mathematics, thus reflecting certain philosophical and practical preferences. In current mathematical practice, various areas of logic and, more broadly, mathematics continue to interact with each other in an essential way leading to new, more general discoveries. The chapters in this section present several areas of logic and mathematics and their interactions with mathematical practice. While the chapters survey some of the

fundamental notions and results of classical logic, they also show modern topics of current research interest.

The main areas of mathematical logic include model theory, set theory, computability theory, proof theory, and others. One of the common themes is the study of definability in various structures and how it captures relevant semantic notions. Work in set theory provided the foundations of mathematics by showing that a great deal of mathematics can be formalized in terms of sets and their axioms. More recently, work in the foundations of mathematics, such as in reverse mathematics, focuses on establishing parts of mathematics within particular formal systems. Reverse mathematics has become a very active area of research. Its goal is to determine which principles are required to prove theorems of ordinary mathematics and is usually carried out using subsystems of second-order arithmetic. Results in reverse mathematics are intricate and involve interplay of mathematical logic with other areas of mathematics.

In the chapter *Model Theory of Nonstandard Structures with Applications*, Kossak focuses on three results in model theory, which he establishes using nonstandard models. Along the way, he presents and surveys many model-theoretic concepts and ideas. Model theory is the study of the relationship between formal theories and algebraic structures. It is closely related to universal algebra, the study of general algebraic structures. Model theory is also related to algebraic geometry, which deals with geometric problems involving zeroes of polynomials of several variables, as well as other related problems.

A *structure* $\mathcal{M}$ consists of a nonempty set M, called the domain or the universe, and certain constants, relations, and functions on the domain. Every relation and every function (or operation) has assigned a length or arity. The corresponding constant, relation, and function symbols form the *language* or the *signature* of the structure. The usual rational, real, or complex numbers with addition and multiplication have an algebraic *field* structure. Both addition and multiplication are associative binary operations. Every number has an additive inverse with 0 being the additive identity. Hence, when restricted to addition, these numbers have a commutative *group* structure. Every nonzero number has a multiplicative inverse with 1 being the multiplicative identity. Hence, the nonzero numbers also have a commutative group structure under multiplication. Integers with addition and multiplication form a *ring* structure. The size of natural numbers, integers, or rational numbers is $\aleph_0$, the smallest infinite size. On the other hand, the size of reals or complex numbers is $2^{\aleph_0}$, which is the same as the size of the power set of the set N of natural numbers, which is the set of all subsets of N.

Here, we are focusing on the first-order language and formulas. This language is fairly expressive for everyday mathematics. Gödel discovered the completeness theorem for first-order logic, which established the correspondence between provability in a formal system and truth in a structure. A *theory* is a set of sentences (formulas with no free variables) in a given language L. The theory of a structure $\mathcal{M}$ is the set of all first-order sentences it satisfies. It is *complete* since for each sentence either the sentence or its negation is true in the model. Two structures for the same language are *elementarily equivalent* if they satisfy the same first-order sentences.

An *automorphism* of $\mathcal{M}$ is a permutation p of its domain, which preserves the structure. For example, if $u * v = w$ in $\mathcal{M}$, then also $p(u) * p(v) = p(w)$ in $\mathcal{M}$. Thus, we can view p as renaming of the elements. More generally, for two structures, a bijection of the domains that preserve the structure is called an *isomorphism*. It is one of the main concepts of mathematics. Isomorphic structures are elementarily equivalent, but the converse is not true.

A theory may have more than one model, as Keisler says (Chang and Keisler 1990): "The mathematical world was forced to observe that a theory may have more than one model in the 19th century, when Bolyai and Lobachevsky developed non-Euclidean geometry, and Riemann constructed a model in which the parallel postulate was false but all the other axioms were true. Later in the 19th century, Frege formally developed the predicate logic, and Cantor developed the intuitive set theory in which our models live."

Any model of some theory not isomorphic to the intended, standard model is called *nonstandard*. The set of natural numbers is $N = \{0, 1, 2, \ldots\}$. The idea of establishing an axiomatic system that captures the *standard model of arithmetic*, $\mathcal{N} = (N, +, \cdot, 0, 1, <)$, was developed in the late nineteenth century by Dedekind and Peano. One of these formal systems became known as Peano arithmetic. It has an infinite but computable set of axioms. Hilbert asked for a proof that such a system is complete. However, an algorithmic set of such axioms generates an incomplete theory, as established by Gödel. The first-order theory of $\mathcal{N}$ is known as the true arithmetic. In 1934, Skolem constructed a nonstandard model of true arithmetic, hence elementarily equivalent to $\mathcal{N}$.

While the notion of a substructure plays an important role in algebra and mathematics in general, model theory has a stronger notion of an elementary substructure. Let $n \geq 1$. For an n-tuple $\overline{a}$ of elements in the domain, the *type* of $\overline{a}$ is the set of all first-order formulas with n variables, which are satisfied by $\overline{a}$. Thus, the type captures all first-order properties that $\overline{a}$ has in $\mathcal{M}$. For example, the element 1 has different types in the structure $(N, <)$ and its substructure $(N - \{0\}, <)$, as witnessed by the formula $\theta(x) : \forall y \neg (y < x)$. If p is an automorphism of $\mathcal{M}$, then the type of $p(\overline{a})$ is the same as the type of $\overline{a}$.

For two structures $\mathcal{S}$ and $\mathcal{M}$ for the same language, $\mathcal{M}$ is an *elementary extension* of $\mathcal{S}$ (equivalently, $\mathcal{S}$ is an elementary substructure or submodel of $\mathcal{M}$) if $S \subseteq M$ and the types of the finite tuples from S are the same in $\mathcal{S}$ and $\mathcal{M}$. It follows that a structure and its elementary extension are elementarily equivalent. One of the main results that is often used is that every infinite structure $\mathcal{M}$ has a proper elementary extension $\mathcal{M}^*$. If $\mathcal{M}^*$ is not isomorphic to $\mathcal{M}$, then $\mathcal{M}^*$ can be considered to be a nonstandard extension of $\mathcal{M}$. Moreover, if the language is at most countable, then there is a proper elementary extension of the same cardinality. The standard model of calculus is the usual ordered field of real numbers. In 1960, A. Robinson preciscely established another approach to calculus and analysis – nonstandard analysis. He extended the standard model to a nonstandard one containing infinite numbers and infinitesimals.

The analysis and classification of definable sets is an important part of model theory and logic in general. For a structure $\mathcal{M}$, an n-ary relation R on the domain

M is *definable* if there is a formula with n free variables, possibly with parameters from M, satisfied in $\mathcal{M}$ exactly by the tuples in R. Clearly, every finite set is definable since its elements can be taken as parameters. Hence, co-finite sets are also definable. A set is called *arithmetical* if it is definable in the standard model of arithmetic $\mathcal{N}$. Parameters are even not needed here since all natural numbers are definable. An infinite structure where the only definable sets are either finite or co-finite is called *minimal*. The ordered set of integers is not minimal since the set of natural numbers is definable. An important example of a minimal structure is the field of complex numbers, a result due to Chevalley and Tarski. Moreover, the field of complex numbers is *strongly minimal* since every elementarily equivalent structure is also minimal.

A structure is called *ordered* if one of its relations (named in the language) is a linear ordering. Kossak uses elementary extensions and automorphisms to show that the ordered set of natural numbers $(N, <)$ is minimal, demonstrating the power and elegance of this method. The structure $(N, <)$ is not strongly minimal since every proper elementary extension of it contains a copy of the ordered set of integers. An ordered structure is o-*minimal* (order-minimal) if each definable set is the union of finitely many open intervals and points. The ordered field of real numbers is o-minimal, a result due to Seidenberg and Tarski. Kossak uses a similar argument as above to show that the ordered set of integers is o-minimal.

The second application of the elementary extension method of the chapter is to establish an infinite Ramsey theorem based on arithmetic sets, a result by Kossak and Schmerl. Here, Kossak uses a conservative proper elementary extension of the standard model of arithmetic. An elementary extension is *conservative* if every definable set in the extension, when intersected with the subdomain remains definable in the substructure.

In the case of the field $\mathcal{C}$ of complex numbers, a proper elementary extension of the same cardinality turns out to be isomorphic to $\mathcal{C}$. On the other hand, no proper elementary extension of the field $\mathcal{R}$ of real numbers is isomorphic to $\mathcal{R}$. Kossak uses properties of reals, complex numbers, and their elementary extensions to show that there is a nontrivial automorphism of $\mathcal{C}$, which is not the complex conjugation. Then he shows that there are $2^{2^{\aleph_0}}$ automorphisms of $\mathcal{C}$, which is as many as there are functions from the set of all complex numbers to itself.

Kossak's examples illustrate how the arguments in nonstandard elementary extensions lead to results about the standard structures.

The chapter *Computability Theory* by Harizanov, Srinivasan, and Verta explains mathematical theory of algorithms, its development, and some of the current trends. The topics include various formalisms, effective enumerations, relative computability, arithmetical and hyperarithmetical hierarchies, and computable structures. Although the algorithmic method has been pervasive in mathematical practice for centuries, it was not sufficiently rigorous to deal with negative solutions to algorithmic problems that are now known as undecidable problems. Modern computability theory started in the 1930s and was founded by Gödel, Church, Petér, Turing, Kleene, Post, and others. In his influential 1936 paper, Turing invented what we

now call a *Turing machine*, which is essentially an abstraction of a computing agent. He also introduced the universal machine, which can simulate any other Turing machine on any input, leading to the idea of stored-program computer. Turing also proved that there are undecidable problems. Gödel was very pleased with Turing's approach. He wrote: "That this really is the correct definition of mechanical computability was established beyond any doubt by Turing."

There were other formalisms for an intuitive concept of an effectively calculable function, which turned out to be equivalent to Turing computability, thus leading to the same class of formally computable functions. Hence, this theory of algorithms provided the foundation for mathematical theory of computability (also known as recursion theory) and the emerging science of computing. Turing's formalism was the most convincing one. Soare (2016) says: "It was Turing who saw the computer itself in the marble, a simple intuitive device equipped with only a finite program and using only a finite sequence of strokes at each stage in a finite computation, the vision closest to our modern computer." The development of computability theory led to the acceptance of the *Church-Turing thesis* which says that a function is intuitively effectively calculable exactly when it is formally computable. This thesis is somewhat unique in mathematics since it is not a statement with a mathematical proof but an assertion that can be explained, defended, or debated.

A Turing machine on a given input may halt or it may not halt, computing forever. This leads to the notion of a partial computable function. Without loss of generality, we can consider only functions and relations on natural numbers. The set of inputs for which a partial function f is defined is called the *domain* of f. A partial function f is *partial computable* if there is a Turing machine that on every input in the domain of f halts and outputs its value, while it does not halt on inputs that are not in the domain of f. *Computable* functions are partial computable functions that are total. Partial computable functions are the same as partial recursive functions defined by Kleene, starting with some basic functions and applying the operations of composition, primitive recursion, and unbounded search. Computable functions are also called *recursive functions* or general recursive functions for emphasis. An important proper subset of recursive functions, known as primitive recursive functions, was previously used by Gödel in his work on formal arithmetic.

A relation R of natural numbers is *computable* if there is a Turing machine that always halts and on the elements in R outputs 1, while it outputs 0 on the elements in the complement (negation) of R. Equivalently, the characteristic function of R is computable. Hence, the negation of a computable relation is also computable. Since each Turing machine is a finite list of instructions, Turing machines can be computably enumerated, even without repetitions. For every $n \geq 1$, this enumeration gives a computable enumeration of all n-ary partial computable functions, now each function in the listing appearing infinitely often since it can be computed by infinitely many Turing machines. For $n = 1$, we have a computable listing of all unary partial computable functions: $\varphi_0, \varphi_1, \varphi_2, \ldots$ For a function φ_e, we can think of its index e as its Gödel code and can use e as an input for another Turing machine. This gives rise to a universal Turing machine, which can run any Turing machine on any input.

Church and Kleene introduced computably enumerable sets in 1936. We say that a set S is *computably enumerable* (also called recursively enumerable) if and only if S is empty or the range of a computable function. For example, the theorems in a formal system with a computable set of axioms form a computably enumerable set. It can be proven that a set is computably enumerable if and only if it is the domain W_e of some partial computable function φ_e. Clearly, every computable set is computably enumerable since a decision algorithm can be transformed into an enumeration algorithm. The converse is not true. The diagonal *halting set* K consists of all inputs e on which the Turing machine with index e halts, i.e., $K = \{e : e \in W_e\}$. It is easy to show that K is computably enumerable. However, K is not computable. It turns out that computable sets are exactly computably enumerable sets that also have computably enumerable complements. Since K is not computable, the relation $\{(e, x) : x \in W_e\}$ is also not computable, hence the halting problem of determining whether e-th Turing machine halts on input x is undecidable.

Computably enumerable sets are closely related to Diophantine equations and Hilbert's tenth problem mentioned earlier, which was posed in 1900 at the International Congress of Mathematicians in Paris. Diophantine equations are polynomial equations in finitely many variables. The problem asked to devise a process that determines whether any given Diophantine equation has integer solutions. The algorithmic solvability of a Diophantine equation in the integers is equivalent to the algorithmic solvability of a Diophantine equation in the natural numbers. The negative solution to the problem was obtained in 1970 after many years of work of Davis, Putnam, J. Robinson, and Matiyasevich. It is not hard to see that a set of natural numbers defined using existential quantifiers and a polynomial equation is computably enumerable. Such sets are called *Diophantine sets*. The corresponding polynomial is called its Diophantine definition. For example, the formula $\theta(x)$: $\exists y \exists z(x = (y + 2)(z + 2))$ defines composite numbers. In 1950, Davis conjectured that every computably enumerable set is definable by an existential polynomial formula. His conjecture was finally proven in 1970 which, together with the existence of computably enumerable sets that are not computable, shows the undecidability of the Hilbert's tenth problem.

Computability theory developed the following classification of sets and problems they encode. A set is Σ_0^0 or Π_0^0 if it is computable. For $n > 0$, a set A is Σ_n^0 if there is a computable $(n + 1)$-ary relation R such that for every $a \in N$, we have $a \in A \Leftrightarrow (\exists x_1)(\forall x_2)\cdots(Qx_n)\ R(a, x_1, x_2, \ldots, x_n)$, where Q is a corresponding quantifier. Π_n^0 sets are defined similarly starting with a universal quantifier. They are the complements of Σ_n^0 sets. It can be shown that computably enumerable sets are exactly Σ_1^0 sets. This hierarchy of sets of natural numbers is a proper hierarchy since Σ_n^0 sets are strictly contained in Σ_{n+1}^0 sets. Clearly, every Σ_n^0 set is also Π_{n+1}^0. It follows from Gödel's work that a set is first-order definable in the standard model of arithmetic $\mathcal{N}$ if and only if it belongs to the union of all Σ_n^0 sets, which is the same as the union of all Π_n^0 sets. Thus, such sets are called arithmetical, and the hierarchy is called *arithmetical hierarchy*. There is also correspondence between the complexity of the sets in the arithmetical hierarchy and the complexity of the defining formulas. A set is Δ_n^0 if it is both Σ_n^0 and Π_n^0.

We can relativize some of the notions of computability theory by using Turing's notion of an *oracle* machine. A machine with an oracle for a set X is a Turing machine which carries out its computation with the additional resource of read-only access to the characteristic function of X. Hence, even if a set Y is not computable, it may be computable with an oracle for another set X. For example, a set is computable in its complement. If an oracle is computable, then it can be eliminated. When Y is computable in X, we also say that Y is Turing reducible to X, or that the Turing degree of Y is $\leq$ than the Turing degree of X: $\deg(Y) \leq \deg(X)$. Two sets have the same Turing degree if they can be computed from each other. All computable sets have the least Turing degree, denoted $\mathbf{0}$. The Turing degree of any noncomputable set is strictly greater than $\mathbf{0}$. Turing degrees are only partially ordered since two Turing degrees can be incomparable, as was first shown by Kleene and Post. There are $2^{\aleph_0}$ Turing degrees and they have a very interesting structure.

The halting set relative to X is defined as K above but replacing the machines with machines with oracle X. It is also called the *jump* of X and denoted X'. Hence, K is the jump of any computable set. The Turing degree of X' is strictly greater than the Turing degree of X. Hence, there is no greatest Turing degree. The jump operator can be iterated, starting with K as the first jump. The second jump is K' and so on. There is following correspondence between arithmetical hierarchy and Turing degrees. While Δ^0_1 sets are the computable sets, Δ^0_2 sets are exactly those computable in the halting set K, and Δ^0_3 sets are exactly those computable in K', and so on. Arithmetical hierarchy can be extended to hyperarithmetical hierarchy by extending the definition of Σ^0_n and Π^0_n sets to Π^0_α and Σ^0_α sets for infinite constructive ordinals α.

In current research, computability theory interacts with other areas of logic and mathematics outside of logic leading to new areas such as computable structure theory, computable analysis, algorithmic randomness, reverse mathematics, etc. The chapter presents some of the ideas of computable structure theory where algebraic structures and constructions are effective. Even in 1930, a famous algebraist Van der Waerden introduced the notion of an explicitly given field as one "the elements of which are uniquely represented by distinguishable symbols with which addition, subtraction, multiplication and division can be performed in a finite number of operations." This led to the notion of a computable structure. A structure for a finite language is *computable* if its domain is computable and its functions and relations are computable. In computable structures, quantifier-free formulas define computable relations, and first-order formulas in general define arithmetical relations. The standard model of arithmetic is a computable structure. In computable structures, computable infinitary formulas define hyperarithmetical relations.

In the chapter *Reverse Mathematics*, Stillwell presents the program of reverse mathematics. The goal of reverse mathematics is to determine what axioms of mathematics are necessary to prove specific mathematical theorems. Partial motivation for this program goes back to the old mathematical questions about Euclid's *Elements* and later about some of the principles of set theory. The program of modern reverse mathematics was introduced by H. Friedman in his lectures at the International Congress of Mathematicians in Vancouver in 1974. It was also further

developed by Simpson and his students who established many of its first results. Many other researchers joined later, making it a very active research area. The context is usually second-order arithmetic, working over a weak base theory. Some of the definitions and methods are inspired by constructive analysis and proof theory. This study has very close connections to computability, as the natural models involved are well-behaved collections of Turing degrees, and the set existence axioms are related to logical definability and computational strength. For example, the common base theory RCA_0 states, roughly, that computable objects exist, and that induction can be performed on computably enumerable sets. Friedman explains in his founding paper (Friedman 1975) two principal themes that emerge: "I. When the theorem is proved from the right axioms, the axioms can be proved from the theorem. II. Much more is needed to define explicitly a hard-to-define set of integers than merely to prove their existence."

Stillwell presents the historical development of mathematical practice that led to reverse mathematics, as well as its main systems that can prove much of mainstream mathematics. He begins with the subsystem of Euclid's geometry without the parallel axiom, which is also called the *neutral geometry*. In this system, there are many interesting equivalents of the *parallel axiom*, which states that for any line and a point outside it, there is exactly one line through the point that does not intersect the line. Eventually, it was shown that the parallel axiom is not a theorem of the neutral geometry. Stillwell presents Beltrami's model from 1868 of neutral geometry where the parallel axiom does not hold since there is more than one parallel line. This leads to non-Euclidean geometries where the parallel axiom and its equivalents do not hold. Thus, the parallel axiom is i*ndependent* from the axioms of neutral geometry. It can neither be proved nor refuted. In general, if a theory T and a statement (sentence) σ are such that $T \cup \{\neg\sigma\}$ is consistent (has a model), then σ cannot be proved from a theory T. Here, T could be a base theory.

Stillwell further presents set theory starting with Cantor's naive set theory from 1874 and discovery of various infinite sizes. Two sets have the same size (cardinality) if there is $1-1$ and onto correspondence (bijection) between them. The size of every infinite countable set is $\aleph_0$. Cantor's diagonal argument can be used to show that for every set of size κ, its power set has a strictly larger size 2^κ. The sets of real and complex numbers are of size $2^{\aleph_0}$, the same size as the set of all infinite binary sequences. Using properties freely to define sets created Russell's paradox. In particular, the property $x \notin x$ gives us the "set of all sets that do not contain themselves," which after all could not be a set. If it were some set D, then we will have a contradiction: $D \in D \Leftrightarrow D \notin D$.

A *well-ordering* of a set is a total (linear) ordering of its elements such that every nonempty subset has the least element. The ordered set of integers is not well-ordered because the subset of negative integers does not have the least element. The orderings of natural numbers ω and other ordinals $\omega + 1, \omega + 2, \ldots, \omega + \omega, \omega + \omega + 1, \ldots$ are well-orderings. Cantor's bold hypothesis that every set can be well-ordered by some ordering presented further challenges. This statement became known as the well-ordering principle. Zermelo showed that the well-ordering principle is equivalent to

the axiom of choice. The *axiom of choice* says that for every set of nonempty sets, there is a function that chooses an element in each set. If the union of the sets can be well-ordered, then the least elements in the sets can be chosen. In 1908, Zermelo gave axioms of set theory by building sets from the empty set by certain constructions such as pairing, union, power set, definable subsets. There is also an axiom of infinity, which says that an infinite set exists. His system avoided Russell's paradox and proved the equivalence of the axiom of choice with the well-ordering principle. Zermelo's axiomatic system was abbreviated by Z. In 1922, Fraenkel added the axiom of replacement, which says that the image of any set under any definable function is also a set. This gave us to a stronger system, abbreviated by ZF, which now serves as a standard base system of set theory. In this system, there are many interesting equivalents of the axiom of choice, which are important in various areas of mathematics. For example, the axiom of choice is equivalent to the existence of a basis in any vector space. It has been shown that the axiom of choice is independent of ZF. Namely, Gödel obtained a model of ZF where the axiom of choice holds, and later Cohen produced a model of ZF where the axiom of choice does not hold. To establish this result, Cohen discovered a new method known as the forcing method.

Stillwell further presents the arithmetization of geometry and introduction of Dedekind cuts which reduce the arithmetic of real numbers to the arithmetic of rational numbers. Cantor's pairing function provides coding of pairs of natural numbers by natural numbers and allows coding of other mathematical objects by natural numbers. This is what Poincarė called at the beginning of the twentieth century the arithmetization of mathematics.

Peano arithmetic mentioned earlier is an axiomatic system for natural numbers with the unary successor function S, constant 0, addition, and multiplication. While the axioms say that the successor function is 1–1, and 0 is not in its range, addition and multiplication are captured by their recursive definitions: $x + 0 = x$ and $x + S(y) = S(x + y)$, and similarly for multiplication. In the first-order Peano arithmetic, there is an induction axiom schema for every first-order formula $\theta(x)$:

$$(\theta(0) \wedge \forall x(\theta(x) \Rightarrow \theta(S(x)))) \Rightarrow \forall x(\theta(x)).$$

In the second-order Peano arithmetic, there are also set variables denoted by capital letters. The second-order induction axiom is:

$$(0 \in X \wedge \forall x(x \in X \Rightarrow S(x) \in X)) \Rightarrow \forall x(x \in X).$$

There is also a comprehension axiom schema for any formula $\theta(x)$:

$$\exists X \forall x[x \in X \Leftrightarrow \theta(x)],$$

where formula θ can contain free set variables different from X. A comprehension scheme states that any set of natural numbers definable by a formula exists.

Gödel introduced the arithmetization of computability. For $n > 0$, a first-order formula is Σ_n^0 if it is equivalent to a formula in the prenex normal form which begins

with a block of existential quantifiers and has n alternations of blocks of quantifiers. Π_n^0 formulas are defined similarly starting with a block of universal quantifiers. The negation of Σ_n^0 formula is a Π_n^0 formula and vice versa. In particular, computably enumerable relations are captured by Σ_1^0 formulas of Peano arithmetic. Furthermore, it can be shown that a property is computable (recursive) if it can be defined both by a Σ_1^0 and a Π_1^0 formula in arithmetic. A formula equivalent to both Σ_1^0 and a Π_1^0 formula is also called a Δ_1^0 formula.

This brings us to the base system for reverse mathematics known as RCA_0 standing for *recursive comprehension axiom* (with the subscript indicating a particular version of the system). In RCA_0, the induction schema is restricted to Σ_1^0 formulas and the set existence axiom schema to Δ_1^0 formulas. This comprehension schema is saying that for every computable property, there is a corresponding set X. More precisely, if there are Σ_1^0 formula γ and Π_1^0 formula δ such that

$$\forall x[(\theta(x) \Leftrightarrow \gamma(x)) \wedge (\theta(x) \Leftrightarrow \delta(x))], \text{then } \exists X \forall x[x \in X \Leftrightarrow \theta(x)].$$

The minimal model of RCA_0 is the set of natural numbers with computable sets. RCA_0 can be viewed as a formalization of constructive mathematics. While RCA_0 can prove few important theorems in analysis, Stillwell shows that it cannot prove even the weak form of Bolzano's principle – that a bounded nondecreasing sequence of rational numbers has a limit.

Many problems in mathematics can be viewed as choosing an infinite path in a tree. A subtree of the full binary tree is a subset of its nodes, which is closed under initial segments. Such a tree is computable if its set of nodes is computable. The full binary tree has $2^{\aleph_0}$ infinite paths. A new axiom which we will consider is called *weak König's lemma*. It states that an infinite binary tree has an infinite path. Weak König's lemma is a theorem in infinite combinatorics since we can choose an infinite path by extending a finite path by adding the leftmost node with an infinitely many successors. However, there are computable infinite binary trees without computable infinite paths, so RCA_0 cannot prove weak König's lemma. When added to RCA_0, it gives us a stronger system WKL_0, which is the right axiomatic system for many theorems. Weak König's lemma has many interesting equivalents in RCA_0. For example, Friedman established that it is equivalent to the Heine-Borel theorem that any covering of the interval $[0, 1]$ by an infinite sequence of open intervals contains a finite subcovering. The full König's lemma states that an infinite finitely branching tree has an infinite path. The full König's lemma is not provable in WKL_0.

In an even stronger system ACA_0, standing for *arithmetic comprehension axiom*, the second-order induction axiom scheme is allowed, and the comprehension axiom scheme is allowed for arbitrary formulas. This system implies the first-order induction for all formulas. ACA_0 can prove all axioms of the first-order Peano arithmetic. The minimal model of ACA_0 is the set of natural numbers with arithmetical sets. ACA_0 can prove a number of important theorems in analysis, the full König's lemma, and some theorems in infinite combinatorics. Friedman proved that ACA_0

is conservative over the first-order Peano arithmetic in the sense that the theorems of the first-order Peano arithmetic are exactly those of ACA_0 that involve only variables for natural numbers.

These three systems are sufficient to prove a great deal of mainstream mathematics, but there are two other well-known systems that capture some theorems beyond the reach of ACA_0. These systems are ATR_0 and Π^1_1-CA_0, standing for arithmetical transfinite recursion, and comprehension for formulas with the second-order universal quantifier, also known as Π^1_1 formulas. ATR_0 can be viewed as a formalization of *predicative* mathematics, a program advocated by Poincaré and Weyl in which a set cannot be defined in terms of a collection that includes the set itself. On the other hand, Π^1_1 comprehension allows nonpredicativity. Together, these five systems are known as "big five." Reverse mathematics always looks for minimal resources needed to prove a theorem, leading to new systems.

The chapter *Countable Nonstandard Models: Following Skolem's Approach* by Dimitrov and Harizanov goes back to Skolem's original construction of a *countable* nonstandard model of arithmetic. The chapter presents this construction and shows how it provides an idea for the construction of more effective nonstandard models, a topic of current research interest. The existence of a nonstandard model of arithmetic is now often proven using the compactness theorem for first-order logic. The compactness theorem says that a set of sentences has a model exactly when every finite subset of sentences has a model. The existence of nonstandard models can also be established by ultrapower constructions. The ultrapower construction is very elegant, but it depends on the axiom of choice and typically produces uncountable structures from infinite structures.

Going back to Skolem's construction from 1934 and in Skolem (1955) was very illuminating since it provided a direct connection with current investigation of effective ultrapowers. Skolem's original proof produces a countable nonstandard model in an explicit way. Skolem (1955) says: "More than 30 years ago I proved by use of a theorem of Löwenheim that a theory based on axioms formulated in the lower predicate calculus could always be satisfied in a denumerable infinite domain of objects. Later one has often expressed this by saying that a denumerable model exists for such a theory. Of particular interest was of course the application of this theorem to axiomatic set theory, showing that also for this an arithmetical model can be found." In 1959, Tennenbaum proved that there is no computable nonstandard model of arithmetic.

The ultraproduct construction is a major mathematical tool that is used in algebra, mathematical logic, and other areas. It allows us to construct new models of theories from old ones. The ultraproduct construction has some striking applications, such as a very elegant proof of the compactness theorem for first-order logic and the construction of a nonstandard model of analysis. The ultraproduct is a quotient of the direct product of structures modulo an equivalence relation determined by an ultrafilter. An ultrapower is an ultraproduct when there is only one structure. Ultrafilters are also used to determine the truth in the ultraproduct. To describe an ultrafilter, first start with a nonempty set I (for example, $I = N$) called the index set, which will be used to index structures. An *ultrafilter* over I is a nonempty set U of subsets of I such that U is closed

under the intersection of two sets and under the superset relation, and for every subset X of I, either X or its complement belongs to U. The construction of nontrivial ultraproducts requires nonprincipal ultrafilters. An ultrafilter is *nonprincipal* if it does not contain any singletons. The existence of nonprincipal ultrafilters, however, cannot be proven in ZF. However, the axiom of choice proves not just the existence of nonprincipal ultrafilter but a stronger statement called the ultrafilter lemma, which is strictly weaker than the axiom of choice. Łoś's Theorem, sometimes called the fundamental theorem of ultraproducts, establishes the satisfiability in the ultraproduct. An important consequence of Łoś's theorem is the following: if $\mathcal{B} = \prod_U \mathcal{A}$ is an ultrapower, then $\mathcal{A}$ and $\mathcal{B}$ are elementarily equivalent.

Dimitrov encountered the need for an effective ultrapower construction while investigating the automorphisms of the structure of computably enumerable vector spaces. It turned out that similar constructions had been used before to study models for fragments of arithmetic, first by Feferman, Scott, and Tennenbaum, and later by Lerman, Hirshfeld, and Wheeler. In 2009, Dimitrov introduced the notion of a cohesive power of computable structures. It is an effective ultrapower construction, which starting with an infinite computable structure produces an infinite countable structure. The role of an ultrafilter is played by a cohesive set. Cohesive sets are infinite sets of natural numbers, which are indecomposable by computably enumerable sets. More precisely, an infinite set C of natural numbers is *cohesive* if for every computably enumerable set W with complement $\overline{W}$, either the intersection $W \cap C$ or the intersection $\overline{W} \cap C$ is finite. Given a cohesive set C, we start with a computable structure and in its countable infinite power consider partial computable sequences modulo C. Hence, an effective ultrapower is always at most countable structure and it can be isomorphic to the original structure. However, in general, by Dimitrov's theorem, effective ultrapowers preserve only first-order properties expressed by sentences at lower levels of arithmetical hierarchy. It is possible for isomorphic computable structures to have non-elementarily equivalent effective ultrapowers over a fixed cohesive set.

We will now give a more precise definition of a cohesive power over a cohesive set C. Let us restrict ourselves to a finite language L. Let $\mathcal{A}$ be a computable structure for L with domain A contained in N. The cohesive power of $\mathcal{A}$ will be denoted by $\prod_C \mathcal{A}$. For convenience, let $\mathcal{B} = \prod_C \mathcal{A}$. Let D be the set of all partial computable sequences ψ with elements in A, which are defined on almost all (i.e., all but finitely many) elements of C. Two such sequences are equal modulo C if on almost all elements of C, they are defined and equal. Equivalence modulo C is an equivalence relation, and the elements of the cohesive power of $\mathcal{B}$ are the equivalence classes $[\psi]$ of partial functions ψ in D. Let R be a relation symbol in L, say a binary one. Then $R^{\mathcal{B}}([\psi], [\phi])$ if and only if the set of all i such that $\psi(i)$, $\phi(i)$ are defined and $R^{\mathcal{A}}(\psi(i), \phi(i))$ contains all but finitely many elements of C. The interpretation of a function symbol in $\mathcal{B}$ is defined pointwise. If c is a constant symbol in L, then the interpretation of c in $\mathcal{B}$ is the equivalence class of the constant sequence with value $c^{\mathcal{A}}$.

Dimitrov proved a variant of Łoś's theorem for cohesive powers: all Π_2^0 and Σ_2^0 sentences are true in $\mathcal{A}$ if and only if they are true in a cohesive power of $\mathcal{A}$. While Π_3^0

sentences true in a cohesive power of $\mathcal{A}$ are also true in $\mathcal{A}$, the converse does not hold. Feferman, Scott, and Tennenbaum found a Π^0_3 sentence that is true in the standard model of arithmetic but not in its cohesive power. Recently, simpler examples of such sentences have been produced for linear orders, the cohesive powers of which has been investigated by Dimitrov, Harizanov, Morozov, Shafer, A. Soskova, and Vatev. They also showed that if a structure $\mathcal{A}$ is n-decidable, then its cohesive power satisfies the same Π^0_{n+2} and Σ^0_{n+2} sentences as $\mathcal{A}$ does. The *elementary diagram* (or complete diagram) of a structure $\mathcal{A}$ is the set of all first-order sentences of L with added constants for the elements of the domain, which are true in $\mathcal{A}$. A Σ^0_n *diagram* of $\mathcal{A}$ is the set of all Σ^0_n sentences in the elementary diagram. A structure is *n-decidable* if its domain is computable and its Σ^0_n diagram is computable. A structure is *decidable* if its domain is computable and its elementary diagram is computable. Computable structures are the same as 0-decidable structures. Hence, for a decidable structure, the effective ultrapower is elementarily equivalent to the structure. Thus, more decidability in the structure leads to more satisfiability in the effective ultrapower.

The chapter *Fermat's Last Theorem* by McLarty presents the historical development of the ideas and knowledge needed for the solution of one of the most famous problems in mathematics, which has had great impact on several different areas. Fermat's last theorem states that no three nonzero integers a, b, and c satisfy the equation $a^n + b^n = c^n$ for any natural number $n > 2$. It has a very long history. Around 1637, Pierre de Fermat wrote on a margin of his copy of *Arithmetica* that he has a "marvelous proof" that there is no such solution, a remark discovered only after his death. For $n = 2$, there are infinitely many such solutions, known as Pythagorean triples. While Fermat himself had a proof for $n = 4$, no general proof of his statement was found, so the statement became known as Fermat's conjecture. For a long time, Fermat's conjecture seemed like an isolated statement of number theory without many connections to other areas of mathematics and without significant philosophical interest. In spite of efforts of many, the conjecture remained unresolved until 1994 when Andrew Wiles (with help of Richard Taylor) completed the proof he announced a year earlier, confirming Fermat's conjecture.

It can be shown that to prove that Fermat's equation has no solution for $n > 2$, it suffices to prove that it has no solution for $n = 4$ and for all odd primes n. The special cases for $n = 3$, 5, and 7 were resolved in the eighteenth and nineteenth century by Euler, Dirichlet and Legendre, and Lamé, respectively. Moreover, in the early nineteenth century, Germain developed several new approaches toward more general solution of the problem and established a theorem about the divisibility of solutions to Fermat's equation. In the mid-nineteenth century, Kummer obtained a proof for prime exponents known as regular primes.

The case $n = 3$ was first established by Euler in the 1770s. Although his proof had a part that needed to be fixed, McLarty argues that it was very clever and contributed to the idea of the emerging field of algebraic number theory. One of the central topics of algebraic number theory is the study of algebraic number fields. An algebraic number field is a finite-degree extension of the field $\mathbb{Q}$ of rational numbers, where degree means the dimension of the field as a vector space over $\mathbb{Q}$. For example, a

field can be extended by the adjunction of the k-th roots of elements of the field. Kummer's work on Fermat's last theorem contributed to the development of this theory. Algebraic number fields contain rings of integers, which may or may not have unique prime factorization, the topic which led to the development of the theory of ring ideals and class field theory. The need for such new concepts illustrates what philosophers call formation of mathematical concepts. While these developments produced many important results, the methods stemming from Kummer's work failed to completely resolve Fermat's conjecture.

It turned out that the solution to Fermat's conjecture was closely related to several other areas of mathematics, including number theory and geometry. McLarty talks about the *Langlands program* which is a broad project in modern mathematical research about various important and influential connections between number theory and geometry. In the 1970s, Hellegouarch and Demyanenko linked Fermat's conjecture to the arithmetic of elliptic curves. A *real elliptic curve* is defined by the cubic equation $y^2 = x^3 + ax + b$, where the coefficients a, b are real numbers and the roots of the right-hand side are all distinct. If a and b are rational numbers, such an elliptic curve is called an *arithmetic elliptic curve*. It is an amazing geometric fact that the intersecting lines with the cubic curve determine rational points on the curve that form a commutative group. A point is rational if both of its coordinates are rational numbers. A point r is torsion if $nr = 0$ for some positive natural number n. Hellegouarch and Demyanenko independently showed that if certain kinds of torsion points can occur on arithmetic elliptic curves, then Fermat's Conjecture will be refuted. However, Mazur proved that such points are not possible.

While quadratic curves have genus 0, and elliptic curves have genus 1, the curves of the Fermat's equations for $n > 3$ have genus >1. Mordell conjectured that every algebraic curve with genus >1 has finitely many rational points. In 1983, Faltings established Mordell's conjecture by proving that any equation in two variables corresponding to a curve of genus >1 has finitely many rational solutions. This led to the result marking a big progress toward establishing Fermat's conjecture, that for each exponent $n > 2$, Fermat's equation has at most finitely many integer solutions.

Frey associated to every integer solution of the Fermat's equation with exponent n an elliptic curve, which later became known as Frey-Hellegouarch curve. Proving Fermat's last theorem amounted to showing that such a curve does not exist. In 1982, Frey suggested that these curves cannot have certain property called modularity. Serre formulated the conjecture precisely, which was later proven by Ribet and published in 1990. The *modularity conjecture*, also known as Shimura-Taniyama-Weil conjecture, which states that every arithmetic elliptic curve is modular would establish Fermat's conjecture. Ribet's theorem showed that establishing the modularity conjecture for a class of elliptic curves called semistable elliptic curves would be sufficient for the proof of Fermat's last theorem. Wiles announced his proof in 1993, but there was a gap, which was circumvented with assistance from Taylor and completed in 1994. (Full modularity conjecture was proved in 2001.)

Ribet's proof builds on many earlier results. McLarty also argues that Ribet's and other proofs implicitly use the language of category theory. Wiles' proof is based on replacing the problems about elliptic curves with the problems of Galois

representations, which are algebraic in nature. He then uses Mazur's theory of deformations. The full proof is contained in two papers, one by Wiles and one written jointly by Wiles and Taylor, which together make up the whole of the May 1995 issue of the *Annals of Mathematics*. Wiles's proof is amazing, suggesting further applications and discoveries. In 1993, Mazur said (Kolata 1993): "A lot more is proved than Fermat's last theorem. One could envision a proof of a problem, no matter how celebrated, that had no implications. But this is just the reverse. This is the emergence of a technique that is visibly powerful. It is going to prove a lot more."

Now, the logic question arises whether Fermat's last theorem is provable in Peano arithmetic or some finitary fragment of Peano arithmetic. This is widely open. Peano arithmetic can interpret polynomials with integer coefficients and can deal with rational approximations to real numbers. McLarthy explains Macintyre's argument that the real challenge to proving Fermat's last theorem in Peano arithmetic is finding approximations to the modularity theorem. Bounded arithmetic with exponentiation is also called exponential function arithmetic and abbreviated by EFA. It is worthwhile to investigate whether Fermat's last theorem is provable in EFA.

McLarty shows how Fermat's last theorem demonstrates the unity of mathematics and interactions of different and seemingly disconnected areas. It inspired new areas to be created. It also demonstrated the need to state results precisely and in a common, uniform, and efficient language so that they are available to other disciplines if needed. It showed that concrete examples are often useful as guide and illustrations of more abstract and more general theories.

Abstract

Every infinite mathematical structure $\mathcal{M}$ has an extension $\mathcal{M}^*$ that has the same first-order properties as $\mathcal{M}$, but is not isomorphic to $\mathcal{M}$. In this sense, $\mathcal{M}^*$ can be considered a nonstandard extension of $\mathcal{M}$. A short discussion of the idea of nonstandard models is followed by proofs of three easy standard results that use nonstandard extensions in essential ways. The aim is to explain basic model-theoretic concepts behind such proofs.

1 Introduction

The set of natural numbers N with addition and multiplication is called the standard model of arithmetic. A model of arithmetic is the set of positive elements of a discretely ordered ring whose addition and multiplication satisfy a set of arithmetic axioms. A model of arithmetic is nonstandard if it is not isomorphic to the standard model.

True Arithmetic, TA, is the set of all first order sentences that hold in the standard model. In a 1934 paper, Thoralf Skolem gave a construction of a nonstandard model of TA. This was originally seen as a negative result: first-order logic is incapable of characterizing the standard model up to isomorphism. The nonstandard models showed up as uninvited guests obfuscating the foundational landscape of mathematics. Hence, perhaps slightly pejorative label "nonstandard."

In the development of mathematical logic in the second half of the 20th century, nonstandard models of arithmetic got vindicated. Here is a quotation from Gaifman (2004):

> Non-standard models are interesting mathematical structures, studied as such. Their interest is to a large extent logic oriented, stemming from the fact that the models share many properties with the standard one, but is very different structurally.

Nonstandardness in set theory has a different nature. In arithmetic, there is one intended object of study – the standard model. There is no intended model in set theory. Set-theorists talk about universes of sets, but what happens in those universes very much depends on the axioms that they satisfy, and there are many axiomatic systems to choose from.

There is no standard model of set theory, but still there is a notion of nonstandardness. The core of each model of set theory is its class of ordinal numbers. Each ordinal number α is a well-ordered set of ordinal numbers smaller than α. Every model of set theory thinks that its ordinals are well ordered. This means that each subset of α, that is an element of the model has a least element. However, α may have other subsets, and those subsets may not have least elements. If this happens, the model is considered nonstandard.

In the 1960s, Abraham Robinson, inspired by Skolem's discovery of nonstandard models of arithmetic, introduced a new approach to infinitesimal calculus – nonstandard analysis. He used model theory to move analysis from the (standard) ordered field of real numbers to its (nonstandard) extension that included infinite numbers and infinitesimals. The standard/nonstandard terminology applies mostly to the distinction between the standard real numbers and the infinite numbers and infinitesimals.

In nonstandard analysis, and in some applications of nonstandard models of arithmetic, one uses elementary extensions to formalize arguments involving infinitely large and infinitely small quantities. It matters that the usual arithmetic and algebraic arguments apply to such quantities as well. Structural, model-theoretic properties of the extension usually do not play a role.

I will present nonstandard proofs of three standard results that use model theory in a different way.

Every infinite structure has an elementary extension. There is an extensive knowledge on where such extensions come from and what properties they may have. If $\mathcal{N}$ is an elementary extension of $\mathcal{M}$, the key observation is that while $\mathcal{M}$ and $\mathcal{N}$ share the same first-order properties, their second-order properties may be very different, and that can be useful.

Here is a quick example. All details are explained in the following two sections. Let (N, <) be the ordered set of the natural numbers. If (N^*, <) is an elementary extension of (N, <) then $N^*\backslash N$ has no least element. While (N, <) is well-ordered, (N^*, <) is not. Being well-ordered is a second-order property. Its definition has a quantifier ranging over all subsets of the ordered set. We will take advantage of the difference between (N, <) and (N^*, <) to prove something about (N, <), namely, we will show that (N, <) is minimal, as defined in the third section. The result itself is just an observation, but its proof is remarkable. Since (N, <) is well ordered, it has no nontrivial automorphism. No elementary extension of (N, <) is well ordered, and all elementary extensions of (N, <) admit nontrivial automorphisms. We will use this structural property to prove the result.

In the fourth section, I will give a nonstandard proof of the infinite Ramsey theorem. The proof is only a modification of the standard proof, but I will also outline a proof of a stronger result that uses a specific result about conservative elementary extensions of model of arithmetic.

The last section is devoted to a proof that the field of complex numbers $\mathcal{C}$ has a nontrivial automorphisms other than complex conjugation. The result formulated this way is a bit unusual. Every permutation of a transcendence basis of $\mathcal{C}$ extends to an automorphism; hence, the automorphism group of the complex field is of cardinality $2^{2^{\aleph_0}}$. However, if we try to come up with an example of nontrivial automorphism that is not complex conjugation, none comes to mind. It is not hard to see that complex conjugation is the only nontrivial continuous automorphism. This suggests that other automorphisms are not easy to come by. In fact it has been shown that the statement that the complex field has only two automorphisms is consistent with the axioms of Zermelo-Fraenkel set theory (ZF) without the axiom of choice. The nonstandard argument, presented in the last section, allows to see that there must be automorphisms in question. The proof is generalized to show that the automorphism group of $\mathcal{C}$ has the maximum number $2^{2^{\aleph_0}}$ of conjugacy classes.

There are deep applications of nonstandard methods in algebra, analysis, topology, functional analysis, probability, stochastic analysis, and number theory. For examples, see Tao (2013) and Loeb and Wolff (2015). The results presented here are chosen for their simplicity. My main goal is to explain the elements of model theory behind them.

2 Preliminaries

This section is brief overview of basic concepts of model theory that will be used in this note.

In model theory, a structure is a set M, called the domain of the structure, together with sets of functions $\{f_i\}_{i\in I}$, relations $\{R_j\}_{j\in J}$, and constants $\{c_k\}_{k\in K}$. For each

i, j, and k, $f_i : M^{n_i} \to M$, $R_j \subseteq M^{m_j}$, and $c_k \in M$. The index sets are arbitrary, in particular, each of them could be empty.

We will use $\mathcal{M}$, $\mathcal{N}$ for structures and M, N, ... for their respective domains. The exceptions are N, Z, Q, R, and C, which stand for the sets of natural, integer, rational, real, and complex numbers.

The logical symbols of first-order logic are variables, Boolean connectives, existential and universal quantifiers, left and right brackets, and the equality symbol. The language of a structure $\mathcal{M}$ consists the set of function symbols f_i, relation, and constant symbols for the functions, relations, and constants of $\mathcal{M}$. The language of a structure is also called its signature.

By a formula of the language of a structure, we mean a first-order formula whose nonlogical symbols are in the language of the structure.

We will use the bar notation for tuples of elements and strings of variables. If $\varphi(\overline{x})$ is a formula in the language of a structure $\mathcal{M}$ and $\overline{a}$ is a tuple of elements of M, then we say that $\varphi(\overline{a})$ is satisfied in $\mathcal{M}$, written if $\mathcal{M} \models \varphi(\overline{a})$, if what $\varphi(\overline{x})$ says holds in $\mathcal{M}$. What I wrote here looks trivial. Just substitute "holds" for "is satisfied." Hidden under the rug is Tarski's formal definition of satisfaction that proceeds by induction on the logical complexity of formulas. What I mean by "$\varphi(\overline{a})$ holds in $\mathcal{M}$" refers to the intuitive understanding of first-order formulas that is taught in discrete mathematics courses. Tarski's definition can be found in any textbook on mathematical logic. For us here, the intuitive approach suffices.

A theory is a set of first-order sentences (formulas without free variables) in a given language. If T is a theory and $\mathcal{M}$ is a structure for the language of T, then $\mathcal{M}$ is a model of T, written $\mathcal{M} \models T$, if $\mathcal{M} \models \varphi$ for all φ in T.

A type of a tuple of elements from the domain of a structure $\mathcal{M}$, written $\mathrm{tp}^{\mathcal{M}}(\overline{a})$, is the set of formulas $\{\varphi(\overline{x}) : \mathcal{M} \models \varphi(\overline{a})\}$, where $\varphi(\overline{x})$ ranges over all formulas of the language of $\mathcal{M}$. In other words, $\mathrm{tp}^{\mathcal{M}}(\overline{a})$ is the set of all first-order properties that $\overline{a}$ has in $\mathcal{M}$.

If $\mathcal{M}$ and $\mathcal{N}$ are structures for the same language and $M \subseteq N$, then $\mathcal{N}$ is an elementary extension of $\mathcal{M}$ if for all tuples $\overline{a}$ from $\mathcal{M}$, $\mathrm{tp}^{\mathcal{M}}(\overline{a}) = \mathrm{tp}^{\mathcal{N}}(\overline{a})$. When we move from $\mathcal{M}$ to an elementary extension, the types of the tuples from $\mathcal{M}$ don't change. Below, when we say that $\mathcal{N}$ is an elementary extension of $\mathcal{M}$, we tacitly assume that M is a proper subset of N.

For an example of an extension that is not elementary, let $\mathcal{M} = (\mathrm{N} \setminus \{0\}, <)$ (0 is a natural number) and $\mathcal{N} = (\mathrm{N}, <)$. Let $\varphi(x)$ be $\forall y \neg (y < x)$. Then $\mathcal{M} \models \varphi(1)$ and $\mathcal{N} \models \neg\varphi(1)$; hence, $\mathrm{tp}^{\mathcal{M}}(1) \neq \mathrm{tp}^{\mathcal{N}}(1)$. In fact, for each $n > 0$, $\mathrm{tp}^{\mathcal{M}}(n) \neq \mathrm{tp}^{\mathcal{N}}(n)$, and that is because each element of either structure is uniquely determined by the number of elements separating it from the least element, and there is a first-order sentence expressing that number is n; one sentence for each natural number n.

The compactness theorem says that if every finite set of sentences of a theory T has a model, then T has a model. The following theorem is an easy consequence of the compactness theorem. It can also be proved directly by an ultrapower construction. Ultraproducts and ultrapowers are in the arsenal of nonstandard methods and are important for applications in algebra. For a full discussion and advanced applications in commutative algebra, see Schoutens (2010).

We say that a structure is infinite if its domain is infinite.

Theorem 1 *Every infinite structure has an elementary extension.*

Let $\mathcal{M}$ be (M, f, R, c), where $f : M \to M$, $R \subseteq M^2$, and $c \in M$. Let α be a permutation of M, then α is an automorphism of $\mathcal{M}$ if for all $a, b \in M$:

- $\alpha(f(a)) = f(\alpha(a))$;
- $(a, b) \in R$ iff $(\alpha(a), \alpha(b)) \in R$
- $\alpha(c) = c$.

A general definition for an arbitrary structure $\mathcal{M}$ has the same conditions for all functions, relations, and constants of $\mathcal{M}$.

The model-theoretic version of the second bulleted condition above is

$$\mathcal{M} \models R(a, b) \Leftrightarrow R(\alpha(a), \alpha(b)).$$

This is the base case in the proof by induction by complexity of formulas of the following very useful fact. Below, if $\overline{a} = a_1, \ldots, a_n$, then $\alpha(\overline{a})$ is $\alpha(a_1), \ldots, \alpha(a_n)$.

Theorem 2 *Let α be an automorphism of $\mathcal{M}$. Then, for all $\overline{a}$, $\mathrm{tp}^{\mathcal{M}}(\overline{a}) = \mathrm{tp}^{\mathcal{M}}(\alpha(\overline{a}))$.*

Let $\mathcal{M}$ be a structure. A set $A \subseteq M^n$, for $n > 0$, is definable in $\mathcal{M}$ if there are a formula $\varphi(\overline{x}, \overline{y})$ of the language of $\mathcal{M}$ a tuple $\overline{b}$ such that

$$A = \left\{\overline{a} : \mathcal{M} \models \varphi\left(\overline{a}, \overline{b}\right)\right\}.$$

3 Minimality and Order-Minimality

In every structure, all finite sets and their complements are definable. For example, the set $\{a, b\}$ is defined by $(x = a) \vee (x = b)$, and its complement is defined by $\neg[(x = a) \vee (x = b)]$. A structure $\mathcal{M}$ such that every definable subset of M is either finite or cofinite is called minimal.

The definition of minimality involves only definable subsets of the domain M. Every infinite structure has definable sets that are neither finite nor cofinite. For example, $\{(x, y) : \mathcal{M} \models x = y\}$.

The ordered set of integers $(Z, <)$ is not minimal. For example, the set of positive integers is definable and it is neither finite nor cofinite.

A prime example of a minimal structure is the field of complex numbers $\mathcal{C}$. The proof that $\mathcal{C}$ is minimal is nontrivial. The result is known as the Chevalley–Tarski theorem, and its equivalent version in algebraic geometry says that the projection of a constructible set is constructible. This formulation of the theorem reveals an important aspect of minimality. The projection of a definable set is definable. For example, if $A \subseteq M^2$ is defined by $\varphi(x, y)$, then its projection onto the first coordinate

is defined by $\exists y\varphi(x, y)$. It is hard to see directly what subsets of the domain of a structure are definable just by inspecting formulas with one free variable. Instead, it is often necessary to analyze definability of sets in higher dimensions, that is, sets defined by formulas with arbitrary numbers of free variables.

The rest of this section is devoted to the proof that $(\mathrm{N}, <)$ is minimal. It is not an important theorem; in Doets (1996), it is just an exercise that follows the argument given for the special case that even numbers are not definable in $(\mathrm{N}, <)$. The result can be proved by an analysis of what first-order formulas of the language with just one binary relation symbol $<$ can define in $(\mathrm{N}, <)$. The proof in Doets (1996) that we will follow here is different. We will use an elementary extension and an automorphism.

To show that $(\mathrm{N}, <)$ is minimal, suppose it is not. Then, there is a formula $\varphi(x)$ that defines a set that is neither finite nor cofinite. Let $(\mathrm{N}^*, <)$ be an elementary extension of $(\mathrm{N}, <)$. Because the extension is elementary, $(\mathrm{N}^*, <)$ is a linearly ordered set, and every element of N^* has an immediate successor, and every element other than 0 has an immediate predecessor.

In $(\mathrm{N}, <)$ every element is uniquely determined by its distance from 0. This cannot change in the elementary extension. Hence, for any standard n and any nonstandard c, $(\mathrm{N}^*, <) \models n < c$. Then, for every nonstandard c, $[c] = \{c + n : n \in \mathrm{Z}\} \subseteq \mathrm{N}^*$, where $c + n$ denotes either n the successor of c or $-n$ predecessor of c, depending on whether n is positive or negative. For the proof that $(\mathrm{N}, <)$ is minimal, we do not need anything more.

Let ψ be the sentence $\forall x\ \exists\ y[x < y \wedge \varphi(y) \wedge\ \neg\ \varphi(y + 1)]$.

Since the set defined by $\varphi(x)$ in $(\mathrm{N}, <)$ is neither finite nor cofinite, $(\mathrm{N}, <) \models \psi$. By elementarity of the extension, $(\mathrm{N}^*, <) \models \psi$. It follows that there is a nonstandard c such that $(\mathrm{N}^*, <) \models \varphi(c) \wedge\ \neg\ \varphi(c + 1)$. For such a c, let $\alpha(x) = x + 1$ if $x \in [c]$, otherwise $\alpha(x) = x$.

Because α is an order-preserving permutation of N^*, it is an automorphism of $(\mathrm{N}^*, <)$. By Theorem 2, c and $\alpha(c)$ have the same type in $(\mathrm{N}^*, <)$, but we also have $(\mathrm{N}^*, <) \models \varphi(c) \wedge\ \neg\ \varphi(\alpha(c))$ and this contradiction finishes the argument.

In the argument, nothing was mentioned about parameters from N that $\varphi(x)$ could have. That was unnecessary. In $\mathcal{N}$ all elements are definable; hence, all formulas have equivalent parameter-free versions, so without loss of generality we could assume that $\varphi(x)$ has no parameters.

Structures $\mathcal{M}$ and $\mathcal{N}$ for the same language are elementarily equivalent if for each first-order sentence φ, $\mathcal{M} \models \varphi$ if and only if $\mathcal{N} \models \varphi$.

Since the type of each element of a structure includes all sentences that hold in the structure, if $\mathcal{N}$ is an elementary extension of $\mathcal{M}$, then $\mathcal{M}$ and $\mathcal{N}$ are elementarily equivalent.

A structure $\mathcal{M}$ is strongly minimal if it is minimal, and every structure that is elementarily equivalent to it is also minimal. The field of complex numbers is strongly minimal, and so are most known minimal structures. The ordered set $(\mathrm{N}, <)$ is a rare exception. Every elementary extension of $(\mathrm{N}, <)$ contains a copy of $(\mathrm{Z}, <)$; hence, none of those extensions is minimal.

A structure is ordered if one of its relations linearly orders the domain. Any ordered structure that has a subset order-isomorphic to (Z, <) is not minimal, but some of them are o-minimal. A structure is o-minimal (short for order-minimal) if each definable subset of its domain is the union of finitely many open intervals, including the unbounded ones, and points. A prime example of an o-minimal structure is the ordered field of real numbers. This nontrivial result is known as the Seidenberg–Tarski theorem. In terms of real analytic geometry, it says that the projection of a semi-algebraic set is semi-algebraic.

A proof similar to the one for the minimality of (N, <) shows that (Z, <) is o-minimal. Unlike (N, <), (Z, <) has nontrivial automorphisms. They are all of the form $\alpha(x) = x + n$, for integer n; but none of them can be used in the proof, since we need automorphisms that fix any finite number of parameters from Z. For that reason, we move to an elementary extension (Z^*, <) and argue as in the case of (N, <).

All dense linear orderings are o-minimal. There is simple proof using automorphisms that the ordered set of the rational numbers (Q, <) is o-minimal. There is no need to move to an elementary extension. The automorphism group of (Q, <) is rich enough.

In conclusion, the point of this section was to show how certain results about an intended, standard structure can be obtained by moving the argument to its nonstandard elementary extension. This works when the extension has some useful second-order properties that the standard structure lacks. The example of (N, <) might be the simplest, but it is not isolated. The analysis and classification of definable sets and types of elements in a structure are often made easier by moving an elementary extensions that admit lots and lots of automorphism, and some very general results in model theory show that such extensions always exist.

4 Infinite Ramsey Theorem

For a set $X \subseteq \mathrm{N}$, $[X]^n$ is the set of all increasing n-tuples of elements of X. The infinite Ramsey theorem says that for all k, $n > 0$, for every function $f: [\mathrm{N}]^n \to \{1, \ldots, k\}$, there is an infinite $X \subseteq \mathrm{N}$ such that f is constant on $[X]^n$. We call X a homogeneous set for f.

We will only prove the theorem for $k = n = 2$. Increasing k only makes some formulas a bit longer. The proof for arbitrary n proceeds by induction. To prove the inductive step, one reduces the problem of finding a homogeneous set X for a given partition of $[\mathrm{N}]^{n+1}$ to the problem of finding a homogeneous set for a partition of $[\mathrm{N}]^n$. We will show how it is done in the case of $n = 2$. For $n = 1$, the theorem just says that in every partition of an infinite set into finitely many parts, at least one of the parts is infinite.

Let $f: [\mathrm{N}]^2 \to \{1, 2\}$ be given. Let $\mathcal{M}$ be $(\mathrm{N}, <, f)$ and $\mathcal{M}^* = (\mathrm{N}^*, <, f^*)$ be an elementary extension of $\mathcal{M}$.

Let c be an element of $\mathrm{N}^* \backslash \mathrm{N}$. As was shown in the previous section, for all standard n, $\mathcal{M}^* \models n < c$.

Since the extension is elementary, f^* extends to f and it is a function from $[\mathrm{N}^*]^2$ to $\{0, 1\}$.

We will define a sequence of natural numbers $\{b_n\}_{n\in\mathrm{N}}$ by recursion. Let b_0 be any natural number, and let $i_0 = f^*(b_0, c)$. We have

$$\mathcal{M}^* \models \exists x[b_0 < x \wedge f^*(b_0, x) = i_0].$$

Since b_0 and i_0 are in N, by elementarity

$$\mathcal{M} \models \exists x[b_0 < x \wedge f(b_0, x) = i_0].$$

Let b_1 be the least such x, and let $i_1 = f^*(b_1, c)$]. We have,

$$\mathcal{M}^* \models \exists x[b_1 < x \wedge f^*(b_0, x) = i_0 \wedge f^*(b_1, x) = i_1].$$

Arguing as above, let b_2 to be the least natural number such that

$$b_1 < b_2 \wedge f(b_0, b_2) = i_0 \wedge f(b_1, b_2) = i_1.$$

Now let $i_2 = f^*(b_2, c)$. . ..

Proceeding in this manner for each $n > 0$, we get an increasing sequence such that for all $j < n - 1$ and all $j < k < n$, $f(b_j, b_k) = i_j = f^*(b_j, c)$. It follows that $\{b_n\}_{n\in\mathrm{N}}$ is partitioned into

$$\{b_i : \forall k[i < k \to f(b_i, b_k) = 0]\} \cup \{b_j : \forall k[\, j < k \to f(b_j, b_k) = 1]\}.$$

At least one of these sets must be infinite, and we can take any of them that is infinite to be the set X required in the conclusion of the theorem.

The proof outlined above is not much different from the standard proof, but its details are simplified by the possibility of referring to the nonstandard c.

The sequence $\{b_n\}_{n\in\mathrm{N}}$ is determined by the values $f^*(n, c)$, for $n \in \mathrm{N}$. Since the extension $\mathcal{M}^*$ and c were chosen arbitrarily, we do not know what those values might be, so what the proof tells are very little about the homogeneous set X. We can get more information from a more advanced variant of the argument.

A set is arithmetic if it is definable in the standard model of arithmetic. The arithmetic version of Ramsey's theorem can be stated as follows.

Theorem 3 *For all k, $n > 0$, for every arithmetic partition $f : [\mathrm{N}]^n \to \{1, \ldots, k\}$ there is an arithmetic infinite homogeneous set.*

We finish this section with an outline of the proof. For details and a more general statement, see Kossak and Schmerl (2006, Theorem 2.2.16).

If $\mathcal{N}$ is an elementary extension of $\mathcal{M}$, then we say that the extension is conservative if for every definable set X in $\mathcal{N}$, $X \cap M$ is definable in $\mathcal{M}$. By a result of Phillips (1974), the standard model of arithmetic has a conservative extension.

Let an arithmetic $f : [\mathrm{N}]^2 \to \{0, 1\}$ be given. Let $\mathcal{M}$ to be the standard model of arithmetic, and let $\mathcal{M}^*$ its conservative elementary extension. Because f and the

ordering of the natural numbers have arithmetic definitions, there is no need to expand (N, +, ·) to (N, +, ·, <, f).

The recursive construction of $\{b_n\}_{n\in\mathrm{N}}$ can be carried out in $\mathcal{M}^*$ up to a nonstandard number d, that is, $\{b_n\}_{n\in\mathrm{N}}$ becomes the standard part of the sequence $\{b_n\}_{n<d}$. Since $\{b_n\}_{n<d}$ is definable in $\mathcal{M}^*$, by conservativity of the extension, $\{b_n\}_{n\in\mathrm{N}}$ is definable in $\mathcal{M}$. The homogeneous set X has a definition that uses $\{b_n\}_{n\in\mathrm{N}}$ as a set parameter; hence X is arithmetic.

5 Automorphisms of the Field of Complex Numbers

Let $\mathcal{C}$ be the field of complex numbers. Any two algebraically closed fields of the same characteristic, cardinality, and transcendence degree are isomorphic. Hence, up to isomorphism, $\mathcal{C}$ is the only algebraically closed field of characteristic 0 and cardinality $2^{\aleph_0}$.

In the case of finite or countable languages, Theorem 1 can be restated as: Every infinite structure has an elementary extension of the same cardinality. If $\mathcal{C}^*$ is such an extension of $\mathcal{C}$, then, by elementarity, it is also algebraically closed; hence, $\mathcal{C}^*$ is isomorphic to $\mathcal{C}$. In this sense, it is not really a nonstandard extension, nevertheless we will use the fact that it is a proper extension to prove something about $\mathcal{C}$, but first we need to represent $\mathcal{C}^*$ in a special way.

Let $\mathcal{R}$ be the field of real numbers. In contrast with $\mathcal{C}$, no elementary extension $\mathcal{R}^*$ is isomorphic to $\mathcal{R}$. It is easy to see that each such an extension has to have infinitely large numbers. It is a non-Archimedean ordered field.

We will prove that $\mathcal{C}$ has a nontrivial automorphism other than complex conjugation.

Let $\mathcal{R}^*$ be an elementary extension of $\mathcal{R}$ of cardinality $2^{\aleph_0}$, and let

$$C^* = \{a + bi : a, b \in R^*\}.$$

There are proofs of the fundamental theorem of algebra that can be adapted to show that $\mathcal{C}^*$, whose domain is C^*, and its addition and multiplication defined as in the field of complex numbers is an algebraically closed field, but there is also a short model-theoretic argument. The field of complex numbers can be represented as R^2 with addition and multiplication that are definable in $\mathcal{R}$. Moreover, the fact that, under this representation, $\mathcal{C}$ is an algebraically closed field is expressed by a set of first-order sentences comprised of the field axioms, and an infinite set of sentences expressing that all polynomial equations of degree n have solutions – one sentence for each n. Since $\mathcal{R}^*$ is an elementary extension of $\mathcal{R}$, all those sentences are true about $\mathcal{C}^*$, and that concludes the argument.

It is also true that $\mathcal{C}^*$ is an elementary extension of $\mathcal{C}$, but this not be used in the argument below.

Since the cardinality of C^* is $2^{\aleph_0}$, $\mathcal{C}^*$ is isomorphic to $\mathcal{C}$, let $F : C^* \to C$ be an isomorphism.

For $a,\ b \in \mathrm{C}^*$, let $\alpha(a+bi) = a - bi$ and let $\beta = F(\alpha)$. Then β is an automorphism of $\mathcal{C}$, and the set of fixed points of β is an ordered non-Archimedean subfield of $\mathcal{C}$. Hence, β is not conjugation in $\mathcal{C}$.

While the result presented above is more of an anecdote, with a bit more of model theory we can prove more.

A real closed field is a field that is elementarily equivalent to the ordered field of real numbers. In particular, all elementary extensions of $\mathcal{R}$ are real closed. There are $2^{2^{\aleph_0}}$ pairwise nonisomorphic real closed fields of the same size. This follows from general results about isomorphism types of ordered structures, but also can be proven in this special case in several different ways. For interesting recent results on model theory of real closed fields, their integer parts, and nonstandard models of arithmetic, see D'Aquino et al. (2010) or Dolich et al. (2015).

Let $\mathcal{G}$ be the automorphism group of a structure $\mathcal{M}$. Then f and g in $\mathcal{G}$ are conjugate if for some h in $\mathcal{G}, f = hgh^{-1}$. Model theoretically, f and g are conjugate if and only if the expanded structures $(\mathcal{M}, f)$ and $(\mathcal{M}, g)$ are isomorphic. The conjugacy class of f is the set of all automorphisms of $\mathcal{M}$ that are conjugate to f.

If $\mathcal{S}$ is a real closed field, then, by the same argument as the one we used at the beginning of this section, there is an automorphism $\alpha_{\mathcal{S}}$ of $\mathcal{C}$ such that the set of fixed points of $\alpha_{\mathcal{S}}$ is isomorphic to $\mathcal{S}$. If $\mathcal{T}$ is a real closed field that is not isomorphic to $\mathcal{S}$, then $\alpha_{\mathcal{S}}$ and $\alpha_{\mathcal{T}}$ are in different conjugacy classes. Thus, we have shown that the automorphism group of $\mathcal{C}$ is of size $2^{2^{\aleph_0}}$. Moreover, we proved the following theorem.

Theorem 4 The automorphism group of $\mathcal{C}$ has $2^{2^{\aleph_0}}$ conjugacy classes.

Another example of an application of a nonstandard extension of $\mathcal{C}$ is the proof of the fundamental theorem of algebra in Leibman (2005). The proof uses a small amount of model theory. It is a standard, nonstandard analysis style proof involving a fixed point lemma applied to a topology on a quotient space of $\mathcal{C}^*$.

Abstract

Computability theory is the mathematical theory of algorithms, which explores the power and limitations of computation. Classical computability theory formalized the intuitive notion of an algorithm and provided a theoretical basis for digital computers. It also demonstrated the limitations of algorithms and showed that most sets of natural numbers and the problems they encode are not decidable (Turing computable). Important results of modern computability theory include the classification of the computational difficulty of sets and problems. Arithmetical and hyperarithmetical hierarchies and the Turing degrees provide important measures of the level of such difficulty. There are uncountably many Turing degrees and they are partially ordered. These classifications are used in contemporary research to investigate the complexity of problems in modern computable mathematics, for example, regarding structures and their properties.

1 Brief History of Computability Theory

Computability theory is the mathematical theory of algorithms. The study of particular algorithms can be traced back to Euclid (330 BCE) and his famous algorithm for determining the greatest common divisor of a pair of integers. The word *algorithm* itself has roots in the name of the mathematician Muhammad ibn Musa al-Khwarizmi who developed methods of solving linear as well as quadratic equations (e.g., completing the square) in the beginning of the ninth century. A set is computable if there is a decision procedure for identifying its elements. Computable sets often encode decidable problems.

In the late 1800s, Frege tried to put arithmetic on solid foundations, but he encountered problems with consistency exemplified by Russell's paradox. Frege used quantifiers and developed predicate logic. During the same period, Cantor worked on set theory and studied ordinal and cardinal numbers. Perhaps most importantly from the perspective of later computability theory, Cantor introduced the diagonal argument to show that an uncountable size existed. This argument will be used crucially in Gödel's incompleteness theorem, as well as to show the undecidability of the halting problem.

Computability theory is closely related to Diophantine equations and Hilbert's Tenth Problem. Diophantine equations, named after Diophantus of Alexandria, are polynomial equations in finitely many variables for which integer solutions are studied in number theory. At the Second International Congress of Mathematicians in 1900, Hilbert posed 23 unsolved problems that would challenge mathematicians of the twentieth century. Hilbert's Tenth Problem asked to devise a process that determines whether any given Diophantine equation with integer coefficients has a solution in the integers. In modern terms, it was a decision problem: asking for an algorithm to determine which Diophantine equations have integer solutions. It was the only decision problem among Hilbert's problems. If such an algorithm existed, all that would be required to solve it would be to write the algorithm down. However, as it turned out, no such algorithm exists.

To demonstrate that no algorithmic solution exists would require considerably more theoretical work, as limitative theorems often do. It is easy to construct an equilateral triangle with straightedge and compass, but the theory of constructible real numbers was needed to show that squaring the circle is impossible. It is easy to solve a quadratic equation with roots, but the development of Galois theory was needed to show that quintic equations cannot be solved with roots. In the same way, it was only after computability theory was developed that it could be shown that no algorithm could ever solve this decision problem. The negative solution to Hilbert's Tenth Problem, that there is no algorithm that determines whether a Diophantine

equation has a solution in the integers, was finally obtained in 1970 by the work of Davis, Putnam, J. Robinson, and Matiyasevich.

At the same conference, Hilbert also famously asked for a proof that arithmetic is consistent. The answer to that problem turned out to be negative. In the 1920s, Hilbert wanted to establish his own program akin to that of Frege's to get a nice axiomatic system from which all of mathematics could be deduced, but this turned out to be impossible. Gödel's famous incompleteness theorem from 1931 (Gödel 1931) established that a consistent system with an algorithmic set of axioms, capable of expressing arithmetic, cannot be complete.

Modern computability theory started in 1936 with Turing's seminar paper (Turing 1936) on "computable numbers, with an application to the Entscheidungsproblem" (decision problem). The Entscheidungsproblem was a problem posed by Hilbert and Ackermann in 1928 to devise an algorithm that decides whether a first-order sentence is universally valid, i.e., true in every first-order structure. It turned out that there is no such algorithm. Turing's paper was recommended for publication by Church, who had himself just published a paper that reached the same conclusion as Turing's, although by a different method. Later that year, Turing moved to Princeton University to study for his PhD in mathematical logic under Church's direction, which he completed in 1938. In (Turing 1936), Turing introduced a Turing machine, or as he would call it an a-machine, which is essentially an abstraction of a computing human that can read and write on a paper line while being in a certain mind state. This formalism had profound significance for the emerging science of computing. The idea of the Turing machine provides a rigorous mathematical formalism to what was until then a rough concept of being effectively calculable or computable. The Church-Turing thesis relates precisely these two concepts, saying that a function that is effectively calculable by a human is so exactly when it is computable by a Turing machine. Turing machine formalism provides an exact account of what functions are not algorithmically computable, allowing for negative solutions to decision problems. At the same time, Post (Post 1936) also worked independently on a formalism for computation, although he did not justify his system as a model of computation as Turing did.

While Turing's work was going on, there was a parallel development in mathematical logic that provided another foundation for computability – the recursive functions. That definitions by recursion could be used as the building blocks of a certain class of functions was an old idea going back to Skolem, but Gödel made it precise in 1931, when he found that he needed to define what we now call the class of primitive recursive functions in order to prove his incompleteness theorems. That is, in order to encode the provability predicate in the language of arithmetic, he needed to show that primitive recursive functions in general were definable in arithmetic. Work by Herbrand, Gödel, and Kleene generalized this notion to what we now call general recursive functions. These functions turned out to be the same as Turing computable ones. Gödel (Gödel 1931) was the first to introduce the diagonal set the complement of which can be viewed as what we now call the halting set. The halting set captures the halting problem: whether the e-th Turing machine halts on input e, which turned out to be undecidable.

The subject of computability theory started as "recursive function theory," established and promulgated by Church and Kleene when talking about

Herbrand-Gödel recursive functions (despite the disapproval of Gödel himself). Davis pushed forward the notion of calling it "computability" as evidenced by his own usage within his book (Davis 1958). In the preface, he wrote "This book is an introduction to the theory of computability and noncomputability, usually referred to as the theory of recursive functions." It became more and more standard throughout the next decades (as it can be seen in Cooper 2004; Cutland 1997; Griffor 1999; Rogers 1967; Soare 1987, 2016; Weber 2012).

Kleene is also known for Kleene-Mostowski arithmetical hierarchy that relates definability to computability in an essential way. Furthermore, Kleene worked on more general computability based on relativization and, along with Post, on Turing degrees. Post investigated various computable reductions of problems to each other and, in particular, studied Turing degrees in the 1940s and 1950s. Post was also very interested in finding a computably enumerable set that is not computable but also not Turing equivalent to the halting set. Although he never succeeded with these constructions, his attempts led to many important notions of sets with various Post-type properties. A set A is computable in a set B, or Turing reducible to B, if given a decision algorithm for membership to B, we can find a decision algorithm for membership to A; equivalently, A can be computed by a Turing machine with oracle B. This idea for oracle Turing machines originated from Turing's PhD dissertation in 1938.

Kleene and Post (Kleene and Post 1954) constructed incomparable Turing degrees computable in the halting set, using a finite extension method (also, see Cooper 2004; Soare 1987). In this method, a binary sequence representing a set is constructed by extending its finite initial segments, while attempting to satisfy certain requirements. We first decompose the conditions of the construction into infinitely many requirements, assign priorities to the requirements by listing them in an infinite sequence, and then attempt to satisfy them in order of their priority. Once satisfied, a requirement will remain satisfied forever. Such construction can be viewed as a diagonal argument, which is sometimes also called a "wait and see argument" or "finite forcing argument." However, Kleene-Post's construction used the halting set as an oracle, so the sets it constructed are computable in the halting set.

Friedberg and Muchnik (Friedberg 1957; Muchnik 1956) independently discovered the priority method with injury in order to obtain two Turing incomparable computably enumerable sets. To obtain computably enumerable sets, the construction has to be computable, so it cannot depend on any non-computable oracle. Friedberg-Muchnik's argument led to the development of a more general method called finite injury priority method, a powerful and intricate mathematical technique unique to computability theory. The finite injury priority method tries to satisfy mutually conflicting requirements arranged in a priority list by fitting together opposite strategies. While attempting to satisfy the requirements in order of their priority, it can possibly injure some lower priority requirements that have already been satisfied. As they became unsatisfied, they will need to be satisfied again, but injury can happen only finitely often for each requirement, so in the limit every requirement will be satisfied. The priority methods can be further classified based on injuries of the requirements and how many limits are needed to eventually satisfy them (see Ash and Knight 2000; Soare 1987).

Computability theory has found many applications to other areas of mathematics. In the 1970s, Metakides and Nerode and other researchers in the West and independently in the Siberian school of constructive mathematics initiated a study of computability in mathematical structures by using modern computability-theoretic tools, such as the priority methods, leading to the development of computable algebra and computable model theory and more generally computable mathematics (see Fokina et al. 2014; Harizanov 1998; Millar 1999). Other interactions of computability theory with other areas of mathematics led to the development of generalized computability, computable analysis, algorithmic randomness, algorithmic learning theory, reverse mathematics, approximate computability, and other areas.

The theory of formal languages, of great importance in computer science, is closely related to computability. Chomsky, a recognized linguist, philosopher, and cognitive scientist, developed in the 1950s a hierarchy of formal grammars and languages. A Chomsky grammar consists of a finite set T of terminal symbols and a finite set V of variables, along with substitution rules of the form $\alpha \to \beta$ for words α, β over $T \cup V$, indicating that a word α can be replaced by a word β. These rules are called productions. We can think of terminal symbols as corresponding to words in a dictionary for a natural language and of variables as corresponding to grammatical categories such as ⟨noun phrase⟩ or ⟨verb⟩. Variables include a special starting symbol, sentential variable S. The formal language generated by a specific grammar is the set of all words over the terminal symbols that can be generated starting with sentential symbol S and using the production rules of the grammar. We can think of a formal language as the set of all grammatically correct words over terminal symbols, where a word in a formal language corresponds to a sentence in a natural language. The constraints that these formal grammars must satisfy determine where they lie in the hierarchy. There are broadly four types of grammars and languages they generate, ranging from the most restrictive to the least restrictive one: regular, context-free, context-sensitive, and phrase structure. These languages have corresponding computational models, which are essentially special kinds of Turing machines where memory may be limited.

Regular languages are exactly those that can be recognized by finite state automata, context-free languages are exactly those that can be recognized by pushdown automata, and context-sensitive languages are exactly those that can be recognized by linear bounded automata. Not every language generated by Chomsky's grammar is computable. That is, the existence of a generative algorithmic grammar does not guarantee the existence of a recognition algorithm for the correct sentences of the language. For example, in Chomsky's hierarchy of languages, regular, context-free, and context-sensitive languages are all computable, while some phrase structure languages may not be computable. One of the most remarkable results in computable mathematics is that Chomsky's phrase structure languages coincide with the recursively enumerable languages. It can be established that a set is computable exactly when both the set and its complement are computably enumerable. Hence, a phrase structure language is computable when its complement (the set of all grammatically incorrect statements) is also a phrase structure language. For more on Chomsky's languages, see (Chomsky 1959; Sipser 2013).

Recently, the authors in Ji et al. (2020) claim that the class of recursively enumerable languages coincides with an important class in quantum complexity theory, thus demonstrating deep connections among quantum physics, computer science, and computability theory.

2 Turing Computable Functions and Sets

In (Turing 1936), Turing introduced a universal Turing machine, one that is capable of copying any other Turing machine and running it on any input. This was instrumental for the development of digital computers.

Each Turing machine has an infinite tape divided into cells holding symbols and has a head that can read a single symbol, write another one, and move left or right one cell at the time. The finite set of states contains a starting state q_{start} and a halting state q_{end}. In addition to a finite set of states, each Turing machine has a finite alphabet, including a blank symbol B, and it computes with words over that alphabet. This action of a specific Turing machine is according to its program applied to a given input. The program consists of finitely many instructions given as tuples of the form

$$(p, a, q, b, X) \text{ or simply } p, a, q, b, X$$

where p, q are states, a, b are symbols from the alphabet, and X stands for L (go left) or R (go right). This instruction says that while in state p and reading symbol a, change to state q (if different from p), replace a by b (if different from b), and move one cell left if $X = L$ or right if $X = R$. The computation begins by placing the input word at the beginning of the tape, one symbol in each cell, while the rest of the tape is blank, and putting the machine head in the starting state over the left-most symbol. The computation then proceeds in steps according to the program. It stops when the program reaches a halting state; otherwise, it computes forever. If a computation reaches a halting state, then it outputs the word that is written on the tape at that final step.

While computer scientists work with various alphabets for the Turing machines, in mathematics we can code symbols and words by natural numbers, $\mathbb{N} = \{0, 1, 2, \ldots\}$, so we may assume that every Turing machine alphabet consists of a single symbol 1, in addition to the blank symbol. Every natural number x is represented in unary, by a string of $x + 1$ consecutive 1's. Hence 0 is represented as 1, while 1 is represented as 11, 2 as 111, etc.

For example, the program with the following two instructions, will compute a function $s(x) = x + 1$:

$$q_{start}, 1, q_{start,}1, R$$
$$q_{start}, B, q_{end}, 1, R$$

This program will scan a given input until it reaches a blank symbol; it will then convert the first blank symbol to 1 and halt.

A unary function g on natural numbers, $g : \mathbb{N} \to \mathbb{N}$, is called *computable* if there is a Turing machine that on every input x halts and outputs $g(x)$. Hence, the successor function above, $s(x)$, is computable. A Turing machine computes a binary function on natural numbers, say $h(x, y) = x + y$, if starting with input x, y, a pair written as x and y in unary separated by a blank symbol, ends the computation in the halting state outputting $x + y$ in unary. We similarly define computable n-ary functions $h : \mathbb{N}^n \to \mathbb{N}$, where the inputs are n-tuples of natural numbers.

We can also consider partial functions on natural numbers, such as $\psi(x) = x - 5$ which is defined only on numbers x such that $x \geq 5$. That is, the domain of ψ, $dom(\psi) = \{5, 6, 7, \ldots\}$. Such a function ψ is *partial computable* if there is a Turing machine M that on every input x in the domain halts and outputs the correct value $\psi(x)$, while it does not halt, computing forever, on the inputs x that are not in the domain. We can show that the function above is partial computable by devising a corresponding Turing machine. Such a Turing machine will compute forever on inputs 0, 1, 2, 3, and 4. We can also show that a binary partial function $\theta(x, y) = x - y$, which is defined only on pairs x, y for which $x \geq y$, is partial computable. Two partial functions are equal if they have the same domains, and for each input in the domain, they output the same value.

Every partial computable function has a corresponding Turing machine.

Conversely, given any Turing machine M and a number $n \geq 1$, there is a corresponding partial computable n-ary function $\varphi_M^{(n)}$ that is (partially) computed by M.

Partial functions include total functions, so partial computable functions include computable functions, which are sometimes called total computable for emphasis.

A set $A \subseteq \mathbb{N}$ of natural numbers is *computable* if there is a Turing machine that on an input x always halts, and outputs 1 if $x \in A$, and outputs 0 if $x \notin A$. This is equivalent to saying a set A is *computable* if its characteristic function c_A is computable, where

$$c_A(x) = \begin{cases} 1, & \text{if } x \in A; \\ 0, & \text{if } x \notin A. \end{cases}$$

It is easy to see that the complement of a computable set is computable. All finite sets and co-finite sets are computable. Many other sets are computable. A set of natural numbers is identified with a unary relation. We similarly define computable binary relations and computable relations of any arity.

3 Partial Recursive Functions and Church-Turing's Thesis

The notion of Turing machines was instrumental in the development of digital computers, since they provided a "machine" realization of the intuitive notion of computability, offering the most intuitive account of what functions are and are not algorithmically calculable. However, in some cases it takes considerable effort to write a Turing machine program, for example, a program that computes the function

$f(x, y) = x^y$. Exponentiation is a recursive operation, so the power of recursion could be exploited. Work by Herbrand and Gödel led to the notion to what we now call general recursive functions. Their original formulation was rather cumbersome though, so we will present here the more standard formulation of recursive functions owing to Kleene (see Kleene 1936; Cooper 2004; Soare 1987). We will start with some basic functions and then describe certain operations to obtain more functions from the existing ones. The defined class of functions will be the smallest class, with respect to inclusion, which can be obtained from the basic functions by a finite number of allowed operations. Thus, recursive functions are defined, fittingly, recursively. We start with three base cases.

The *zero function* $Z : \mathbb{N} \to \mathbb{N}$ is defined by $Z(x) = 0$.

The *successor function* $s : \mathbb{N} \to \mathbb{N}$ is defined by $s(x) = x + 1$.

For each $n \in \mathbb{N}$ and each $i \in \{1, \ldots, n\}$, the *projection function* $U_i^n : \mathbb{N}^n \to \mathbb{N}$ is defined by $U_i^n(x_1, \ldots, x_n) = x_i$.

Hence for every $n \geq 1$, there are n projection functions; and $U_1^1(x) = x$. The zero function, successor function, and projection functions are called *basic functions*.

We now have recursion steps that start with functions and define further functions. The first operation on functions is composition.

If $f : \mathbb{N}^k \to \mathbb{N}$ and $g_1, \ldots, g_k : \mathbb{N}^n \to \mathbb{N}$ are given functions, then the function c obtained by *composition* is defined by

$$c(x_1, \ldots, x_n) = f(g_1(x_1, \ldots, x_n), \ldots, g_k(x_1, \ldots, x_n)).$$

Hence, $c : \mathbb{N}^n \to \mathbb{N}$. Composition is also called substitution.

For example, for a function $Z_2 : \mathbb{N}^2 \to \mathbb{N}$ such that $Z_2(x, y) = 0$, we have

$$Z_2(x_1, x_2) = Z(x_1) = Z\big(U_1^2(x_1, x_2)\big),$$

so Z_2 is obtained by composition, according to the above definition, from functions $f = Z$ and $g_1 = U_1^2$ for $n = 2$ and $k = 1$.

Similarly, $s_3(x, y, z) = z + 1$ is obtained by composition as

$$s_3(x, y, z) = s\big(U_3^3(x, y, z)\big).$$

The next operation is called primitive recursion.

If $f : \mathbb{N}^n \to \mathbb{N}$ and $g : \mathbb{N}^{n+2} \to \mathbb{N}$ are given functions, then the function p obtained by *primitive recursion* is defined by

$$p(x_1, \ldots, x_n, 0) = f(x_1, \ldots, x_n) \text{ and}$$
$$p(x_1, \ldots, x_n, y + 1) = g(x_1, \ldots, x_n, y, p(x_1, \ldots, x_n, y)).$$

Hence, $p : \mathbb{N}^{n+1} \to \mathbb{N}$.

Note that the second part in the definition is not self-referential since we have $y + 1$ on the left-hand side and y on the right-hand side. Recursion here is on y, while

$x_1, \ldots, x_n$ can be viewed as parameters. For brevity, let us write $\vec{x} = x_1, \ldots, x_n$. Then, we have

$$p\left(\vec{x}, 0\right) = f\left(\vec{x}\right),$$
$$p\left(\vec{x}, 1\right) = g\left(\vec{x}, 0, p\left(\vec{x}, 0\right)\right), \text{etc.}$$

For example, for the addition function $p(x, y) = x + y$, we have

$$p(x, 0) = x = U_1^1(x),$$
$$p(x, y + 1) = p(x, y) + 1 = s(p(x, y)) = s_3(x, y, p(x, y))$$
$$\text{where } s_3(x, y, z) = z + 1.$$

The set of *primitive recursive functions* is the smallest set of functions containing the basic functions that is closed under composition and primitive recursion.

Hence, addition is primitive recursive. Similarly, we can show that multiplication $x \cdot y$ and exponentiation x^y are primitive recursive functions. A set or a relation is primitive recursive if its characteristic function is primitive recursive. For example, the set of even numbers, the set of prime numbers, and the usual order relation on natural numbers are primitive recursive. We can further show that some other kinds of recursion also lead to primitive recursive functions. For example, the function $f : \mathbb{N} \to \mathbb{N}$ defined by

$$f(0) = 1,\ f(1) = 2 \text{ and } f(x + 2) = f(x) + f(x + 1),$$

and known as the *Fibonacci sequence* 1, 2, 3, 5, 8, ... is primitive recursive.

While many important functions in elementary number theory are primitive recursive, and every primitive recursive function is intuitively computable, not every intuitively computable function is primitive recursive. One such function is the *Ackermann function* $\psi : \mathbb{N}^2 \to \mathbb{N}$ defined by double recursion as follows:

(i) $\psi(0, y) = y + 1$,
(ii) $\psi(x + 1, 0) = \psi(x, 1)$,
(iii) $\psi(x + 1, y + 1) = \psi(x, \psi\ (x + 1, y))$.

It can be shown that ψ is a well-defined total function that is intuitively computable. For example, let us compute $\psi(1, 1)$.

$$\psi(1, 1) = \psi(0, \psi(1, 0)) \text{ by (iii)}$$
$$= \psi(1, 0) + 1 \text{ by (i)}$$
$$= \psi(0, 1) + 1 \text{ by (ii)}$$
$$= 1 + 1 + 1 \text{ by (i)}$$
$$= 3$$

We can show that for every primitive recursive function $f : \mathbb{N}^n \to \mathbb{N}$, there is a constant a_f such that

$$\forall x_1 \ldots \forall x_n \big(f(x_1, \ldots, x_n) < \psi\big(a_f, x_1 + \cdots + x_n\big)\big).$$

Hence, if $\psi(x, y)$ is primitive recursive, then the unary function obtained by setting $x = y$, $g(x) = \psi(x, x)$, is also primitive recursive so for some fixed a we have

$$\forall x(\psi(x, x) < \psi(a, x)), \text{hence}$$

$\psi(a, a) < \psi(a, a)$, which is a contradiction.

The third operation that we will introduce on total or partial functions is called minimalization or unbounded search or μ-operator. Here, μy stands for the "least y such that." For a unary partial function g by $g(y)\downarrow$, we denote that $y \in dom\,(g)$ so g is defined on y. If we want to emphasize the value $v = g(y)$, we write $g(y)\downarrow = v$. By $g(y)\uparrow$, we denote that $y \notin dom\,(g)$ so $g(y)$ is undefined. In the following definition, we may have parameters $\vec{x} = x_1, \ldots, x_n$.

If $g : \mathbb{N}^{n+1} \to \mathbb{N}$ is a partial function, then an n-ary function h obtained from g by *minimalization* is defined as $h\left(\vec{x}\right)$ is the least y, if it exists, such that $g\left(\vec{x}, y\right)\downarrow = 0$ and $g\left(\vec{x}, z\right)\downarrow$ for all $z < y$. If such y does not exist, then $h\left(\vec{x}\right)\uparrow$.

We write $h\left(\vec{x}\right) = \mu y\left(g\left(\vec{x}, y\right) = 0\right)$. Even if g is a total function, h may not be total.

The set of *partial recursive functions* is the smallest set of functions containing the basic functions that is closed under composition, primitive recursion, and minimalization.

A *recursive function* is a partial recursive function which is total.

When composition or primitive recursion is applied to partial functions on an input and undefinability is encountered at any point, then the resulting function will not be defined either on that input. Recursive functions are also called general recursive.

For example, nowhere defined function ε, i.e., one with the empty domain, is partial recursive since

$$\varepsilon(x) = \mu y(y \neq y).$$

For a computable permutation of natural numbers f, the inverse function f^{-1} is also a computable permutation since

$$f^{-1}(x) = \mu y(f(y) = x).$$

On the other hand, it can be shown that the inverse function of a primitive recursive permutation is not always primitive recursive.

We can prove the following important result about the equivalence of two formal definitions of computability. Both total and partial recursive functions have Turing machine counterparts.

A total function is recursive if and only if it is computable by a Turing machine.

A partial function is partial recursive if and only if it is partial computable by a Turing machine.

Like Turing machines, recursive functions also capture our intuition of computability. After all, the three base case functions can be trivially calculated by hand, and the three recursion step operations can all be computed through straightforward algorithms, provided that unbounded search ends. It is a remarkable fact that a function is computable via a Turing machine if and only if it is recursive in the above sense. This fact lends credence to the Church-Turing thesis that intuitively computable functions (also called effectively computable functions) coincide with formally computable functions.

The minimalization operator only yields a recursive function when the function is total, and how do we know when such a function is total? The aforementioned equivalence makes this the same as asking, how do we know when a given Turing machine halts on all inputs? This is an algorithmically unsolvable (hence undecidable) problem. For partial recursive functions, we allow the minimalization operator to yield partial functions and not just total ones. It is just that we cannot algorithmically determine which partial recursive functions are general recursive.

Church-Turing's Thesis

(i) *A total function is intuitively computable iff it is formally computable, say by a Turing machine, or is a recursive function.*

(ii) *More generally, a partial function is intuitively partial computable iff it is partial recursive or partial computable by a Turing machine.*

Another reason to accept Church-Turing's thesis is that all other formalisms of algorithms lead to the same classes of computable functions and partial computable functions. Furthermore, we do not know of any example of an intuitively computable function that cannot be shown to be formally computable.

We often use Church-Turing's thesis when we want to show that we have an algorithm or partial algorithm by describing it informally, without writing the exact Turing machine program or a partial recursive function derivation. For example, a natural number is prime if it is divisible only by 1 and by itself; i.e., it has only trivial factors. The set of all prime numbers is computable since there is an algorithm that for a given natural number determines whether it has a nontrivial factor by checking all its possible divisors. For more on partial computable functions and Church-Turing's thesis, see (Cooper 2004; Davis 1958; Rogers 1967; Soare 1987).

4 Enumerations and Computably Enumerable Sets

We know that every finite set is computable. It is not hard to see that if an infinite set A is computable, then there is a computable function f that enumerates its elements in the increasing order:

$$A = \{a_0 < a_1 < a_2 < \cdots\},$$

where $a_n = f(n)$ for every n.

This leads to the following more general definition. Recall that for a partial function ψ, by $ran(\psi)$ we denote its range, the set of all outputs or values it produces, $\{\psi(n) : n \in dom(\psi)\}$.

A set A of natural numbers is *computably enumerable* if A is empty or there is a computable unary function f such that

$$A = ran(f) = \{f(0), f(1), \ldots\}.$$

For an infinite set, an enumeration $f(0), f(1), \ldots$ can be modified by crossing repetitions to be one-to-one. However, it does not have to be in an increasing order, so we cannot know at any stage in advance whether a number that has not been enumerated in A will later be enumerated or not. Assume that there is a computable enumeration in the increasing order:

$$f(0) < f(1) < f(2) < \cdots.$$

From such an enumeration, we can design a decision algorithm since given x we can find n such that $x < f(n)$ and then decide whether $x \in \{f(0), \ldots, f(n-1)\}$. If "yes," output 1, if "no," output 0. Hence, computable infinite sets are exactly those computably enumerable sets for which there is a computable enumeration in the increasing order.

The *partial characteristic function* of a set A is defined by

$$pc_A(x) = \begin{cases} 1, & \text{if } x \in A; \\ \text{undefined}, & \text{if } x \notin A. \end{cases}$$

We can show that A is computably enumerable if and only if the partial characteristic function of A is partial computable. It is easy to see that from a computable characteristic function we can construct a partial computable partial characteristic function. The converse is not always possible.

It can also be shown that a set A is computably enumerable if and only if it is the domain of a partial computable function ψ: $A = dom(\psi)$. Moreover, a set A is computably enumerable if and only there is a computable binary relation R such that for every x,

$$x \in A \Leftrightarrow (\exists y) R(x, y).$$

All pairs of natural numbers can be computably listed without repetitions, for example, by placing them first into infinitely many infinite lists as

$$\begin{aligned} &(0,0), (0,1), (0,2), (0,3), \ldots \\ &(1,0), (1,1), (1,2), \ldots \\ &(2,0), (2,1), \ldots \\ &\ldots \end{aligned}$$

and then systematically listing them all in a single infinite list, say by following finite diagonals, to obtain

$$(0,0);(1,0),(0,1);(2,0),(1,1),(0,2);\ldots$$

This method gives us computable bijection $f\colon \mathbb{N}^2 \to \mathbb{N}$:

$$f(x,y) = \frac{1}{2}(x+y+1)(x+y)+y.$$

That is, because (x, y) is the y^{th} entry in its diagonal and the previous diagonals contain $1 + 2 + \cdots + (x + y)$ entries. Sometimes, instead of $f(x, y)$, we write $\langle x, y\rangle$ emphasizing that this is a computable pairing function that codes a pair of natural numbers by a single one.

Similarly, we can computably enumerate all k-tuples of natural numbers for $k > 2$, as well as the set of all finite tuples of natural numbers. These computable enumerations or numberings can be viewed as algorithmically coding various mathematical objects by natural numbers. This idea goes back to Gödel, so we often call the object's position in the list its Gödel number. In particular, all computably enumerable sets can be simultaneously computably listed by first listing in a computable manner all Turing machines. Each Turing machine is a finite list of instructions that consist of finite sequences of symbols. Let

$$M_0, M_1, M_2, \ldots$$

be a fixed computable enumeration of all Turing machines. We can assure that there are no repetitions in this enumeration, i.e., that the enumeration is one-to-one. For a Turing machine M_e, we will denote the unary partial computable function it computes by φ_e and, for $n > 1$, an n-ary partial computable function it computes by $\varphi_e^{(n)}$. Hence,

$$\varphi_0, \varphi_1, \varphi_2, \ldots$$

is a computable enumeration of all unary partial computable functions. For each partial computable function ψ, there are infinitely many Gödel codes e such that $\psi = \varphi_e$. This statement is known as the *Padding Lemma*. This is true since to the Turing machine M_e that computes φ_e, we can add extraneous instructions to obtain new programs computing the same function.

Kleene has established a normal form for partial computable functions, which shows that every partial recursive function can be obtained from primitive recursive functions by using at most one application of the μ-operator.

Kleene Normal Form Theorem

There is a ternary primitive recursive predicate T and a primitive recursive unary function U such that for every Gödel code e and input x, we have

$$\varphi_e(x) = U(\mu z T(e, x, z)).$$

This normal form generalizes to n-ary partial computable functions with the corresponding Kleene's predicate $T_n(e, x_1, \ldots, x_n, z)$.

For φ_e, we denote its domain $dom(\varphi_e)$ by W_e.

A set A is computably enumerable if and only if $A = W_e$ for some e.

Thus,

$$W_0, W_1, W_2, \ldots$$

is a computable enumeration of all computably enumerable sets. Hence, there are countably many computably enumerable sets. They are partially ordered by set-theoretic inclusion $\subseteq$ and are closed under intersection $\cap$ and union $\cup$, so they form a lattice. A *lattice* is a partially ordered set in which any two elements have a least upper bound (also called supremum) and a greatest lower bound (also called infimum). Here, given computably enumerable sets U and V, the union $U \cup V$ is their supremum, and the intersection $U \cap V$ is their infimum. The least element in this lattice is the empty set ø, and the greatest element is $\mathbb{N}$. For more on the lattice of computably enumerable sets, see (Odifreddi 1989; Soare 1987).

5 The Halting Set, Diophantine Sets and Hilbert's Tenth Problem

There are computably enumerable sets with complements that are not computably enumerable. These are exactly the noncomputable computably enumerable sets. For example, the halting set K is computably enumerable, but not computable. The set K consists of all inputs e on which the Turing machine with index e halts. That is,

$$K = \{e : e \in W_e\} = \{e : \varphi_e(e)\downarrow\}.$$

The set K is computably enumerable because it can be algorithmically listed by the procedure that simultaneously runs

$$\varphi_0(0), \varphi_1(1), \ldots, \varphi_e(e), \ldots$$

and enumerates those e for which $\varphi_e(e)$ converges, as soon as the convergence occurs. Here, simultaneously means that we start with the first Turing machine and run it for one step, and then at each step we add a new Turing machine program and also run all activated machines for an additional computational step.

We will now prove that K is not a computable set.

The proof is by contradiction, so we will assume that K is computable. The complement of K is the *divergence set*:

$$\overline{K} = \{e : \varphi_e(e) \uparrow\}.$$

Since we assumed that K is computable, $\overline{K}$ would also be computable and hence computably enumerable. If $\overline{K}$ were computably enumerable, then for some i we have $\overline{K} = W_i$. Then,

$$i \in K \Leftrightarrow i \in W_i \text{ (by definition of } K)$$

$$\Leftrightarrow i \in \overline{K} \left(\text{since } \overline{K} = W_i\right),$$

which is a contradiction.

Another proof that K is not computable is a diagonal argument that uses Church-Turing's thesis. Assuming that K is computable, define the following total function

$$g(x) = \begin{cases} \varphi_x(x) + 1 & \text{if } x \in K \\ 0 & \text{if } x \notin K \end{cases}$$

By Church-Turing's thesis, g is a computable function; hence $g = \varphi_i$ for some i. Since g is total, $i \in K$. Then,

$$g(i) = \varphi_i(i) + 1 = \varphi_i(i),$$

which is a contradiction.

Noncomputability of the halting set K implies the undecidability of the *halting problem* given as a set of pairs

$$H = \{(x, e) : \varphi_e(x) \downarrow\}.$$

If H were computable, then K would be computable since

$$e \in K \Leftrightarrow (e, e) \in H.$$

However, H is still a computably enumerable binary relation.

There are many characterizations of a computably enumerable set. Another equivalent notion of a computably enumerable set arose from number theory and involved Diophantine equations. A Diophantine equation is an equation of the form

$$p(x_0, \ldots, x_{m-1}) = 0,$$

where p is a polynomial in the variables $x_0, \ldots, x_{m-1}$ with integer coefficients. Diophantine equations are named after Diophantus of Alexandria, who wrote *Arithmetica* in 13 books in the third century.

When Hilbert proposed his list of unsolved problems in mathematics, the Tenth Problem was the following:

> "Given a Diophantine equation with any number of unknown quantities and with rational integral numerical coefficients: To devise a process according to which it can be determined in a finite number of operations whether the equation is solvable in rational integers."

Solving Hilbert's Tenth Problem was by no means easy even after the advent of computability theory. It required decades of groundbreaking work, starting with the development of a robust theory of Diophantine sets. In 1970, Matiyasevich added the final link to the proof chain forged over many years by Davis, Putnam, and J. Robinson. Matiyasevich used interesting facts about Fibonacci numbers to get the negative result. He established that there is no algorithm that determines whether a Diophantine equation has a solution in the integers.

Lagrange's four-square theorem from 1772 establishes that every natural number can be expressed as the sum of squares of four integers. Hence, the algorithmic solvability of a Diophantine equation in the integers is equivalent to the algorithmic solvability of a Diophantine equation in the natural numbers. Moreover, by Skolem's result of 1934, it is sufficient to consider only Diophantine equations of total degree four.

Thus, without loss of generality, we will only consider natural number solutions to Diophantine equations. We say that an n-ary relation R on natural numbers is *Diophantine* if there exists a polynomial $p(x_1, \ldots, x_m, y_1, \ldots, y_n)$ such that for every n-tuple of natural numbers $a_1, \ldots, a_n$, we have

$$R(a_1, \ldots, a_n) \Leftrightarrow \exists x_1 \exists x_2 \cdots \exists x_m p(x_1, x_2, \ldots, x_m, a_1, \ldots, a_n) = 0.$$

Note that $a_1, \ldots, a_n$ can be viewed as parameters for which the corresponding equations in variables $x_1, \ldots, x_m$ have or do not have solutions as determined by relation R.

We say that a k-ary function f is a *Diophantine function* if its graph G_f is a $(k+1)$-ary Diophantine relation, where

$$G_f = \{(a_1, \ldots, a_k, b) : f(a_1, \ldots, a_k) = b\}.$$

Davis, Putnam, and J. Robinson showed that the set of Diophantine sets is closed under unions and intersections, but not under complements. They further showed that under the assumption that exponentiation is a Diophantine relation, relations defined through existential quantifiers and bounded universal quantifiers are Diophantine relations, from which it follows that Hilbert's Tenth Problem is algorithmically unsolvable, as we shall see shortly. Matiyasevich completed their work by showing that the exponentiation is, in fact, Diophantine (see Matiyasevich 1993).

Here is the main thrust of the proof that Diophantine functions are exactly recursive functions. It is clear that any Diophantine function is a computable function; it is simply a matter of running a search for the quantified variables along with the output variable. We show the converse by induction on the complexity of recursive functions. To start with the base cases, $Z(a) = b$ if and only if $b = 0$, so Z is Diophantine. Clearly, $s(a) = b$ if and only if $b - a - 1 = 0$, so s is Diophantine; and $U_i^n(a_1, \ldots, a_n) = b$ if and only if $a_i - b = 0$, so U_i^n is Diophantine. Now there are

three induction steps. For primitive recursion, we use the fact that exponentiation is Diophantine, which allows us to show that Gödel's coding β function is Diophantine. For minimalization, we also use the fact that exponentiation is Diophantine, which allows us to use bounded universal quantifiers in addition to existential quantifiers to define Diophantine relations. Therefore, we can show by induction on the complexity of recursive functions that every recursive function is a Diophantine function.

It is not hard to see that every Diophantine set is computably enumerable. Say we have that

$$a \in A \text{ if and only if } \exists x_1 \exists x_2 \cdots \exists x_m p(x_1, \ldots, x_m, a) = 0.$$

We can produce an effective listing of all $(m + 1)$-tuples of integers, evaluate the polynomial at each $(m + 1)$-tuple, and, every time the polynomial is equal to 0, output the value a.

The following key result is due to Davis, Putnam, J. Robinson, Matiyasevich:

Every computably enumerable set of integers is Diophantine.

Since not all computably enumerable sets are computable, it follows that there exist Diophantine sets that are not computable. The last statement immediately implies a negative answer to Hilbert's question. Indeed, the halting set K is a noncomputable Diophantine set, and let $p(x_1, \ldots, x_m, y)$ be its Diophantine definition. If we had an algorithm to decide when polynomial equations have solutions in $\mathbb{N}$, thinking of the value of a as a coefficient of the polynomial equation $p(x_1, \ldots, x_m, a) = 0$, we would have an algorithm to determine for which values a of y there exist $x_1, \ldots, x_m \in \mathbb{N}$ such that the polynomial equation is satisfied. Thus, we would have an algorithm to decide membership in K, which would make K computable.

It should be noted that Hilbert's Tenth Problem is still open for solutions in the field of rational numbers. We do not know much about Hilbert's Tenth Problem over the rational numbers. It is easy to show that if it were undecidable, it would then follow that it is undecidable over integers. At the same time, attempts to approach Hilbert's Tenth Problem over rationals from different perspectives have produced many interesting developments and results (see Shlapentokh 2007).

6 Undecidable Problems and Arithmetical Hierarchy

Kleene established the following result.

Fixed Point Theorem (also called *Recursion Theorem*)

For a standard enumeration of all partial computable functions

$$\varphi_0, \varphi_1, \varphi_2, \ldots, \varphi_e, \ldots$$

if a (total) computable function f (say a virus) changes all indices by producing

$$\varphi_{f(0)}, \varphi_{f(1)}, \varphi_{f(2)}, \ldots, \varphi_{f(e)}, \ldots$$

then it will fail in the following sense. For some e we will have

$$\varphi_{f(e)} = \varphi_e.$$

The last equality is the equality of partial functions, and e is called a fixed point. In fact, f will have infinitely many such fixed points.

The following result due to Rice provides many examples of undecidable problems given as index sets. A set of unary partial recursive functions is nontrivial if it is nonempty and does not contain all functions.

Rice's Theorem

Let $\mathcal{X}$ be a nontrivial set of unary partial recursive functions. Consider its index set defined as

$$X = \{i : \varphi_i \in \mathcal{X}\}.$$

Then, X is noncomputable.

To prove this theorem by contradiction, assume otherwise, that X is computable. Since $\mathcal{X}$ is nontrivial, fix some a and b such that $\varphi_a \in \mathcal{X}$ and $\varphi_b \notin \mathcal{X}$. Hence, $a \in X$ and $b \notin X$. Define the following total function:

$$f(x) = \begin{cases} a & \text{if } x \notin X \\ b & \text{if } x \in X. \end{cases}$$

It follows by definition of X that

$$\forall x (f(x) \in X \Leftrightarrow x \notin X).$$

The function f is computable by Church-Turing's thesis since we assumed that X is computable. We apply Kleene's fixed point theorem to f to obtain a fixed point e. Then,

$$\varphi_{f(e)} = \varphi_e,$$

but we have

$$f(e) \in X \Leftrightarrow e \notin X,$$

contradicting the fact that X is an index set.

For example, let $\mathcal{X}$ be the set of all unary partial computable functions with non-empty domain. It is a nontrivial set of functions, so its index set $\{i : W_i \neq \emptyset\}$ is not computable. If other words, the problem of determining whether W_i is a non-empty or empty set is undecidable.

We can show that the halting set K is not an index set as defined above. On the other hand, we can use Rice's theorem to show that the following decision problems are undecidable:

whether W_e is finite or infinite,
whether W_e is computable or not,
whether φ_e is total (equivalently, recursive or $W_e = \mathbb{N}$) or not,
whether φ_e is a constant function,
whether φ_e is a zero function Z,
whether W_e is cofinite (i.e., its complement is finite).

Also, the problem of deciding whether two partial computable functions are equal, given by $\{(x, y)$: $\varphi_x = \varphi_y\}$, is undecidable since otherwise its characteristic function $c(x, y)$ is computable, so if we fix an index a for a zero function, $Z = \varphi_a$, we get that the unary function $c(x, a)$ is computable, so the problem of determining whether φ_x is a zero function Z would be decidable, which is a contradiction.

We can use a diagonal argument to show that there is partial recursive function that cannot be extended to a (total) recursive function. Let a partial function g be defined as follows:

$$g(x) = \begin{cases} \varphi_x(x) + 1 & \text{if } \varphi_x(x) \downarrow \\ \text{undefined} & \text{if } \varphi_x(x) \uparrow . \end{cases}$$

We can use Church-Turing's thesis to show that g is partial recursive: on input x, computably find Turing machine M_x and run M_x on x. If it halts and outputs y, halt and output $y + 1$; otherwise, compute forever. We will show by contradiction that g cannot be extended to a (total) recursive function. Assume otherwise, that g can be extended to some recursive function f. Fix e such that $f = \varphi_e$.

Then, $\varphi_e(x)$ is defined for every x.

$$\begin{aligned} g(e) &= \varphi_e(e) + 1 \text{ (since } \varphi_e(e) \downarrow) \\ &= f(e) \text{ (since } f \text{ extends } g) \\ &= \varphi_e(e) \text{ (since } f = \varphi_e), \end{aligned}$$

which is a contradiction.

Thus, we can use Rice's theorem to show that the problem of determining whether φ_e is extendible or not to a (total) recursive function is undecidable.

We would like to further classify the undecidable problems. The Kleene-Mostowski *arithmetical hierarchy* provides framework for classification of some of these problems. It relates quantifier complexity of relations with their computability in an important way. We also have the following classification of sets of

natural numbers. A set A is $\Sigma_0^0 = \Pi_0^0$ if it is computable. Let n be a positive natural number. A set A is Σ_n^0 if there is a computable $(n+1)$-ary relation R such that for every $a \in \mathbb{N}$,

$$a \in A \Leftrightarrow (\exists m_1)(\forall m_2)(\exists m_3)\cdots(Qm_n)R(a, m_1, m_2, m_3, \ldots, m_n),$$

where Q is $\exists$ if n is an odd number, and Q is $\forall$ if n is an even number. The existential quantifier here can be viewed as a projection. The negation corresponds to complementation, and the universal quantifier can be expressed using the existential quantifier and negation.

A set B is Π_n^0 if and only if its complement $\overline{B}$ is Σ_n^0.

For a partial computable function φ_e with Gödel code (index) e, we write $\varphi_{e,s}(x) \downarrow$ if e, $x < s$, and there is an output $< s$ of $\varphi_e(x)$ after $< s$ in the corresponding computation, i.e., this computation halts by stage s. If the output is y, we also write $\varphi_{e,s}(x) \downarrow y$. The relations

$$R(e, x, s) \Leftrightarrow \varphi_{e,s}(x) \downarrow \text{ and}$$
$$P(e, x, s, y) \Leftrightarrow \varphi_{e,s}(x) \downarrow y$$

are computable relations since there is a bound on the number of computation steps.

The predicate defined as

$$T(e, x, z) \Leftrightarrow (P(e, x, s, y) \wedge z = \langle s, y \rangle)$$

is Kleene's T predicate from Kleene's normal form.

The relation $\exists s(\varphi_{e,s}(x)\downarrow)$ is a Σ_1^0 binary relation which says that the computation for φ_e on input x halts at some stage.

Thus, the relation $\forall s(\varphi_{e,s}(x)\uparrow)$ is a Π_1^0 binary relation which says that the computation for φ_e on input x never halts.

The above hierarchy of sets of natural numbers is a proper hierarchy since Σ_n^0 sets are strictly contained in Σ_{n+1}^0 sets, and Π_n^0 sets are strictly contained in Π_{n+1}^0 sets. Clearly, every Σ_n^0 set is also Π_{n+1}^0, and every Π_n^0 set is also Σ_{n+1}^0. It then follows that the union of all Σ_n^0 sets is the same as the union of all Π_n^0 sets. A set is called *arithmetical* if it belongs to this union.

A set A is arithmetical iff A is Σ_k^0 or Π_k^0 for some $k \geq 0$.

Equivalently, a set $\mathcal{A}$ is arithmetical if it can be obtained from a computable relation by finitely many projections and complementations.

We say that a set is Δ_n^0 if it is both Σ_n^0 and Π_n^0. We have that Δ_n^0 sets are strictly contained in Π_n^0 (or Σ_n^0) sets. By definition, Δ_0^0 sets are the computable sets. The following theorem is due to Post.

If a set A is Δ_1^0, then A is computable.

If a set A is Δ_1^0, then A is both Σ_1^0 and Π_1^0. Then both A and $\overline{A}$ are computably enumerable. By computably enumerating them simultaneously, we can devise a decision algorithm for A since every natural number will appear either in A or $\overline{A}$.

Let $\mathcal{N} = (\mathbb{N}, +, \cdot, S, 0)$ be the *standard model of arithmetic* in the language of arithmetic, $L = \{+, \cdot, S, 0\}$ denoting plus, times, successor, and zero. The name comes from the fact that a relation is arithmetical if and only if it is definable in $\mathcal{N}$ by a first-order formula. Gödel established that all computable relations are definable in $\mathcal{N}$, and hence all arithmetical relations are definable in $\mathcal{N}$. Hence for every arithmetical set A, there is a first-order formula $\alpha(x)$ such that

$$A = \{n : \mathcal{N} \vDash \alpha(n)\}.$$

This can be generalized to all arithmetical relations. Recall the classification of first-order formulas. The upper subscript 0 signifies that the quantification is only over variables that stand for individual elements. A formula is a $\Sigma_0^0 = \Pi_0^0$ formula if it contains no quantifiers, so it is quantifier-free. For $n > 0$, a formula is a Σ_n^0 (Π_n^0, respectively) formula if it is equivalent to a formula in the prenex normal form which begins with a block of existential (universal, respectively) quantifiers and has n alternations of blocks of like quantifiers.

A relation definable in $\mathcal{N}$ by a quantifier-free formula is computable. It follows that a relation definable in $\mathcal{N}$ by a Σ_n^0 formula (Π_n^0 formula, respectively) is a Σ_n^0 relation (Π_n^0 relation, respectively).

For any computable relation, there are two natural defining formulas: one with a block of existential quantifiers followed by a formula with only bounded quantifiers, $\forall x < y$ and $\exists x < y$, and the other one with a block of universal quantifiers followed by a formula with only bounded quantifiers. A block of existential (universal) quantifiers can be replaced by a single existential (universal) quantifier by coding tuples of natural numbers by a single natural number. Matiyasevich proved that bounded quantifiers can be eliminated from the above formulas, so a computable set is definable in $\mathcal{N}$ both by a Σ_1^0 and a Π_1^0 formula (see A.7 of Appendix in Ash and Knight 2000). Moreover, a set that is Σ_n^0 (Π_n^0, respectively) is definable in $\mathcal{N}$ by a Σ_n^0 (Π_n^0, respectively) first-order formula.

Given a set complexity class $\mathfrak{C}$, we say that a set A is $\mathfrak{C}$-*complete* if A is in $\mathfrak{C}$, and A is $\mathfrak{C}$-hard, that is, every set X in $\mathfrak{C}$ can be reduced to A. The reduction means that there is a computable function $f : \mathbb{N} \to \mathbb{N}$ such that for every n we have

$$n \in X \Leftrightarrow f(n) \in A.$$

The reduction function f does not have to be one-one, it can be many-one, so the above reduction is called an m-reduction. We can show that the halting set K is complete for the set of all computably enumerable sets.

Furthermore, we can, for example, show that the set $FIN = \{e: W_e \text{ is finite}\}$ is Σ_2^0 as follows:

$$\begin{aligned} e \in FIN &\Leftrightarrow \exists s\big(dom(\varphi_{e,s}) = dom(\varphi_e)\big) \\ &\Leftrightarrow \exists s \forall t \forall x\big(t > s \Rightarrow \big(\varphi_{e,t}(x) \downarrow \Rightarrow \varphi_{e,s}(x) \downarrow\big)\big) \end{aligned}$$

We can further show that every Σ_2^0 set can be reduced to *FIN* via a computable function. Hence, *FIN* is Σ_2^0-complete. The complement set $INF = \{e\text{: } W_e \text{ is infinite}\}$ will be Π_2^0-complete.

For more on arithmetical hierarchy and complexity of problems, see (Fokina et al. 2014; Montalbán 2021; Shoenfield 1993; Soare 1987).

7 Oracles and Turing Degrees

In his 1938 PhD dissertation (Turing 1938), Turing briefly wrote about a Turing machine with an oracle. An oracle will supply additional information presented on a read-only oracle tape about the characteristic function of some set of natural numbers. Unlike a standard Turing machine that computes functions autonomously, an oracle Turing machine at some steps must query the outside world, i.e., oracle, before continuing. The oracle contains information about membership of elements in some set. If the oracle set is $Y \subseteq \mathbb{N}$, then the corresponding oracle Turing machines will compute *Y*-partial computable functions. Hence, we will have an effective enumeration of all unary *Y*-partial computable functions:

$$\varphi_0^Y, \varphi_1^Y, \varphi_2^Y, \ldots$$

If the oracle *Y* is computable, then it is not needed since each answer given by its characteristic function $c_Y(n)$ can be replaced by a program that computes $c_Y(n)$, so we can omit the superscript *Y*. Oracle Turing machines lead to relative computability and the notion of Turing reducibility. Post developed the notion of Turing reducibility in his paper (Post 1944). For sets *X* and *Y*, we say that *X* is *Turing reducible* to *Y*, or *X* is Turing computable in *Y*, or *X* is *Y*-computable if $c_X = \varphi_e^Y$ for some *e*. We denote this relative computability by $X \leq_T Y$. The relation $\leq_T$ is a partial order relation on the subsets of the set of natural numbers. Every set is computable in itself, so $X \leq_T X$. Furthermore, the reducibility relation is transitive since $X \leq_T Y$ and $Y \leq_T Z$ implies $X \leq_T Z$.

By $X \equiv_T Y$, we denote that *X* is Turing equivalent to *Y*, i.e., $X \leq_T Y$ and $Y \leq_T X$. We also say that *X* and *Y* have the same *Turing degree* and write $\deg(X) = \deg(Y)$. Post referred to Turing degrees as the degrees of unsolvability. Every set *X* and its complement $\overline{X}$ have the same Turing degree. To prove that $X \leq_T \overline{X}$, for a given *x*, we ask oracle $\overline{X}$ whether *x* belongs to $\overline{X}$ and change "yes" to "no" (i.e., $c_{\overline{X}}(x) = 1$ to $c_X(x) = 0$) and vice versa. Hence, we also have that $\overline{X} \leq_T X$.

There are countably many sets in each Turing degree since there are countably many *Y*-computable functions for every *Y*. By $X <_T Y$, we denote that $X \leq_T Y$ but $Y \not\leq_T X$. For the order on degrees, we use the usual notation $\leq$, $<$, and $=$. We write

$$\deg(X) \leq \deg(Y) \text{ if } X \leq_T Y.$$

All computable sets are Turing equivalent, so they have the computable Turing degree, which we denote by boldface $\mathbf{0}$.

The computable degree **0** *is the least Turing degree.*

Every Turing degree is an equivalence class containing all sets that are computable in each other. Each equivalence class is countable, but there are continuum many sets of natural numbers. Hence:

There are continuum many Turing degrees. They are partially ordered.

The partially ordered set of Turing degrees forms an upper semi-lattice since there is always supremum. The supremum (least upper bound) of Turing degrees deg(X) and deg(Y) is the Turing degree of the set

$$X \oplus Y = \{2n : n \in X\} \cup \{2n+1 : n \in Y\}.$$

Hence, every finite set of Turing degrees has supremum. It can be shown that the infimum (greatest lower bound) of two Turing degrees may not exist.

For a set Y, the Turing *jump of* Y is defined as follows:

$$Y' = \left\{e : \varphi_e^Y(e) \text{ halts}\right\} = \left\{e : \varphi_e^Y(e)\downarrow\right\}.$$

The set $K = \{e\text{: } \varphi_e(e)\downarrow\}$ is also denoted by $\emptyset'$. We showed that K is non-computable; hence $\emptyset <_T K = \emptyset'$. Similarly, we can show that

$$Y <_T Y'$$

Hence:

There is no greatest Turing degree.

The jump operator can be iterated:

$$Y^{(k+1)} = \left(Y^{(k)}\right)' = \left\{e : \varphi_e^{Y^{(k)}}(e)\downarrow\right\}.$$

We say that for $n \geq 1$, $Y^{(n)}$ is the n-th Turing jump of Y. Let $\mathbf{y}^{(n)} = \deg(Y^{(n)})$. Hence, for every Turing degree $\boldsymbol{y}$ we have an ascending sequence of Turing degrees:

$$\mathbf{y} < \mathbf{y}' < \mathbf{y}'' < \mathbf{y}''' < \cdots.$$

We define the *ω-jump* of Y by

$$Y^{(\omega)} = \left\{\langle x, n\rangle : x \in Y^{(n)}\right\},$$

and let $\mathbf{y}^{(\omega)} = \deg(Y^{(\omega)})$. The degree $\mathbf{y}^{(\omega)}$ is a natural upper bound for the sequence above, but we can prove that no infinite ascending sequence of Turing degrees has a supremum.

The following facts show the connection between arithmetical hierarchy and Turing degrees. Let $n \geq 2$.

A set A is Σ_n^0 *iff A is computably enumerable relative to* $\emptyset^{(n-1)}$.
A set A is Δ_n^0 *iff A is computable relative to* $\emptyset^{(n-1)}$*; that is,* $A \leq_T \emptyset^{(n-1)}$.

Kleene and Post (1954) proved that there are incomparable Turing degrees, $\boldsymbol{a}$ and $\boldsymbol{b}$, by constructing sets A and B such that neither $A \leq_T B$ nor $B \leq_T A$. Moreover, they showed that the sets A and B are Turing reducible to K.

In fact, we can show that there are continuum many pairwise Turing incomparable degrees. Furthermore, for any given non-computable Turing degree $\boldsymbol{d}$, we can construct a Turing degree that is incomparable with it. A Turing degree $\boldsymbol{a}$ is called *minimal* if it is non-computable, i.e., $\boldsymbol{a} > \mathbf{0}$ and there are no Turing degrees strictly between $\mathbf{0}$ and $\boldsymbol{a}$. Spector showed that such degrees exist. In fact, there are continuum many minimal degrees, and Sacks established that there is such a degree strictly below the degree of the halting set. For more on Turing degrees, see (Cooper 2004; Lerman 1983; Odifreddi 1989; Soare 1987).

8 Computable Ordinals and Hyperarithmetical Hierarchy

One development in computability theory that has found applications in many different areas of mathematical logic is the notion of computable ordinals. To review terminology, we say that two ordered sets have the same order type if there exists an order isomorphism between them. Ordinal numbers are order types of well-ordered sets. A well-ordering of a set is a total (linear) ordering of its elements such that every nonempty subset has a least element. For finite well-ordered sets, the ordinals look like the natural numbers, but then they go far beyond them for infinite well-ordered sets:

$$0, 1, 2, 3, \ldots, \omega, \omega + 1, \omega + 2, \omega + 3, \ldots, \omega + \omega, \ldots, \omega + \omega + \omega, \ldots,$$
$$\omega^2, \ldots, \omega^3, \ldots, \omega^\omega, \ldots, \omega^{\omega^\omega}, \ldots, \epsilon_0, \ldots$$

The ordinals form a well-ordered proper class, which enables us to do transfinite induction and transfinite recursion with them.

Now, a *computable ordinal* is the order type of a computable well-ordering, i.e., the order type of a well-ordered set (X, R) where X is a computable set and R is a computable relation. Since there are only countably many Turing machines, it follows that there are only countably many computable well-orderings and thus only countably many computable ordinals. Yet there are uncountably many countable ordinals, so the fact that the class of ordinals is well-ordered implies that there exists a least non-computable ordinal, and it is easy to see that this must be a countable ordinal, i.e., the order type of a countable well-ordering. We call this

ordinal ω_1^{CK}, in analogy to ω_1, the least uncountable ordinal. The CK stands for Alonzo Church and Stephen Kleene, who arrived at this ordinal through very different means.

Kleene was not studying computable well-orderings, but rather the seemingly unrelated problem of giving names to ordinals. Kleene proposed that we use natural numbers to denote ordinals. We define this notation system by transfinite recursion.

Let 1 be a notation for 0.

If a is a notation for α, then let 2^a be a notation for $\alpha + 1$.

If the e^{th} Turing machine halts on all inputs and outputs only notations for strictly increasing ordinals with limit β, then let $3 \cdot 5^e$ be a notation for β.

The set of all natural numbers which are the notations for some ordinals is called Kleene's $\mathcal{O}$, and we say that an ordinal is *constructive* if it has a notation in $\mathcal{O}$. Since $\mathcal{O}$ is countable, it follows that there are only countably many constructive ordinals and thus there exists a least non-constructive ordinal, and it is easy to see that this ordinal must be countable. In 1955, Spector surprisingly showed that this ordinal is actually equal to ω_1^{CK} and more than that, the set of computable ordinals is the same as the set of constructive ordinals. This result allows us to encode transfinite induction on countable ordinals in natural numbers via Kleene's ordinal notation. This will prove critical in defining the hyperarithmetical hierarchy.

The *hyperarithmetical hierarchy* will allow us to iterate Turing jumps through the computable ordinals. We use transfinite recursion on Kleene's ordinal notation.

Let $H(1)$ be the empty set.

Let $H(2^a)$ be the Turing jump of $H(a)$.

If $3 \cdot 5^e$ is a notation for β, let $H(3 \cdot 5^e)$ be the set of all ordered pairs (u, v) such that u is a notation for some $\alpha < \beta$ and $v \in H(u)$.

Now, it is not in general the case that $H(a) = H(b)$ if a and b are notations for the same ordinal α, but $H(a)$ and $H(b)$ have the same Turing degree, which is what ultimately matters.

In analogy to the arithmetical hierarchy, we can now define Σ^0_α, Π^0_α, and Δ^0_α relations for arbitrary computable ordinals α. Let a be a notation for an infinite α. Then we say that a relation is Σ^0_α if it is computably enumerable relative to $H(a)$, it is Π^0_α if its complement is computably enumerable relative to $H(a)$, and is Δ^0_α if it is computable relative to $H(a)$. (This is well-defined by the property above about different notations for the same ordinal yielding the same Turing degree.) And we say that a relation is *hyperarithmetical* if it is Δ^0_α for some computable ordinal α.

This hyperarithmetical hierarchy is only one way to generalize the arithmetical hierarchy, however. Another, seemingly unrelated, generalization is the analytical hierarchy, which is a way of classifying relations definable in the language of second-order logic. Arithmetical relations are defined in the language of first-order logic, where we only allow quantifiers ranging over individual elements. Second-order logic permits quantifiers ranging over arbitrary sets and relations, but for our purpose it suffices to restrict quantifiers to functions. We say that a relation is $\Sigma^1_0 = \Pi^1_0 = \Delta^1_0$ if it is arithmetical, noting that it is permitted to carry free function variables. If R is a Π^1_n relation, then

$$\exists f_1 \exists f_2 \cdots \exists f_k R$$

is Σ^1_{n+1}. If R is a Σ^1_n relation, then

$$\forall f_1 \forall f_2 \cdots \forall f_k R$$

is Π^1_{n+1}. We say that a relation is Δ^1_n if it is both Σ^1_n and Π^1_n. We say that a relation is *analytical* if it is Δ^1_n for some natural number n.

Kleene found a surprising connection between these two generalizations of the arithmetical hierarchy. He showed that every hyperarithmetical set is analytical, and more specifically that

A set is hyperarithmetical if and only if it is Δ^1_1.

An example of a hyperarithmetical set that is not arithmetical is the set of all Gödel codes of formulas of Peano arithmetic that are true in the standard model of arithmetic. That is because $\emptyset^{(\omega)}$ is a hyperarithmetical set that is not arithmetical. Kleene's O is not even hyperarithmetical; it is a Π^1_1-complete set. Here are a few amazing results that involve hyperarithmetical sets.

Kleene constructed a computable tree that is non-finitely branching and has infinite paths but has no infinite hyperarithmetical path. Hence, we have a computable structure with very noncomputable properties.

On the other hand, Spector obtained a surprising result that if a well-ordering has a hyperarithmetical copy, then it has a computable copy.

For more on hyperarithmetical hierarchy, see (Ash and Knight 2000; Sacks 1990).

9 Computable Models and Computable Infinitary Formulas

We consider countable structures for computable languages. A computable language is a countable language with algorithmically presented set of symbols and their arities. The universe A of an infinite countable structure $\mathcal{A}$ can be identified with the set of natural numbers. If L is the language of $\mathcal{A}$, then L_A is the language L expanded by adding a constant symbol for every $a \in A$, and $\mathcal{A}_A = (\mathcal{A}, a)_{a \in A}$ is the corresponding expansion of $\mathcal{A}$ to L_A. The *open diagram* of a structure $\mathcal{A}$, $D(\mathcal{A})$, is the set of all quantifier-free sentences of L_A true in $\mathcal{A}_A$. A structure is *computable* if its open diagram is computable. The *Turing degree of* $\mathcal{A}$ is the Turing degree of the atomic diagram of $\mathcal{A}$. Hence a structure is computable if its Turing degree is $\mathbf{0}$. If a structure has a finite language, then it is computable if its domain is computable and its relations and functions are computable.

For example, consider the following linear ordering $\prec$ on the set of natural numbers:

$$0 \prec 2 \prec 4 \prec \cdots \prec 5 \prec 3 \prec 1.$$

We say that this ordering has order type $\omega + \omega^*$ where order type ω^* stands for the usual ordering of negative integers, which is the reverse order type of the usual ordering for the natural numbers. The structure $\mathcal{A} = (\mathbb{N}, \prec)$ is computable because its domain is computable and its only relation $\prec$ is computable. Specifically, there is a procedure to decide for every pair of elements from the domain, natural numbers a, b, whether $a \prec b$ or $b \prec a$. First, we determine whether the numbers are even or odd (every even number is smaller than any odd number), and if the numbers are of the same parity, their natural ordering determines their $\prec$ ordering (the same for even numbers and reverse for odd numbers).

The *elementary diagram* of $\mathcal{A}$, denoted by $D^c(\mathcal{A})$, is the set of all first-order sentences of L_A that are true in $\mathcal{A}_A$. Henkin's construction of a model for a consistent complete decidable theory is effective and produces a structure $\mathcal{A}$ with a computable domain such that the elementary diagram of $\mathcal{A}$ is computable. A structure $\mathcal{A}$ is called *decidable* if its elementary diagram $D^c(\mathcal{A})$ is computable. It is easy to see that not every computable structure is decidable. For example, the *standard model of arithmetic*, $\mathcal{N} = (\mathbb{N}, +, \cdot, S, 0)$, is computable but not decidable. For more on computable and decidable models, see (Ershov 1980; Ershov and Goncharov 2000; Harizanov 1998; Millar 1999).

We can use computable ordinals to define computable infinitary formulas. The computable Σ_0 and Π_0 formulas are the finitary quantifier-free formulas. The computable $\Sigma_{\alpha+1}$ formulas are of the form

$$\bigvee_{n \in W_e} \exists \vec{y}_n \psi_n \left(\vec{x}, \vec{y}_n \right),$$

where for $n \in W_e$, ψ_n is a Π_α formula indexed by its Gödel number, and $\exists \vec{y}_n$ is a finite block of existential quantifiers. That is, $\Sigma_{\alpha+1}$ formulas are computably enumerable disjunctions of $\exists \Pi_a$ formulas. Similarly, $\Pi_{\alpha+1}$ formulas are computably enumerable conjunctions of $\forall \Sigma_\alpha$ formulas. It can be shown that a computable Σ_1 formula is of the form

$$\bigvee_{n \in \mathbb{N}} \exists \vec{y}_n \theta_n \left(\vec{x}, \vec{y}_n \right),$$

where $\left(\theta_n \left(\vec{x}, \vec{y}_n \right) \right)_{n \in \mathbb{N}}$ is a computable sequence of quantifier-free formulas. If α is a limit ordinal, then Σ_α (Π_α, respectively) formulas are of the form $\bigvee_{n \in W_e} \psi_n$ ($\bigwedge_{n \in W_e} \psi_n$, respectively), such that there is a sequence $(\alpha_n)_{n \in W_e}$ of ordinals having limit α, given by the ordinal notation for α, and every ψ_n is a Σ_{α_n} (Π_{α_n}, respectively) formula.

There is a version of *compactness theorem* due to Kreisel and Barwise, which states that if Γ is a Π^1_1 set of computable infinitary sentences such that every Δ^1_1 subset of Γ has a model, then Γ has a model. As a corollary, we obtain that if Γ is a Π^1_1 set of computable (infinitary) sentences, and if every Δ^1_1 subset of Γ has a computable model, then Γ has a computable model (see Ash and Knight 2000).

Ash established that in a computable structure, a computable infinitary Σ_α formula defines a Σ^0_α relation in the hyperarithmetical hierarchy, and similarly a computable infinitary Π_α formula defines a Π^0_α relation.

For example, consider a computable relation R on the above introduced computable linear ordering $\mathcal{A}$ of order type $\omega + \omega^*$, which is its initial segment of type ω; that is, $R = 2\mathbb{N}$. This relation can be defined in $\mathcal{A}$ by a computable Σ_2 formula:

$$x \in R \Leftrightarrow \bigvee_{n\in\mathbb{N}} \exists x_0 \cdots \exists x_n [x_0 \prec x_1 \prec \cdots \prec x_n \wedge x = x_n \wedge$$
$$\forall y[\neg(y \prec x_0) \wedge \neg(x_0 \prec y \prec x_1) \wedge \cdots \wedge \neg(x_{n-1} \prec y \prec x_n)]].$$

Similarly, the complement of R, the final segment of $\mathcal{A}$ of order type ω^*, can be defined by the following computable infinitary Σ_2 formula:

$$x \in \neg R \Leftrightarrow \bigvee_{n\in\mathbb{N}} \exists x_0 \cdots \exists x_n [x_0 \succ x_1 \succ \cdots \succ x_n \wedge x = x_n \wedge$$
$$\forall y[\neg(y \succ x_0) \wedge \neg(x_0 \succ y \succ x_1) \wedge \cdots \wedge \neg(x_{n-1} \succ y \succ x_n)]].$$

Tennenbaum and Denisov showed independently that there is an isomorphic computable copy $\mathcal{B}$ of $\mathcal{A}$, a computable linear ordering of order type $\omega + \omega^*$ in which the initial segment of type ω is not computable. It can be shown that it does not even have to be computably enumerable. However, because of definability of R and $\neg R$, by Ash's result, such a relation must be Δ^0_2 on $\mathcal{B}$. For more on computable formulas and their connections with computability, see (Ash and Knight 2000; Fokina et al. 2014; Ha et al. 2021).

Abstract

Reverse mathematics is a new take on an old idea: asking which axioms are necessary to prove a given theorem. This question was first asked about the parallel axiom in Euclid's geometry and later about the axiom of choice in set theory. Obviously, such questions can be asked in many fields of mathematics, but in recent decades, it has proved fruitful to focus on subsystems of *second-order arithmetic*, where much of mainstream mathematics resides. It has been found that many basic theorems of analysis and topology, as well as certain parts of infinite algebra and combinatorics, can be proved in such systems. And, remarkably, almost all the basic theorems fall into one of five particular systems:

a base system RCA_0 of "constructive mathematics" and four others defined by certain axioms about real numbers. Moreover, many of the theorems not provable in RCA_0 turn out to be *equivalent to* one of these defining axioms, so we know precisely which axiom is needed to prove them. Thus, after some motivational remarks about the parallel axiom and the axiom of choice, we will concentrate on the study of RCA_0 and its extensions, which is what "reverse mathematics" is generally taken to mean today.

Reverse mathematics · Logic · Computability · Arithmetization · Analysis

1 The Parallel Axiom

The role of the parallel axiom in geometry has been questioned since the time of Euclid himself, if not earlier. In Book I of his *Elements*, Euclid needs the parallel axiom to prove the Pythagorean theorem but first he proves many theorems without it, such as his Proposition 5: in a triangle with two equal sides, the angles opposite those sides are equal. The subsystem of Euclid's geometry without the parallel axiom is known as *neutral geometry*, and we may call theorems A and B in Euclid's geometry *equivalent* if the implications $A \Rightarrow B$ and $B \Rightarrow A$ are provable in neutral geometry.

The parallel axiom can be stated in many equivalent ways, but perhaps the simplest was given by Playfair (1795), asserting the existence of exactly one parallel to a given line through a given point:

Parallel Axiom For any line $\mathcal{L}$ and a point P outside it, there is exactly one line $\mathcal{M}$ through P that does not meet $\mathcal{L}$.

It has been observed since ancient times that many consequences of the parallel axiom are actually equivalent to it. Among them are:

- The angle sum of any triangle is π.
- The points at constant distance from a given line (on one side) form a line.
- Similar triangles of different sizes exist.
- The Pythagorean theorem.

In fact, many equivalents of the parallel axiom arose from attempts to *prove* the parallel axiom in neutral geometry, by searching for absurd consequences of its negation. For example, if the parallel axiom is false then the angle sum of some triangle is not π. This may seem unlikely, but it is not clearly absurd. In particular, it is not clearly absurd for the angle sum of a triangle to be less than π, as would happen under the hypothesis that there is *more than one parallel* $\mathcal{M}$ to a given line $\mathcal{L}$ through a point P outside $\mathcal{L}$.

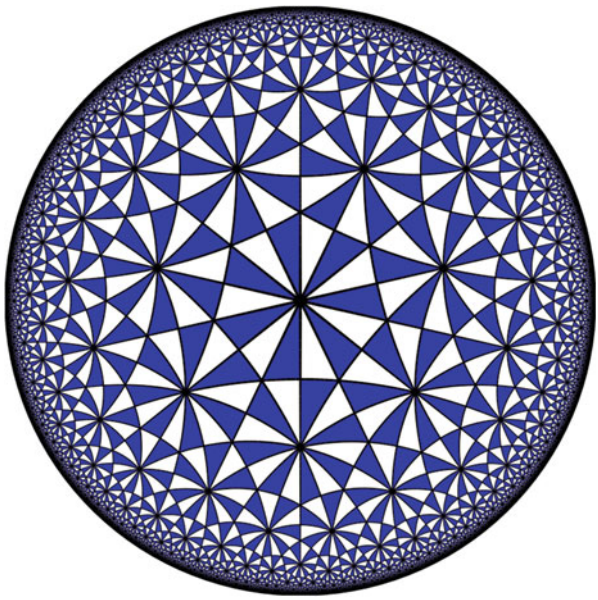

Fig. 1 The conformal disk model

The search for absurd consequences of the latter hypothesis ended when Beltrami (1868) found *models* of neutral geometry plus the hypothesis of more than one parallel, thus establishing that:

- The hypothesis of more than one parallel is consistent with neutral geometry.
- Therefore, the parallel axiom is not provable in neutral geometry.

Perhaps the clearest of Beltrami's models is the *conformal disk model* (also called the Poincaré disk, because Poincaré rediscovered it in 1882), shown in Fig. 1. The figure shows an open disk (the "plane" of the model) tiled with curvilinear triangles, each with angles $\pi/2$, $\pi/3$, and $\pi/7$. (Image from Wikimedia Commons, due to Claudio Rocchini.)

The "points" of this model are points inside the unit circle, its "lines" are circular arcs orthogonal to the unit circle, and its "angles" are the angles between these circular arcs. "Distance" is not ordinary distance in the plane; it is given by a formula that makes all the triangles of equal size. The distance function was rediscovered by Poincaré (1882) as an invariant of the mappings $z \mapsto \frac{az+b}{\bar{b}z+\bar{a}}$ of the unit disk $\{z: | z| <1\}$ in the plane $\mathbb{C}$ of complex numbers, where $|a|^2 - |b|^2 = 1$. These mappings are the *isometries* of the model and they include mappings sending any triangle in the tiling to any other, thereby showing that all these triangles are "congruent" in the sense of the model.

Since there are infinitely many triangles between any "point" and the unit circle, each "line" has infinite length. It can be checked, using the distance formula, that all the axioms of neutral geometry are satisfied in this model. It is also clear that the parallel axiom is *not* satisfied, because one can find a "line" $\mathcal{L}$, a "point" P outside $\mathcal{L}$, and several "lines" $\mathcal{M}$ through P that do not meet $\mathcal{L}$.

Thus Beltrami's model shows that the parallel axiom is *not* a theorem of neutral geometry, so its many equivalents are not theorems of neutral geometry either. On the contrary, there is an equally valid *non-Euclidean geometry* in which the parallel axiom and its equivalents are false. To prove any of these equivalents, it is *necessary* to add the parallel axiom to neutral geometry.

The train of thought we followed to arrive at this conclusion is the prototype of reverse mathematics. It involves:

- A weak "base theory" T (in this case, neutral geometry).
- An axiom A, seemingly not provable in T, but with many interesting equivalents.
- Construction of a *model* of T plus the negation $\neg A$ of A, thus showing that A and its equivalents are not provable in the base theory T.

The crucial (and typically most difficult) step is the construction of the model. In the case of Euclid's geometry, there was an interval of over 2000 years between the question of proving the parallel axiom and its negative answer by means of the Beltrami's models. In the next case, history speeds up, but the models are still formidably difficult to construct.

2 The Axiom of Choice

A host of new axiomatic issues in mathematics arose from the discovery of Cantor (1874) that the infinite sets $\mathbb{N}$ of natural numbers and $\mathbb{R}$ represent *different kinds of infinity*. Specifically, $\mathbb{R}$ is *uncountable*, in the sense that there is no bijection between $\mathbb{R}$ and $\mathbb{N}$. The easiest proof of uncountability is the one found by Cantor (1891) for $\mathcal{P}(\mathbb{N})$, the set of subsets of $\mathbb{N}$. Namely, any countable collection S_0, S_1, S_2, ... of subsets of $\mathbb{N}$ is not all of $\mathcal{P}(\mathbb{N})$, because it omits the "diagonal" set $S = \{n : n \notin S_n\}$. The uncountability of $\mathbb{R}$ follows by pairing subsets of $\mathbb{N}$ with real numbers.

Before the discovery of uncountable sets, infinity was thought to be manageable by the proof method of *induction*, whereby one proves that a property P holds for all members of $\mathbb{N}$ by proving first that P holds for 0 and then proving that P holds for $n + 1$ whenever it holds for n. The method of induction rests on the *well-ordering* property of $\mathbb{N}$, according to which each subset of $\mathbb{N}$ has a least member, and it can be used for any infinite set in bijection with $\mathbb{N}$; that is, any *countable* set.

Cantor (1883) boldly hypothesized, as a "law of thought," that every set S can be well-ordered. That is, there is relation $\prec$ on S with the properties:

- For all $a \in S$, $a \not\prec a$
- For all $a, b \in S$, $a \prec b$, or $b \prec a$
- For all $a, b, c \in S$, if $a \prec b$ and $b \prec c$ then $a \prec c$

which define a *linear order*, together with the property:

- For each set $T \subseteq S$, there is a $\prec$ least member of T

which defines a *well-order*.

Cantor's hypothesis brings the advantage of inductive proofs to uncountable sets but seems doubtful even for $\mathbb{R}$. The usual ordering $<$ on $\mathbb{R}$ is a linear ordering, but certainly not a well-ordering – for example, the set of positive numbers has no least member – and no way to define a well-ordering seems apparent. Thus, the existence of a well-ordering for each infinite set seems at best to be an unprovable axiom.

This raises the question: what axioms are suitable for set theory and, in particular, what is a base theory against which axioms such as well-ordering might be studied? Cantor himself did not propose axioms for set theory. With the exception of his well-ordering hypothesis, he used plausible but informal reasoning about infinite sets. However, even plausible reasoning about infinite sets can lead to contradictions.

For example, it seems plausible that every property $P(x)$ of sets x corresponds to a set S; namely, $S = \{x : P(x)\}$. But, as Russell (1902) famously pointed out, what if $P(x)$ is the property $x \notin x$? In this case, if $S \notin S$ then $S \in S$ by definition of S, and likewise $S \in S$ implies $S \notin S$. This contradiction became known as the *Russell paradox*. To avoid it, axioms for set theory must avoid identifying sets with properties – sets must be produced in some other manner. This in fact is not hard to do, but it was not done until after Zermelo (1904) had wrestled with the problem of proving Cantor's well-ordering hypothesis.

With remarkable ingenuity, Zermelo succeeded in proving well-ordering from an apparently much more plausible hypothesis we now call the *axiom of choice*.

Axiom of Choice Any set S of nonempty sets x has a *choice function*; that is, a function f with domain S such that $f(x) \in x$ for each $x \in S$.

It is easy to prove, conversely, that existence of a well-ordering for every set implies the axiom of choice. Suppose that S is a set of nonempty sets x, and consider the union, U, of all the sets x in S. Then a well-ordering $\prec$ of U gives a choice function f for S; namely, let $f(x) =$ - least member of x in U.

Zermelo (1908) gave the first set of axioms for set theory, simultaneously avoiding the Russell paradox and providing a base theory in which the axiom of choice could be proved equivalent to Cantor's well-ordering hypothesis. The idea of Zermelo (and probably of Cantor before him) was that sets should arise from the empty set by certain set construction operations, much as the natural numbers

arise from 0 by the successor operation. Zermelo's set construction operations are:

- **Pairing.** From any sets a and b form the set $\{a, b\}$.
- **Union.** From any set S form the union of all sets x in S.
- **Power Set.** From any set x form the set $\mathcal{P}(x) = \{y : y \subseteq x\}$ of all subsets of x.
- **Definable Subset.** For any set S and any formula $P(x)$ in the language of set theory form the subset $\{x \in S : P(x)\}$. (The language of set theory has symbols only for the relations $\in$ and $=$ plus parentheses and symbols for logical terms such as "and," "or," "not," "implies," "for all," and "there exists.")

In addition, there are axioms stating the existence of the empty set and an infinite set (essentially $\mathbb{N}$).

Zermelo's axioms suffice to prove the equivalence of the axiom of choice and well-ordering, and they avoid the Russell paradox by disallowing the collection of *all* sets x with a given property $P(x)$ into a set. The definable subset axiom allows collection of sets with property $P(x)$ only within a set S already constructed. Indeed, in Zermelo's set theory, there is no largest set because, for any set S, $\mathcal{P}(S)$ is larger, as was proved by Cantor (1891). This is not unlike the fact that there is no largest natural number, since every natural number has a successor.

The Zermelo axiom system Z is a candidate for a base system in which to study the axiom of choice and its equivalents; however, it is more usual to use a somewhat stronger system ZF, with a set construction axiom called *replacement* instead of Zermelo's definable subset axiom. Replacement was introduced by Fraenkel (1922), and it can be expressed as follows:

Replacement For any function definition $f(x)$ in the language of set theory, and any set y, form the range of f on y; that is, the set $\{f(x) : x \in y\}$.

ZF is stronger than Z because it allows the construction of sets such as:

$$\{\mathbb{N}, \mathcal{P}(\mathbb{N}), \mathcal{P}\,\mathcal{P}(\mathbb{N}), \ldots\},$$

which is the range of the function f on $\mathbb{N}$ defined inductively by $f(0) = \mathbb{N}$ and $f(n+1) = \mathcal{P}(\,f(n))$. Because of its strength, ZF has become the standard system of set theory in mathematics, and it can still serve as a base for studying the axiom of choice, because the axiom of choice is not provable in ZF, and nor is its negation.

We know this by the construction of models. Assuming the consistency of ZF, Gödel (1938) found a model of ZF plus the axiom of choice, thereby showing that the axiom of choice is not *dis*provable in ZF. Cohen (1963) found a model of ZF in which the axiom of choice does not hold, thereby showing that the axiom of choice is not provable in ZF. Thus the axiom of choice, and all of its equivalents,

are *independent* of ZF, much as the parallel axiom is independent of neutral geometry.

In another echo of the situation in geometry, there are many interesting equivalents of the axiom of choice. One example from mainstream mathematics is *existence of a basis for any vector space*. Hamel (1905) essentially proved that the axiom of choice implies existence of a basis; the reverse was proved by Blass (1984).

3 Arithmetization of Analysis

The discovery of non-Euclidean geometry raised doubts about the value of Euclid's *Elements* as a foundation of mathematics and as a guide to the mathematical study of space. At the same time, the use of geometric intuition to study lines and curves was confronted by the difficulty of proving the fundamental theorem of algebra. The proof of Gauss (1816), in particular, relied on a special case of the *intermediate value theorem*, according to which a continuous real function that passes from negative to positive values somewhere takes the value zero.

Bolzano (1817) noticed this difficulty and made a start on proving the intermediate value theorem by giving essentially the modern ε-δ definition of continuity. But he could not complete the proof without making a new assumption about the real numbers. He had to assume the *least upper bound* property, which states that any bounded set of real numbers has a least upper bound.

The way out of this difficulty, ironically, was found by looking more closely at the *Elements*, particularly Book V. The solution is to *arithmetize* the line, by viewing some of its points as rational numbers. This was first done by Dedekind in 1858 and published in his book Dedekind (1872). Book V of the *Elements* observes that any point on the line is determined by rational points above and below it, because if points p and q are different, there is a rational point r between them. Dedekind tweaked this idea by considering the *sets* L and U of rational numbers respectively less than, or greater than or equal to, a given point p. Then p corresponds to the pair $\langle L, U\rangle$, where L and U are *any* nonempty subsets of $\mathbb{Q}$ with the properties:

- Each member of L is less than every member of U.
- L has no greatest member.
- $L \cup U = \mathbb{Q}$.

Such a pair is called a *Dedekind cut,* and L (which by itself suffices to determine the point p) is called a *lower Dedekind cut*.

The Dedekind cut idea shows that each real number p may be encoded by a set L of rational numbers, and hence ultimately by a set of natural numbers, as we will see below. Also, the sum and product of real numbers, and their algebraic properties, reduce to corresponding properties of the rational numbers. For example, if:

$L_1 =$ lower Dedekind cut for p_1,
$L_2 =$ lower Dedekind cut for p_2,
then $L_1 + L_2 = \{r_1 + r_2 : r_1 \in L_1, r_2 \in L_2\} =$ lower Dedekind cut for $p_1 + p_2$.

We can then prove that the sum $L_1 + L_2$ of lower Dedekind cuts is commutative, associative, and so on, directly from the corresponding properties of the sum $r_1 + r_2$ of rational numbers. It is similar, with the appropriate modifications to deal with negative numbers, to prove the algebraic properties of product for real numbers. One can also give rigorous proofs of results such as $\sqrt{2}\sqrt{3} = \sqrt{6}$, which Dedekind believed had never been done before.

Thus Dedekind cuts reduce the *arithmetic* of real numbers to the arithmetic of rational numbers. They also prove Bolzano's least upper bound property, and very easily. Given any set of real numbers p_i, with corresponding lower Dedekind cuts L_i, the lower Dedekind cut for the least upper bound for the p_i is simply the *union* of the L_i. This follows immediately from the fact that $p_i \leq p_j$ just in case $L_i \subseteq L_j$.

With the real numbers "arithmetized" by reducing them to rational numbers and their arithmetic, it became possible to describe the line, the plane, and all manner of geometric figures in terms of rational numbers and sets of rational numbers, so arithmetization extended to essentially all of analysis and geometry. At the International Congress of Mathematicians in 1900, Poincaré expressed the state of affairs at the end of the nineteenth century:

> Today in analysis there remain only natural numbers or finite or infinite systems of natural numbers ... Mathematics, as one says, has been arithmetized. Poincaré (1902), p. 120.

He was able to say "natural numbers" instead of "rational numbers" because rational numbers m/n can be encoded by ordered pairs $\langle m, n \rangle$ of integers, integers m can be encoded by ordered pairs $\langle i, j \rangle$ of natural numbers with $i - j = m$, and ordered pairs of natural numbers can be encoded by single natural numbers. Perhaps the most obvious way to number the pairs $\langle i, j \rangle$ of natural numbers is by their position in Fig. 2, where

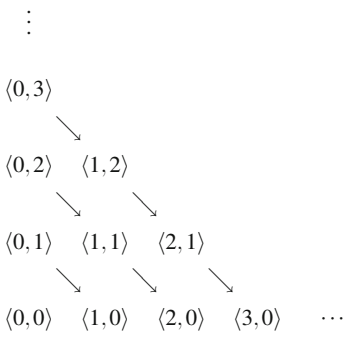

Fig. 2 Listing the ordered pairs of natural numbers

the zeroth pair is in the bottom left corner and any other pair is reached by following the arrows on successive diagonals in the left-to-right order.

In this ordering, the pair $\langle i, j\rangle$ is numbered by the *Cantor pairing function*:

$$P(i,j) = i + \frac{(i+j)(i+j+1)}{2},$$

so-called because it is essentially due to Cantor (1895). A more direct encoding of rational numbers by natural numbers can be seen in the list:

$$0;\ \frac{1}{1}, -\frac{1}{1};\quad \frac{1}{2},\quad -\frac{1}{2}, \frac{2}{1}, -\frac{2}{1};\quad \frac{1}{3}, -\frac{1}{3}, \frac{3}{1}, -\frac{3}{1};\quad \frac{1}{4}, -\frac{1}{4}, \frac{2}{3}, -\frac{2}{3}, \frac{3}{2},\ -\frac{3}{2}, \frac{4}{1}, -\frac{4}{1};\quad \ldots\ ,$$

which includes all the fractions $\pm m/n$, in lowest terms, in order of the sums $m + n$.

Rather surprisingly, it is not only the line and plane (and higher-dimensional spaces) that can be arithmetized, but any continuous real function $f : \mathbb{R} \to \mathbb{R}$. Such a function can in fact be encoded by a *single real number*, and hence by a single subset of $\mathbb{N}$. This result is implicit in results of Cantor from the 1880s, but it seems to have been first stated explicitly by Borel (1898), p. 109.

To see why a continuous $f : \mathbb{R} \to \mathbb{R}$ can be encoded by a real number, first note that f is determined by its values on the rational numbers, since any value $f(x)$ is the limit of values $f(r)$, for rational r, as r tends to x. Then, since there are countably many rational numbers $r_0, r_1, r_2, \ldots$, as the list above shows, f is determined by the countably many real numbers $x_0 = f(r_0)$, $x_1 = f(r_1)$, $x_2 = f(r_2), \ldots$. Finally, countably many real numbers $x_0, x_1, x_2, \ldots$ can be encoded by a single real number, in various ways.

For example, if we assume for simplicity that the reals are in the open interval $(0, 1)$ (which can be achieved by mapping $\mathbb{R}$ into this interval), then the decimal expansions of $x_0, x_1, x_2, \ldots$ can be woven into a single decimal expansion x as shown in Fig. 3.

Similar ideas can be used to encode points of $\mathbb{R}^2$, or more generally of any $\mathbb{R}^m$, as real numbers. This paves the way to encode any continuous $f : \mathbb{R}^m \to \mathbb{R}^n$ by a single real number and hence by a set of natural numbers. To sum up: *classical analysis, at least as far as it concerns continuous functions on $\mathbb{R}^m$, can be written in a language with variables ranging over natural numbers and sets of natural numbers*.

This is what it meant to say, in 1900, that "mathematics has been arithmetized."

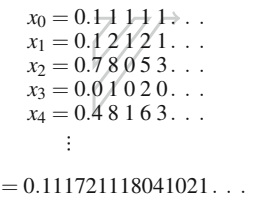

Fig. 3 Weaving a sequence of decimals into a single decimal

4 Axioms for Numbers and Sets of Numbers

Sets of natural numbers play a role not only in analysis, but even in arithmetic, as was evident from the first axiom system for arithmetic, proposed by Peano (1889). The Peano axioms take the *successor function* S as given, subject only to the conditions that 0 is not a successor, and that different numbers have different successors. Following an idea of Grassmann (1861), the axioms also define the sum and product functions *inductively* in terms of successor, and ensure the validity of induction in general by an *induction axiom*. Peano's statement of the induction axiom involves arbitrary sets of natural numbers, so two sorts of variable are required: one sort for natural numbers and the other sort for sets of natural numbers. We distinguish the two sorts by lower- and upper-case letters. The axioms are:

1. For all n, $0 \neq S(n)$.
2. For all m and n, if $m \neq n$ then $S(m) \neq S(n)$.
3. For all m and n, $m + 0 = m$ and $m + S(n) = S(m + n)$ (definition of sum).
4. For all m and n, $m \cdot 0 = 0$ and $m \cdot S(n) = (m \cdot n) + m$ (definition of product).
5. For all X, if $0 \in X$ and, for all n, $S(n) \in X$ when $n \in X$, then $X = \mathbb{N}$. (Induction.)

These axioms are sometimes called the *second-order* Peano axioms, because they involve *sets of* natural numbers as well as natural numbers. There are also *first-order* Peano axioms, which avoid the set variable X at the expense of replacing the single induction axiom by an infinite family of axioms, one for each property $\varphi(n)$ that can be written in the language with number variables, constant 0, function symbol S, relation symbol $=$, and the usual parentheses and logic symbols. In the first-order Peano axiom system, axiom 5 above is replaced by the *induction axiom schema*:

$5'$. If $\varphi(0)$ holds and, for all n, $\varphi(S(n))$ holds when $\varphi(n)$ holds, then $\varphi(n)$ holds for all n.

The induction axiom schema overcomes a certain vagueness in the second-order induction axiom, which does not tell us what it would mean to be "given" a set X. By writing down all properties φ that might define X – the so-called *arithmetically definable* properties – the first-order induction schema covers all uses of induction likely to occur in practice.

In fact, some believe that the only meaningful properties $\varphi(n)$ are those for which there is an algorithm that decides, for each n, whether $\varphi(n)$ holds or not. These "decidable properties" are a small subset of the arithmetically definable properties, as we will see when we formalize the concept of algorithm in the next section. This makes them suitable as part of a base system for analysis, in which only such "decidable" subsets of $\mathbb{N}$ are assumed to exist. It turns out that only a few of the basic theorems of analysis can be proved in this system, so one needs to add stronger set existence assumptions to prove the rest. What is more, most of the basic theorems of analysis are *equivalent* to one of a small number of set existence axioms. So set existence axioms play a role in analysis not unlike that played by the parallel axiom in geometry and the axiom of choice in set theory.

5 Computability

The origins of the computability concept are in logic, going back to a speculation of Leibniz that the validity of arguments might someday be tested by calculation. The first important step towards this goal was made by Boole (1847), who showed how to test validity in propositional logic by computation in what we now call Boolean algebra. Such computation is conceptually simple (essentially arithmetic mod 2) but propositional logic is unfortunately *too* simple to express most mathematical arguments. A logic strong enough for mathematics was introduced by Frege (1879). This *predicate logic,* as it is called, extends propositional logic by symbols for predicates (properties and relations between objects), variables x, y, z, ... for objects, and the quantifiers $\forall x$ and $\exists x$. Frege generated the valid formulas of predicate logic from axioms, by certain rules, in the manner of theorems in Euclid's *Elements*, rather than by computation as it was then understood. Moreover, it was not clear that Frege's axioms and rules were adequate to generate all logically valid formulas.

Much later, Gödel (1930) showed that Frege's system does indeed generate all logically valid formulas. At the same time, the concept of computation was being transformed, in imitation of logic itself.

Between the discoveries of Frege and Gödel, the most influential publication in logic was the *Principia Mathematica* of Whitehead and Russell (1910). Their three volumes, building on the work of Frege and Peano, gave axioms for logic and mathematics and derived many basic theorems – enough, they thought, to demonstrate that their system could prove all mathematical truths. They used a symbolic language in which conclusions were drawn from previously derived formulas in a "mechanical" manner, without needing to consider the meaning of the symbols. For example, the classical rule of *modus ponens* is of this kind: from A and $A \Rightarrow B$ derive B. We can apply this rule without knowing the meaning of A, B, or $\Rightarrow$. In the early 1920s, Post reduced the whole *Principia* system to a set of purely "mechanical" rules of this kind, each operating on strings of symbols (the "hypotheses") to produce a new string (the "conclusion").

Post's goal was to simplify the rules, hopefully to the point where one could determine whether a given string was producible from the axioms, and thus to determine whether a given mathematical sentence is true.

At first, this idea seemed promising. Post was able to reduce all derivation rules to the very simple type

from gA derive Ag', written $gA \rightarrow Ag'$ for short,

where A is an arbitrary string of symbols, and $\langle g, g' \rangle$ is a fixed pair of strings. He called a finite set of such rules a *normal system* and found that a certain normal system, applied to the axioms of *Principia*, could generate precisely its theorems. But, even with simple rules, it may be hard to foresee which strings they produce. Post was stymied by the rules below, on strings of 0s and 1s. The rules may be concisely described by saying: if a string has 0 on the left, attach 00 on the right and remove the first three symbols on the left; if the string has 1 on the left, attach 1101 on the right and remove the first three symbols on the left.

$$
\begin{array}{lll}
000A & \text{produces} & A00 \\
001A & \text{produces} & A00 \\
010A & \text{produces} & A00 \\
011A & \text{produces} & A00 \\
100A & \text{produces} & A1101 \\
101A & \text{produces} & A1101 \\
110A & \text{produces} & A1101 \\
111A & \text{produces} & A1101
\end{array}
$$

In all the cases Post tried, the string either dwindled to the empty string or else became periodic. However, he was unable to prove this, or to give an algorithm to decide whether a given string occurs as an outcome. To this day, the problem has not been solved!

At this point, as he recounted in Post (1941), Post's whole train of thought went into reverse. If there is no *apparent* algorithm to decide which strings are output by an arbitrary normal system, perhaps there is no such algorithm! If, as he thought, normal systems generate *all* sets that can be computably listed, then a set that is not the output of a normal system cannot be listed by any algorithm at all. One such "unlistable" set is a set of numbers *not* equal to the output set of any normal system. And we find such a set by the Cantor (1891) "diagonal" argument that $\mathcal{P}(\mathbb{N})$ is larger than $\mathbb{N}$.

In more detail: if $S_0, S_1, S_2, \ldots \subseteq \mathbb{N}$, then $D = \{n : n \notin S_n\}$ is a subset of $\mathbb{N}$ not among the S_n, because D differs from S_n with respect to the number N. Post's idea was to consider the subsets of $\mathbb{N}$ output by normal systems, which he called the *recursively enumerable* subsets of $\mathbb{N}$ (today, often called *computably* enumerable). The normal systems, being finite strings of symbols, can be enumerated and hence there are countably many recursively enumerable subsets of $\mathbb{N}$, which Post (1944) denoted by $W_0, W_1, W_2, \ldots$. Now, by Cantor's diagonal argument:

$$D = \{n : n \notin W_n\}$$

is *not* a recursively enumerable set, because it differs from each W_n with respect to the number n. But, interestingly, the *complement* of D,

$$\mathbb{N} - D = \{n : n \in W_n\}$$

is recursively enumerable. Informally speaking, we can list each member of $\mathbb{N} - D$ in a computation that proceeds by stages: at stage s do s steps in the generation of W_0, $W_1, W_2, \ldots, W_s$ and list any $n \leq s$ that occurs in the output of W_n.

It then follows, since D is *not* recursively enumerable, that there is no algorithm to decide membership in $\mathbb{N} - D$—otherwise, by applying the algorithm to 0,1,2, ... in turn we could recursively enumerate both D and $\mathbb{N} - D$.

To sum up: *assuming that any set whose members can be computably listed is recursively enumerable*, we can find a *normal system* (whose output is $\mathbb{N} - D$) *for*

which there is no algorithm to decide membership in its output set. Such a set is called *nonrecursive*.

Post discovered this nonrecursive recursively enumerable set $\mathbb{N} - D$ around 1921 but did not publish it at the time because he was troubled by the assumption that normal systems precisely capture the concept of computable enumeration. He felt, not unreasonably, that this was not a mathematical definition but more like a "law of nature," in need of eternal testing. It was not until 1936 that this remarkable assumption became generally accepted, thanks mainly to the paper of Turing (1936) which presented a more intuitively convincing model of computation.

Gödel, in particular, was not convinced until he saw Turing's paper. Later, in Gödel (1946), he pronounced it "a kind of miracle" that computability has a precise mathematical definition.

6 Arithmetization of Computation

Even before Gödel accepted that computability was a precise mathematical concept, he made a crucial contribution to computability theory by *arithmetizing* it. His famous proof of the incompleteness of *Principia Mathematica*, Gödel (1931), depends on numbering formulas and translating deductions into arithmetical processes, ultimately definable in Peano arithmetic. Gödel's arithmetization carries over to normal systems, with the result that any sentence of the form $n \in W$, where W is a recursively enumerable set, is equivalent to a sentence of Peano arithmetic of the form:

$$\exists x_1 \exists x_2 \ldots \exists x_k R(x_1, x_2, \ldots, x_k, n)$$

where R is quantifier-free. Such a formula is called a Σ_1^0 formula. Since R involves only the successor, sum, and product functions, equality, and symbols of propositional logic, we can decide, for any particular values of $x_1, x_2, \ldots, x_k, n$ whether $R(x_1, x_2, \ldots, x_k, n)$ holds. (In fact it was later shown, by Matijasevič (1971), that $R(x_1, x_2, \ldots, x_k, n)$ can be of the form $p(x_1, x_2, \ldots, x_k, n) = 0$, for where p is a polynomial with integer coefficients.)

Conversely, for any quantifier-free formula $R(x_1, x_2, \ldots, x_k, n)$ of Peano arithmetic, the set

$$W = \{n : \exists x_1 \exists x_2 \ldots \exists x_k R(x_1, x_2, \ldots, x_k, n)\}$$

is recursively enumerable. To enumerate the numbers n in this set, we enumerate the $(k+1)$ tuples of natural numbers $\langle x_1, x_2, \ldots, x_k, n\rangle$, and for each one add n to the list of members of W if $R(x_1, x_2, \ldots, x_k, n)$ holds.

Thus, Gödel's arithmetization shows that recursive enumerability is captured by the Σ_1^0 formulas of Peano arithmetic. This allows the concept of computability to be imported into Peano arithmetic, and finally brings us to the base system for reverse

mathematics: RCA_0. RCA stands for "recursive comprehension axiom," and the subscript denotes a refinement to the system originally proposed.

RCA_0 extends Peano arithmetic by a set existence axiom saying that, for any recursive property $\varphi(n)$, there is a set $X \subseteq \mathbb{N}$ such that:

$$n \in X \Leftrightarrow \varphi(n).$$

To express this axiom in the language of Peano arithmetic, we use the fact that a recursive property is one whose positive and negative cases are both recursively enumerable (the reason for this was given in the previous section, when we argued that an algorithm for membership in D would allow us to recursively enumerate both D and $\mathbb{N} - D$). Thus a recursive property $\varphi(n)$ is one for which there are Σ_1^0 formulas $\chi(n)$ and $\psi(n)$ such that:

$$\varphi(n) \Leftrightarrow \chi(n) \quad \text{and} \quad \chi(n) \Leftrightarrow \neg\psi(n).$$

Given such Σ_1^0 formulas, we can state the set existence axiom (schema) of RCA_0 as:

$$\exists X \forall n[n \in X \Leftrightarrow \varphi(n)] \tag{RCAx}$$

The other axioms are those of first-order Peano arithmetic, except that the φ in the induction axioms $5'$ are restricted to Σ_1^0 formulas. This is in keeping with the intention of keeping proofs in RCA_0 "constructive." It should also be mentioned that the formula $\varphi(n)$ can contain free set variables $Y, Z, \ldots$ other than X, so that X can be a set *constructed from* the sets $Y, Z, \ldots$. For example, for any set $Y \subseteq \mathbb{N}$, we can assert that the set X of even members of Y exists.

The existence of nonrecursive sets is the starting point of reverse mathematics, because it enables the construction of models that separate "constructive" theorems of analysis from "nonconstructive" ones. An obvious model of RCA_0 consists of the set $\mathbb{N}$ of natural numbers together with all its recursive subsets. We will call this the *minimal model,* because any model of RCA_0 necessarily include all recursive sets. It follows that anything RCA_0 can prove must hold in the minimal model. This creates opportunities for computability theory, where situations that give rise to *non*-recursive sets have been studied since the 1930s.

7 Theorems and Nontheorems of RCA_0

RCA_0 turns out to be a good base theory because it is strong enough to prove equivalences between statements, even though it cannot prove many of them outright. For example, in RCA_0 one cannot prove even the following weak form of Bolzano's least upper bound principle: *each bounded nondecreasing sequence of rational numbers has a limit.*

To see why, let f be a computable function that enumerates the members of a recursively enumerable but nonrecursive set W. Thus

$$W = \{\, f(n) : n \in \mathbb{N}\}$$

but the characteristic function of W,

$$\chi_W(m) = \begin{cases} 1 & \text{if } m \in W \\ 0 & \text{if } m \notin W, \end{cases}$$

is not computable.

Now consider the sequence $a_0, a_1, a_2, \ldots$, where

$$a_m = \sum_{i=1}^{m} 2^{-f(i)}.$$

This is a nondecreasing sequence of rational numbers, bounded by 1, whose limit a has binary expansion essentially the same as χ_W, because it has 1 in the mth place if $m \in W$, and 0 in the mth place otherwise. Thus the real number a is *not* computable and hence does not belong to the computable model of RCA_0.

On the other hand, the sequence $a_0, a_1, a_2, \ldots$ is the set of ordered pairs $\langle m, a_m \rangle$ which is recursive and hence *does* belong to the computable model. (To decide whether $\langle m, n \rangle$ belongs to the sequence, compute $f(0), f(1), \ldots, f(m)$ and see whether $n = \sum_{i=1}^{m} 2^{-f(i)}$.) Thus there is a sequence in the model whose limit is not in the model, which shows that RCA_0 cannot prove the existence of the limit.

Nevertheless, there are a few important theorems of analysis that RCA_0 *can* prove, because it is possible to construct the objects asserted to exist. One of these is the intermediate value theorem. Given a continuous function f (encoded as a set of natural numbers) on an interval $[a, b]$, with $f(a) < 0$ and $f(b) > 0$, one can compute a value c where $f(c) = 0$ by successive approximations. The idea is to repeatedly bisect the interval and to evaluate f at the bisection point. Either we will find c as a bisection point or else we can compute a nested sequence of intervals $[a_n, b_n]$ such that $f(a_n) < 0$ and $f(b_n) > 0$. Then c is the common point of these intervals, and the successive bisections eventually give us successive binary digits of c.

The axiom RCAx then allows us to assert the existence of c and hence prove the intermediate value theorem in RCA_0. We also get the fundamental theorem of algebra, by plugging the intermediate value theorem into the Gauss (1816) proof.

8 Trees in Analysis

The process of repeated bisection just described in the proof of the intermediate value theorem reappears in several well-known proofs in basic analysis. Here is another important example.

Bounded Value Theorem *If f is a continuous function on a closed interval $[a, b]$ then f is bounded on $[a, b]$.*

Proof. Suppose on the contrary that f is *not* bounded on $[a, b]$. Then f is unbounded on at least one half of $[a, b]$. Let $[a_1, b_1]$ be the leftmost half of $[a, b]$ on which f is unbounded, and repeat the argument on $[a_1, b_1]$. That is, f must be unbounded on at least one half of $[a_1, b_1]$; let $[a_2, b_2]$ be the leftmost such half, and so on.

Proceeding in this way, we obtain a sequence of intervals:

$$[a, b] \supseteq [a_1, b_1] \supseteq [a_2, b_2] \supseteq \cdots,$$

on which f is unbounded, and with a common point p whose binary expansion is computable from the sequence. Also, since f is continuous, $f(p)$ is defined and, in a sufficiently small interval containing p, the value of $f(x)$ differs from $f(p)$ by at most ε. But this contradicts f being unbounded on each $[a_n, b_n]$, since these intervals become arbitrarily small □.

Although it looks quite similar, this proof differs from the proof of the intermediate value theorem in one important respect. While the intermediate value c is computable from the given continuous function f, there is no apparent way to compute the common point p from the given function f. Finding the intervals $[a_n, b_n]$ depends on knowing all values of f over a given interval, and there would seem to be no finite computation that finds this information. We need a set existence axiom *stronger* than RCAx in order to claim the existence of the sequence of intervals $[a_n, b_n]$. It is convenient to take this axiom to be about *infinite paths in a binary tree*.

A binary tree underlies the proofs above. Its vertices are the interval $[a, b]$ and the infinitely many subintervals obtained from $[a, b]$ by halving. From each vertex, which is an interval I, there are edges to the left and right halves of I. This binary tree is shown in Fig. 4, with the vertex $[a, b]$ at the top.

The tree in the figure is called the *full* binary tree because there are two edges below every vertex v. In general, there may be only one edge below a vertex v, or none (in which case none of the vertices below v is in the tree). The sequence $[a, b] \supseteq [a_1, b_1] \supseteq [a_2, b_2] \supseteq \cdots$ found in the proof above is an example of an *infinite path* in the full binary tree, because each vertex $[a_{n+1}, b_{n+1}]$ is a half of the

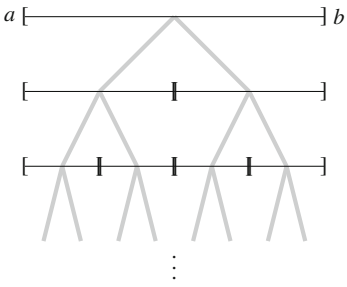

Fig. 4 A full binary tree

vertex $[a_n, b_n]$ and hence is connected to it by an edge. However, since we were not able to compute this path, we cannot necessarily prove, in RCA_0, that it exists. To guarantee its existence, we appeal to an axiom called the *weak Kőnig lemma,* which gets its name from a slightly stronger lemma due to Kőnig (1927).

The weak Kőnig lemma can be stated in terms of sets of natural numbers, but it is clearer to view it as a theorem of infinite graph theory. In this context, the lemma says: *if T is an infinite subtree of the full binary three, then T has an infinite path.* Its proof echoes the construction of the infinite path in the proof above. Start at the top vertex v_0 of *T*. Since *T* has infinitely many vertices, one of the (at most two) edges out of v_0 must have infinitely many vertices of *T* below it. Take the leftmost vertex, v_1, with infinitely many vertices below it, and repeat the argument. We can proceed in this way indefinitely, and hence find an infinite sequence of vertices, $v_0, v_1, v_2, \ldots$, each connected to the one before by an edge. This is an infinite path.

Although this argument is just as convincing as the proof above, it does not *compute* the path, so it is not expressible in RCA_0. Indeed, Kreisel (1953) found a recursive infinite binary tree *T* with *no* recursive infinite path. So, in the minimal model of RCA_0, *T* exists but its infinite paths do not, showing that RCA_0 cannot prove the weak König lemma. This makes the lemma a candidate for a new axiom. The resulting system RCA_0+weak König lemma is called WKL_0, and it can prove the bounded value theorem for continuous functions. RCA_0 cannot prove this theorem, but it can prove it *equivalent* to the weak König lemma. Thus, the weak König lemma is not just a convenient axiom to prove the theorem; it is in some sense the *right* axiom to prove it.

Similar discoveries about the weak König lemma, and other set existence axioms, led Friedman (1975) to view reverse mathematics as a program for finding "right" axioms.

> When the theorem is proved from the right axioms, the axioms can be proved from the theorem. Friedman (1975), p. 235.

9 Theorems and Nontheorems of WKL_0

As mentioned in the previous section, WKL_0 can prove the boundedness of continuous functions on closed intervals. The latter theorem is the first step towards the *extreme value theorem,* which says that a continuous function *f* on a closed interval attains a maximum and minimum. The classical proof of the extreme value theorem – if no maximum, let *l* be the least upper bound of *f*, so $1/(l - f(x))$ is continuous but unbounded – does not carry over directly to WKL_0. Nevertheless, the extreme value theorem can be proved in WKL_0, and RCA_0 proves it equivalent to the weak König lemma.

Another classical theorem provable by the weak König lemma is the *Heine-Borel theorem* for sequences, which says that any covering of [0,1] by open intervals

$(c_0, d_0), (c_1, d_1), (c_2, d_2), \ldots$ contains a finite subcovering $(c_0, d_0), \ldots, (c_k, d_k)$. (The full Heine-Borel theorem is for *sets* of open intervals, but in the language of arithmetic, we can only talk about countable sets, and this is usually all we need.) This theorem is also provable in WKL_0, as are the following consequences:

- Any function continuous on a closed interval is uniformly continuous.
- Any function continuous on a closed interval is Riemann integrable there.

Moreover, all of these theorems are provably equivalent to the weak König lemma in RCA_0. The equivalence of the weak König lemma and Heine-Borel for sequences was discovered by Friedman (1975). For proofs of all these results, and many others, see Simpson (2009).

The weak König lemma can also be used to prove the *Brouwer fixed-point theorem* in topology, which says that any continuous map of the n-dimensional ball into itself has a fixed point. This theorem is also equivalent to the weak König lemma in RCA_0. Moreover, Takayuki Kihara has recently shown that the same is true of two other celebrated topological theorems due to Brouwer:

- Invariance of domain: A continuous injective map of an open subset of $\mathbb{R}^m$ into $\mathbb{R}^m$ has an open image.
- Invariance of dimension: $\mathbb{R}^m$ and $\mathbb{R}^n$ are homeomorphic only if $m = n$.

Since these theorems are equivalent to the weak König lemma, they share in its "nonconstructive" character. Brouwer, after he made his name by his discoveries in topology, became a strong campaigner against nonconstructive methods, and in fact he rejected his own fixed-point theorem in a lecture in Berlin in 1927 (see van Dalen 2013, pp. 382 and 503). To my knowledge, he never rejected the invariance of domain and invariance of dimension, though we can now say that, relative to RCA_0, they are precisely as nonconstructive as the fixed-point theorem.

We have been speaking until now of the *weak* König lemma, which came to light because of its many interesting equivalents. The original lemma of Kőnig (1927) was not about binary trees, but the more general case of *finitely branching trees*; that is, trees in which each vertex belongs to finitely many edges. The full *König lemma* states that such an infinite tree T contains an infinite branch, and the proof is almost identical with that of the weak Kőnig lemma. Namely, pick a vertex v_0 and consider the finitely many edges out of v_0. One of them leads into an infinite subtree of T, so we let v_1 be such a vertex (say, the one with least index in the list of vertices of T). We repeat the argument with v_1 and continue indefinitely, thus defining an infinite branch.

Despite its similarity to the weak Kőnig lemma, the full Kőnig lemma is *not* provable in WKL_0. In WKL_0 we also lack guarantees for the convergence of sequences, already noticed as a failing of RCA_0. For both these things, we need a stronger set existence axiom.

10 Arithmetic Comprehension

A natural set existence axiom in second-order arithmetic, which is considerably easier to motivate than the recursive comprehension axiom RCAx or the weak König lemma, is the *arithmetic comprehension axiom* (schema), which simply removes the restriction on the formula φ in RCAx:

$$\exists X \forall n[n \in X \Leftrightarrow \varphi(n)], \qquad \text{(ACAx)}$$

where $\varphi(n)$ is now any formula in the language of Peano arithmetic, possibly with free set variables (but not including X). Arithmetic comprehension is stronger than recursive comprehension or the weak Kőnig lemma, which is why we have delayed its introduction until now: having seen the capabilities of recursive comprehension and the weak König lemma, we are in a better position to appreciate the need for extra strength.

When ACAx is the set existence axiom, it is also natural to remove the restriction on the induction axiom, and to bring back Peano's second-order induction axiom,

5. For all X, if $0 \in X$ and, for all n, $S(n) \in X$ when $n \in X$, then $X = \mathbb{N}$.

The system consisting of the Peano axioms plus ACAx is called ACA_0.

Since ACA_0 allows X to be defined by any arithmetic formula φ, Peano's induction axiom implies the first-order induction schema:

5′. If $\varphi(0)$ holds and, for all n, $\varphi(S(n))$ holds when $\varphi(n)$ holds, then $\varphi(n)$ holds for all n.

Thus ACA_0 can prove all the axioms of first-order Peano arithmetic, and hence all of its theorems. Rather surprisingly, the theorems of first-order Peano arithmetic are *precisely* the "purely arithmetic" theorems of ACA_0; that is, those that involve only variables for natural numbers. This was discovered by Friedman (1976), and we say that ACA_0 is *conservative over* first-order Peano arithmetic.

It means that the ability to reason about sets of natural numbers (or, equivalently, about real numbers and continuous functions) in ACA_0 does not help to prove purely arithmetic theorems. This is surprising in view of the common belief that analysis is needed to prove certain theorems of number theory. We will see shortly that quite a lot of analysis can be developed in ACA_0 – but Friedman's theorem shows that it gives no purely arithmetic theorems beyond those already be proved in first-order Peano arithmetic.

Like RCA_0, ACA_0 has a rather obvious minimal model; namely, $\mathbb{N}$ together with all its arithmetically definable subsets. As one would expect, there are models of WKL_0 that lie between the minimal models of RCA_0 and ACA_0, but describing them (and consequently showing that WKL_0 has strength strictly between RCA_0 and ACA_0) requires some deeper results from computability theory that are beyond the scope of this chapter. For more information on models of WKL_0, see Simpson (2009), pp. 318–319.

11 Theorems and Nontheorems of ACA_0

ACA_0 can prove all the theorems of WKL_0, because in any infinite arithmetically definable tree, the leftmost infinite path is arithmetically definable, and hence the weak König lemma follows by the axiom ACAx. Less obviously, ACA_0 can prove several theorems of analysis that WKL_0 cannot, such as:

- The sequential Bolzano-Weierstrass theorem: *any bounded infinite sequence of real numbers has a convergent subsequence*.
- The sequential least upper bound principle: any bounded sequence of real numbers has a least upper bound.
- Cauchy convergence criterion: a sequence $x_0, x_1, x_2, \ldots$ is convergent if, for any $\varepsilon > 0$, there is an n such that $|x_m - x_n| < \varepsilon$ for all $m > n$.
- Monotone convergence theorem: *any bounded monotonic sequence is convergent*.

Moreover, these theorems are all equivalent to each other, and to the axiom ACAx, over RCA_0.

Outside of analysis, ACA_0 also proves some interesting theorems of infinite combinatorics, many of them equivalent to ACAx. One interesting equivalent that we have already mentioned is the full König lemma.

Another interesting part of combinatorics around the level of ACA_0 is *Ramsey theory,* which originates in the paper Ramsey (1930). Ramsey theory typically concerns "coloring" the k-element subsets of natural numbers by finitely many colors, then showing that $\mathbb{N}$ contains an infinite subset M that is "monochromatic" in the sense that all k-element subsets of M have the same color. This result may be called RT(k) for short. For example, to prove RT(1), we have $k = 1$ so we color the members of $\mathbb{N}$ by finitely many colors. It is clear that infinitely many members of $\mathbb{N}$ get the same color. This almost obvious result RT(1) (also known as a "pigeonhole principle") can be leveraged to prove the less obvious RT(2), which in turn can be used to prove RT(3), and so on.

All of these theorems RT(k) can be proved in ACA_0, and in fact for $k > 2$, they are each *equivalent* to ACAx over RCA_0. However, RT(2) does *not* imply ACAx, and the sentence $\forall k$ RT(k), known as the infinite Ramsey theorem, is *not* provable in ACA_0. One interesting reason for its unprovability is that it is known to imply a purely arithmetic statement not provable in first-order Peano arithmetic, and hence not in ACA_0. This is the famous *Paris-Harrington theorem* of Paris and Harrington (1977). For more about Ramsey theory and ACA_0, see Hirschfeldt (2015).

This example, incidentally, helps to explain the subscript 0 in ACA_0. Friedman (1975) originally proposed a system ACA with a stronger comprehension axiom in place of ACAx, in which the formula $\varphi(n)$ defining membership in a set X was allowed to include quantified set variables. The infinite Ramsey theorem and the Paris-Harrington theorem are provable in ACA, so the purely arithmetic theorems of ACA go beyond first-order Peano arithmetic. Disallowing quantified set variables creates the system ACA_0 with exactly the same first-order strength as Peano

arithmetic, but with second-order theorems that are important for analysis. The subscripts 0 in RCA_0 and WKL_0 arise from similar restrictions on the systems originally proposed in Friedman (1975). Friedman (1976) himself proposed these restrictions along with his proof that ACA_0 is conservative over first-order Peano arithmetic.

12 The Big Five

The systems RCA_0, WKL_0, and ACA_0 are the most interesting from the viewpoint of mainstream mathematics, but there are two higher systems that cover parts of analysis with some flavor of set theory. Altogether, the five systems are known as "big five." From the historical viewpoint, the two higher systems round off the story of analysis and set theory nicely, by ending where Cantor began – with the introduction of countable ordinals and the analysis of closed subsets of $\mathbb{R}$. The two higher systems of the "big five" are:

- ATR_0, which stands for "arithmetical transfinite recursion," has the ability to handle countable ordinals. ATR_0 is strong enough to prove the infinite Ramsey theorem that lies beyond ACA_0. We will not go into detail about countable ordinals and ATR_0; for more see Simpson (2009), pp. 173–199.
- Π^1_1-CA_0, which stands for "Π^1_1 comprehension." The symbol Π^1_1 refers to a defining property $\varphi(n)$ of the form $\forall Y R(Y, n)$, where R is a formula of second-order arithmetic with no bound set variables other than Y. Π^1_1-CA_0 is the only one of the big five systems that allows a set-defining property $\varphi(n)$ with a set quantifier in its set existence axiom,

$$\exists X \forall n [n \in X \Leftrightarrow \varphi(n)].$$

Thus Π^1_1 comprehension takes us into the territory logicians call *impredicative*, where sets X are defined in terms of a totality that includes themselves.

The set existence axiom of ATR_0 is equivalent, over RCA_0, to Cantor's *perfect set theorem,* according to which any uncountable closed set contains a perfect set; that is, one that is closed and has no isolated point. For a proof, see Simpson (2009), pp. 185–188.

The set existence axiom of Π^1_1-CA_0 is equivalent, over RCA_0, to the *Cantor-Bendixson theorem,* according to which any uncountable closed subset of $\mathbb{R}$ is the union of a countable set and a perfect set. Again, we refer to Simpson (2009), particularly pp. 217–220. The ideas behind this equivalence go back to the first published paper on these systems of analysis, Friedman (1969), which was actually about a slightly stronger system Π^1_1-CA. Thus the history of reverse mathematics really begins at the level where analysis shades into set theory, as is also evident in Friedman's thesis, Friedman (1967). Only later, in Friedman (1975), was it noticed that weaker systems nicely capture more basic theorems of analysis. Then Friedman

(1976) introduced the slightly weaker "subscript 0" systems that make up the "big five" today.

For reasons we do not completely understand, RCA_0 seems to be an ideal base system, because it pulls noteworthy theorems into the logical equivalence classes of the set existence axioms for the other four members of the "big five." These include not only theorems of analysis, topology, and combinatorics – as we have seen – but also many theorems of countable algebra, which may be seen in Simpson (2009).

Nevertheless, as we have come to expect since the incompleteness theorem of Gödel (1931), some theorems remain out of reach.

In particular, there are two combinatorial theorems of the form "infinite sequence contains an infinite monotonic subsequence," modelled on the following consequence of the Bolzano-Weierstrass theorem, but more difficult to prove.

Ascending/Descending Sequence Principle (ADS) *Any infinite sequence of rational numbers contains an infinite monotonic subsequence.*

ADS easily follows from Bolzano-Weierstrass, hence it is provable in ACA_0. However, it is not provable in RCA_0, or in WKL_0. The complicated known facts about ADS are described in Hirschfeldt (2015), pp. 130–149. Perhaps the situation with the following analogues of ADS is just as complicated, but what is remarkable is their lofty position among the big five systems.

Kruskal's Tree Theorem *Any infinite sequence of finite trees contains an infinite subsequence that is increasing under the "embeds in" relation.*

Graph Minor Theorem *Any infinite sequence of finite graphs contains an infinite subsequence that is increasing under the graph minor relation.*

The tree theorem is due to Kruskal (1960). A proof may be found in Diestel (2010), along with a definition of the graph minor relation. The graph minor theorem was proved by Robertson and Seymour (2004) (the last in a series of papers that spanned 20 years!). Friedman showed that Kruskal's theorem is not provable in ATR_0. With Robertson and Seymour, he topped this result, in Friedman et al. (1987), by showing that the graph minor theorem is not provable in Π^1_1-CA_0.

13 Conclusions

While the idea of reverse mathematics applies in principle to many fields of mathematics, it has been particularly fruitful in subsystems of second-order arithmetic. This is where analysis and computability theory come together, thanks to their common foundations in arithmetic, and it becomes possible to exploit the wealth of results about computable and noncomputable structures that have been developed since the 1930s.

In particular, the "big five" systems give a precise analysis of the assumptions about infinity needed to prove basic theorems of analysis. The weakest system, RCA_0, in which only computable infinite objects are assumed to exist, may be viewed as a formalization of constructive mathematics. It is strong enough to prove the intermediate value theorem and the fundamental theorem of algebra, but not much else. However, RCA_0 is strong enough to prove many *equivalences* between statements, and it turns out that just four of these equivalence classes capture many basic theorems – not only in analysis but in topology, infinite combinatorics, and countable algebra. These four classes lie in four nonconstructive extensions of RCA_0: in order of inclusion, WKL_0, ACA_0, ATR_0, and Π^1_1-CA_0.

The defining axioms of WKL_0 and ACA_0 reveal principles not previously viewed as fundamental in analysis. In WKL_0, the defining axiom is the *weak König lemma*, which says that any infinite binary tree contains an infinite branch. This is a nonconstructive assumption, since there exists a computable infinite tree with no computable infinite branch. But its nonconstructive content is, in a sense that can be made precise, of "low degree." Despite its low nonconstructive content, the weak König lemma is equivalent to a version of the Heine-Borel theorem and the related properties of continuous functions: their uniform continuity and Riemann integrability, and the extreme value theorem. The weak König lemma is also equivalent to Brouwer's theorems in topology – the fixed-point theorem and the invariance of domain and dimension – so it pinpoints the nonconstructive content of these famous theorems.

The defining axiom of ACA_0 is *arithmetical comprehension*, which states the existence of sets defined in the language of arithmetic. Arithmetical comprehension includes both RCA_0 and WKL_0, since computability is definable in the language of arithmetic, but it goes further. In particular, arithmetical comprehension is equivalent to various sentences about convergence that WKL_0 cannot prove. Arithmetical comprehension is also equivalent to various statements of infinite combinatorics, such as the full König lemma (which is about finitely branching trees, not just binary trees) and various statements of Ramsey theory. Another measure of the strength of ACA_0 is its ability to prove all the theorems of first-order Peano arithmetic, whereas WKL_0 can match Peano arithmetic only for theorems with a limited number of quantifiers.

Nevertheless, there are theorems beyond the reach of ACA_0, and the systems ATR_0 and Π^1_1-CA_0 capture some of the important ones. They include some of the stronger theorems of Ramsey theory, and also theorems of analysis brought to light by Cantor, whose proofs involve countable ordinals. Just as RCA_0 may be viewed as a formalization of constructive mathematics, ATR_0 has been viewed as a formalization of *predicative* mathematics, in which set definitions are extended as far as possible as long as a set is not defined in terms of a collection that includes itself. Thus ATR_0 and Π^1_1-CA_0 allow us to pinpoint the position of certain theorems at or beyond the boundary of predicativity: the perfect set theorem belongs to predicative mathematics, but the Cantor-Bendixson theorem does not.

Thus reverse mathematics, even when restricted to the "big five" systems, illuminates the mathematics of infinite processes from the constructive to the predicative, and beyond.

Abstract

In 1934, Skolem gave a remarkable construction of a countable nonstandard model of arithmetic. His construction contains ideas of the ultrapower construction which was introduced in model theory 20 years later. However, typical ultrapower constructions produce uncountable models. Skolem's construction can also be connected with ideas from computability theory, formalized by Turing and others in 1936. The proof of one of Skolem's key statements can be interpreted using computability-theoretic notions of indecomposable sets developed in the late 1950s. We favor the computability-theoretic approach and

describe the connections of Skolem's ideas with our current study of cohesive powers of models in computable model theory.

Keywords

Model theory · Computability · Countable models · Cohesive ultrapower

1 Models and Theories

Model theory studies in a rigorous and general way the intuitive notion of a mathematical model, which is used in all the sciences. In the abstract language of model theory, a *model* (also called *structure*) is a nonempty set of elements, called the domain, with certain relations, functions (operations), and constants on the domain. The names for these objects are called relation symbols, function symbols, and constant symbols. These symbols constitute the *language* (also called *signature*) $\mathcal{L}$ of the model. Every relation symbol or a function symbol in $\mathcal{L}$ has arity (length) and is interpreted in a model as a relation or a function of the same arity. We consider first-order formulas with equality, which allow existential ($\exists$) and universal ($\forall$) quantification only over first-order variables (standing for elements of the domain of the structure). A structure is countable if its domain is countable.

A *magma* is a nonempty set with a binary operation, $(M, *)$. If the operation is associative, it is called a *semigroup.* A semigroup with a unit element is called a *monoid,* and a monoid where every element has an inverse is called a *group.* A *field* is a structure with two binary operations and two constants, $(F, +, \cdot, 0, 1)$, such that $(F, +, 0)$ and $(F - \{0\}, \cdot, 1)$ are groups. Examples of familiar countable structures are the ordered sets of natural numbers $(N, <)$, the ordered set of integers $(Z, <)$, and the ordered set of rational numbers $(Q, <)$; the monoid $(N, +, 0)$ of the natural numbers with addition, the additive group of integers $(Z, +, 0)$, and the field of rational numbers $\mathcal{Q} = (Q, +, \cdot, 0, 1)$.

A *sentence* (or a statement) in $\mathcal{L}$ is a formula where all variables are quantified. Every sentence in $\mathcal{L}$ can be assigned a truth value in a structure for the same language $\mathcal{L}$. A *theory* is a (consistent) set of sentences. The theory of a structure $\mathcal{A}$, in symbols $Th(\mathcal{A})$, is the set of all first-order sentences true in $\mathcal{A}$. Let n be a positive integer. We classify a formula in prenex normal form as Σ_n (or Π_n) if it has n blocks of like quantifiers, beginning with a block of $\exists$ (or $\forall$) quantifiers. For a formula α, in prenex normal form, we let $neg(\alpha)$ denote the dual formula that is logically equivalent to the negation $\neg\alpha$. If α is Σ_n, then $neg(\alpha)$ is Π_n, and vice versa. In other words, Σ_1 formulas are existential formulas and Π_1 formulas are universal formulas, Π_2 formulas are $\forall\exists$ formulas, Σ_2 formulas are $\exists\forall$ formulas, Π_3 formulas are $\forall\exists\forall$ formulas, etc. The quantifier-free formulas are considered to be both Σ_0 and Π_0.

Peano arithmetic, introduced by Giuseppe Peano in 1889, is a theory axiomatized by a finite set of axioms plus an induction axiom scheme, thus by countably many axioms. Peano arithmetic is intended to be an explicit axiomatic description of what we call the familiar structure of *natural numbers*,

$$\mathbb{N} = \left(N; S^{\mathbb{N}}, +^{\mathbb{N}}, \cdot^{\mathbb{N}}, 0^{\mathbb{N}}, =^{\mathbb{N}}\right),$$

which we study since elementary school, with the domain $N = \{0, 1, 2, \ldots\}$, with the usual successor function, addition and multiplication functions (operations), the constant zero, and the equality relation, in the language $\mathcal{L} = \{S, +, \cdot, 0, =\}$. Note that we often do not include equality as part of $\mathcal{L}$ since it is assumed. Here, we do include equality because of a historical reference (Skolem 1955) to Skolem's presentation. We often do not write the superscript $\mathbb{N}$ when it is clear from the context what the intended interpretation of the symbol is in the structure, thus using the same notation for the relations, operations, and constants in the structure and their names in the language. Here are the axioms of Peano arithmetic.

1. $S(x) \neq 0$,
2. $S(x) = S(y) \Rightarrow x = y$,
3. $x + 0 = x$,
4. $x + S(y) = S(x + y)$,
5. $x \cdot 0 = 0$,
6. $x \cdot S(y) = x \cdot y + x$,
7. Induction scheme: for every first-order formula $\alpha(x, \overline{y})$ with a free variable x and a finite sequence of parameters $\overline{y}$, we have

$$(\alpha(0, \overline{y}) \& (\forall z)(\alpha(z, \overline{y}) \Rightarrow \alpha(s(z), \overline{y}))) \Rightarrow (\forall x)\alpha(x, \overline{y}).$$

Axioms 1–2 state that 0 is not a successor and that the successor function is one-to-one; axioms 3–4 give a recursive definition of addition, and axioms 5–6 give a recursive definition of multiplication. *Peano arithmetic* (abbreviated as PA) is the set of all sentences that can be deduced from the axioms of PA using the inference rules of a formal system:

$$\mathrm{PA} = \{\sigma : \mathit{Axioms}(\mathrm{PA}) \vdash \sigma\}.$$

Other familiar relations on N can be defined. For example, the relation $\leq$ can be defined as:

$$a \leq b \Leftrightarrow (\exists c)(a + c = b).$$

We say that a set is *countable* if it is infinite but its elements can be enumerated in a sequence indexed by natural numbers. The enumeration does not have to be algorithmic. There are countably many $\mathcal{L}$-sentences in PA. Its set of axioms is not logically equivalent to a finite set of axioms as shown in 1952 by Ryll-Nardzewski (1952) (see also Mostowski 1952). Whether a sentence in the language of arithmetic is an axiom can be algorithmically verified.

A consistent theory T is complete if for every first-order sentence θ in the language of T we have $T \vdash \theta$ or $T \vdash \neg\theta$. It is a consequence of the Gödel incompleteness theorem that PA is incomplete. The incompleteness of PA means

that there is a sentence γ in $\mathcal{L}$ such that neither γ nor $\neg\gamma$ is in PA. The collection of all $\mathcal{L}$-sentences true in $\mathbb{N}$, the theory of $Th(\mathbb{N})$, is called *True arithmetic.* That is,

$$Th(\mathbb{N}) = \{\theta : \theta \text{ is a first-order sentence } \& \ \mathbb{N} \models \theta\}.$$

The theory of any model is complete, and hence $Th(\mathbb{N})$ is complete. Note that for the sentence γ (as above), either γ or $\neg\gamma$ is in $Th(\mathbb{N})$ and hence PA $\subsetneq Th(\mathbb{N})$.

Structures $\mathcal{A}$ and $\mathcal{B}$ in the same language $\mathcal{L}$ are *elementarily equivalent* if they satisfy the same first-order sentences, i.e., they have the same first-order theory. Such two structures are *isomorphic* if the elements of $\mathcal{A}$ can be "renamed" so the structure $\mathcal{A}$ becomes essentially the same as the structure $\mathcal{B}$. More precisely, there is a bijection h (one-to-one and onto function), mapping the domain of $\mathcal{A}$ to the domain of $\mathcal{B}$ so that for each relation symbol R, each function symbol f, and each constant symbol c, we have:

$$\begin{aligned} &R^{\mathcal{A}}(\overline{a}) \Leftrightarrow R^{\mathcal{B}}(h(\overline{a})), \\ &f^{\mathcal{A}}(\overline{a}) = b \Leftrightarrow f^{\mathcal{B}}(h(\overline{a})) = h(b), \\ &h(c^{\mathcal{A}}) = c^{\mathcal{B}}. \end{aligned}$$

In particular, isomorphic structures have the same cardinality (size) since there is a bijection between their domains. While isomorphic structures are elementarily equivalent, the converse does not hold for infinite structures. Thus, nonisomorphic structures may be the models of the same first-order theory. Intended models of such theory (as determined by mathematical practice) as well as their isomorphic copies are called *standard,* while all other models of the theory are considered to be *nonstandard.*

Neither PA nor $Th(\mathbb{N})$ fully "captures" the structure $\mathbb{N} = (N; S, +, \cdot, 0, =)$. There are models of PA (and of $Th(\mathbb{N})$) that are not isomorphic to $\mathbb{N}$ and are thus nonstandard. Both the ultrapower construction and the compactness theorem from model theory provide such nonstandard models. For more on model theory see (Chang and Keisler 1990; Bell and Slomson 1974), and on models of PA see (Kaye 1991; Kossak and Schmerl 2006).

2 Constructing Models via Ultraproducts

2.1 Ultrafilters

Various product constructions have been one of the major tools for building models of theories. These constructions often produce nonstandard models. We will now define a family of sets that will be used to determine truth in one type of products, called ultraproduct. Consider a nonempty set I, which will be used to index structures. We will call it an index set. A *filter* over I is a nonempty set D of subsets of I such that D is closed under the finite intersections of sets and under the superset relation. That is,

(1) if X and Y belong to D, then $X \cap Y$ belongs to D, and
(2) if V belongs to D and $V \subseteq Z \subseteq I$, then Z belongs to D.

The notion of a filter was introduced by Cartan in 1937 and it can be defined more generally with respect to some partially ordered set. In our case, the subsets of I are ordered by the partial relation of set-theoretic inclusion $\subseteq$, and a filter includes some subsets that are large enough to satisfy properties (1) and (2).

The set of all subsets of I is called the power set of I and is denoted by $\mathcal{P}(I)$. Hence a filter is a subset of $\mathcal{P}(I)$. An important filter is a Fréchet filter, which consists of all co-finite subsets of I, i.e., those subsets of I with finite complements. A proper filter U is called an *ultrafilter* over I if, in addition to properties (1) and (2), we have

(3) for every subset X of I, either X or $I - X$ belongs to U.

It can be shown that for any $i \in I$, the set of all $X \subseteq I$ such that $i \in X$ forms an ultrafilter. Such an ultrafilter is called *principal.* Hence an ultrafilter U is *nonprincipal* if for every $i \in I$, we have that $\{i\} \notin U$.

A set of sets $\mathcal{K}$ has the *finite intersection property* if no intersection of finitely many elements of $\mathcal{K}$ is empty. It can be shown that a set U of subsets of I is an ultrafilter over I exactly when U has the finite intersection property and is a maximal such family with respect to inclusion $\subseteq$. Moreover, if there is a nonprincipal ultrafilter U over I, then I must be infinite. That is, if, to the contrary, $I = \{a_1, \ldots, a_n\}$, then $\{a_i\} \notin U$ for every i with $1 \leq i \leq n$, so $I - \{a_i\} \in U$. Hence,

$$(I - \{a_1\}) \cap \cdots \cap (I - \{a_n\}) = \emptyset,$$

which is a contradiction.

Another way to describe an ultrafilter U over I is to replace property (3) with the property:

(3a) if U contains the union of two sets, then it contains at least one of them.

The last property generalizes to finitely many sets, so if an ultrafilter contains a finite set of elements, it must contain at least one of these elements. Hence if U is a nonprincipal ultrafilter over I, then U contains all co-finite subsets of I. Thus, assuming that I is infinite, is there a nonprincipal ultrafilter over I? We can show that we can establish this assuming Zorn's lemma, also called Kuratowski-Zorn lemma. Zorn's lemma is equivalent to the axiom of choice. For partial order of set inclusion, Zorn's lemma states that if $\mathcal{K}$ is a nonempty set of sets that is closed under unions of nonempty chains then $\mathcal{K}$ has a maximal element.

Theorem 1 *(assuming Zorn's lemma) Let I be any infinite set. Then there is a nonprincipal ultrafilter over I.*

For proof see (Bell and Slomson 1974).

2.2 Ultraproducts of Structures

The notion of the ultraproduct of first-order structures in general has been introduced by Łoś (1955) in 1955. We will now give a series of definitions and results related to the ultraproduct construction.

Let I be an infinite set, and let $\mathcal{A}_i$ for $i \in I$ be a family of structures for the same language $\mathcal{L}$ with domains A_i. Let U be an ultrafilter over I. Then the *ultraproduct* of $\mathcal{A}_i$ over U, denoted by $\mathcal{B} = \Pi_U \mathcal{A}_i$, is a structure for $\mathcal{L}$ defined as follows.

(1) The domain of the ultraproduct consists of the equivalence classes of functions f such that $f(i) \in A_i$ for every $i \in I$, modulo the equivalence relation $=_U$ defined below. We can write f as a sequence $(f(i))_{i \in I}$ choosing for each i an element of A_i. The *equality modulo U* relation $=_U$ is defined as follows:

$$f =_U g \text{ iff } \{i : f(i) = g(i)\} \in U.$$

We think of elements of U as "large sets," so the agreement of f and g is on a large set. We can easily verify that $=_U$ is an equivalence relation (reflexive, symmetric, and transitive binary relation, such as equality). The equivalence class of a function f is denoted by $[f]$. The equivalence classes are the elements of the domain $\Pi_U A_i$ of the ultraproduct.

(2) Let R be an n-ary relation symbol in $\mathcal{L}$. We define its interpretation in $\mathcal{B}$:

$R^{\mathcal{B}}([f_1], \ldots, [f_n])$, holds iff

$$\{i \in I : R^{\mathcal{A}_i}(f_1(i), \ldots, f_n(i))\} \in U.$$

We can show that this relation is well defined.

(3) Let F be an n-ary function symbol in $\mathcal{L}$. We define its interpretation in $\mathcal{B}$:

$F^{\mathcal{B}}([f_1], \ldots, [f_n]) = [g]$, where for every $i \in I$, we have

$$g(i) = F^{\mathcal{A}_i}(f_1(i), \ldots, f_n(i)).$$

We can show that this function is well defined.

(4) Let c be a constant symbol in $\mathcal{L}$. We define its interpretation in $\mathcal{B}$:

$c^{\mathcal{B}} = [f]$ where for every $i \in I$,

$$f(i) = c^{\mathcal{A}_i}.$$

The following theorem, sometimes called the fundamental theorem of ultraproducts, establishes the satisfiability in the ultraproduct.

Theorem 2 *(Łoś 1955)*

If $\alpha(x_1, \ldots, x_n)$ *is a formula in language* $\mathcal{L}$*, then*

$$\mathcal{B} \models \alpha([f_1], \ldots, [f_n]) \text{ iff } \{i : \mathcal{A}_i \models \alpha(f_1(i), \ldots, f_n(i))\} \in U.$$

Hence if σ *is a sentence, then*

$$\mathcal{B} \models \sigma \text{ iff } \{i : \mathcal{A}_i \models \sigma\} \in U.$$

If all structures $\mathcal{A}_i$ are the same structure $\mathcal{A}$, then the ultraproduct is called an *ultrapower* and denoted by $\Pi_U \mathcal{A}$. An important consequence of Łoś's theorem is the following:

Corollary 1 *If* $\mathcal{B} = \Pi_U \mathcal{A}$ *is an ultrapower, then* $\mathcal{A}$ *and* $\mathcal{B}$ *are elementarily equivalent.*

Example: Let $\mathcal{A} = (N, +)$, the additive semigroup (in fact, monoid) of natural numbers. Additive number theory, also called Presburger-Skolem arithmetic, is the set of all first-order sentences true in $\mathcal{A}$ (see Smoryński 1991). A standard model of this theory is any model isomorphic to $\mathcal{A}$. Let $I = N$, and let U be a nonprincipal ultrafilter over I. Consider the ultrapower $\mathcal{B} = \Pi_U \mathcal{A}$ with domain B. Notice that for $a = [(a_0, a_1, a_2, \ldots)] \in B$ and $b = [(b_0, b_1, b_2, \ldots)] \in B$, we have

$$a + b = [(a_0 + b_0, a_1 + b_1, a_2 + b_2 \ldots)],$$

and

$$a + [(0, 0, 0, \ldots)] = a.$$

Łoś's theorem implies that $\mathcal{A}$ and $\mathcal{B}$ satisfy the same first-order sentences. Hence $\mathcal{B}$, although uncountable, is also a model of additive number theory. However, it has some very different properties from $(N, +)$. For example, consider $a = [(a_0, a_1, a_2, \ldots)] \in B$, where $a_0 = 0$, $a_1 = 1$, $a_2 = 1 \cdot 2$, $a_3 = 1 \cdot 2 \cdot 3, \ldots$ Then we can show that a has the property that for every natural number $n > 0$, there is a b such that:

$$a = b + \cdots + b \ (n \text{ times})$$

So, in the structure $\mathcal{B}$, a is divisible by every natural number $n > 0$.

Let U be a principal ultrafilter over N. If $U = \{X : X \subseteq N \,\&\, m \in X\}$, then $\Pi_U \mathcal{A}_i$ is isomorphic to $\mathcal{A}_m$.

Definition 1 A filter D is *countably incomplete* if it is not closed under countable intersections.

Let U be a nonprincipal ultrafilter over N. Clearly, N can be partitioned into countably many finite sets, so their co-finite complements are elements of U, and form a countable collection of sets with empty intersection. Hence any nonprincipal ultrafilter U over N is countably incomplete. Frayne, Morel, and Scott (1962) showed that for a countably incomplete ultrafilter U, the ultraproduct $\Pi_U \mathcal{A}_i$ is either finite or of cardinality at least continuum. Continuum is the cardinality of the power set of N, which is the same as the cardinality of the set of real numbers. Thus, such an ultraproduct $\Pi_U \mathcal{A}_i$ is never countably infinite.

Hence any ultrapower $\Pi_U \mathbb{N}$ of the standard model of arithmetic, $\mathbb{N} = (N; S, +, \cdot, 0, =)$, over a nonprincipal ultrafilter U has the same first-order theory as $\mathbb{N}$, but is not isomorphic to $\mathbb{N}$ since it is uncountable.

2.3 Compactness Theorem

Compactness theorem is another convenient tool for building nonstandard models. Compactness is a property of topological spaces and was introduced by Fréchet in 1906. In our case it means that satisfiability of an infinite theory is guaranteed by the satisfiability of all of its finite subtheories. Compactness theorem is often proved as a consequence of the Gödel completeness theorem. It can also be proved using the ultraproduct construction (see Frayne et al. 1962).

Theorem 3 *Let Σ be an infinite first-order theory. Assume that every finite subset of Σ has a model. Then Σ has a model.*

Proof idea Let the index set I be the set of all finite subsets of Σ. For every $i \in I$, let $\mathcal{A}_i$ be a model for i. Then a model $\mathcal{B}$ of Σ is produced as an ultraproduct $\Pi_U \mathcal{A}_i$ of the models $\mathcal{A}_i$ over a suitably defined ultrafilter U on I.

We can use compactness theorem to produce models with nonstandard elements. We first expand the original language with names for nonstandard elements and describe their properties using an infinite set of sentences in the expanded language.

Theorem 4 *There is a model of Th*$(\mathbb{N})$ *with nonstandard numbers*.

Proof Let $\mathcal{L}$ be the language of arithmetic. Let c be a new constant, and $\mathcal{L}' = \mathcal{L} \cup \{c\}$. Define the following set of sentences in $\mathcal{L}'$:

$$\Sigma = Th(\mathbb{N}) \cup \{c \neq 0, c \neq 1, c \neq 1+1, c \neq 1+1+1, \ldots\}.$$

We will apply compactness theorem to Σ. Let Σ' be a finite subset of Σ and let n be the largest number such that the following sentence

$$c \neq 1 + 1 + \cdots + 1(n \text{ ones})$$

belongs to Σ'. Then the standard model $\mathbb{N}$, with the constant c interpreted as the number $n+1$, is a model of Σ'.

By compactness theorem, Σ has a model $\mathcal{A}$. The reduct of $\mathcal{A}$ to $\mathcal{L}$ is a model of $Th(\mathbb{N})$ and it cannot be isomorphic to $\mathbb{N}$ because the interpretation of c in $\mathcal{A}$ is one of its nonstandard elements.

The ultraproduct proof of the compactness theorem may produce uncountable models. A different proof of the compactness theorem produces a countable model of $Th(\mathbb{N})$. Namely, it is easy to see that in any formal system a set of sentences Σ is consistent if and only if every finite subset of Σ is consistent. Assume that every finite subset of Σ is satisfiable (and thus consistent). Then Σ itself is consistent. Assuming that the language of Σ is finite or countable, we can use the proof of Gödel completeness theorem due to Henkin (in 1949) to construct a countable model of Σ. Thus, $Th(\mathbb{N})$ also has a countable nonstandard model.

By PA^- we denote essentially PA without the induction axiom scheme. Gödel and Rosser showed that if T is a theory in the language of arithmetic with a computable set of axioms, which extends PA^-, then there is a sentence (in fact, Π_1 sentence) ψ such that neither ψ nor $\neg\psi$ can be deduced from T. Thus both $T \cup \{\neg\psi\}$ and $T \cup \{\psi\}$ are consistent. Continuing this process we can show that there are continuum many countable nonstandard models of T (and hence of PA). Regarding the order type of such nonstandard models of arithmetic, Henkin showed that they are order isomorphic to a copy of the natural numbers followed by countably densely many (without ends) copies of integers.

3 Computability Theory and Skolem's Model of Arithmetic

Computability theory, the exact theory of algorithms, studies the power and inherent limitations of algorithmic methods. The most fundamental concept in computability theory is that of a computable set. A set, or more generally a relation, is *computable* if there is a decision procedure for determining in finitely many steps whether a given tuple of elements belongs to that relation.

A set of natural numbers is *computably enumerable* if there is an algorithm that enumerates (lists) its elements. Computably enumerable sets are often abbreviated by c.e. All c.e. sets can be simultaneously algorithmically listed by systematically coding all Turing machine programs

$$P_0, P_1, P_2, \ldots, P_e, \ldots$$

Let

$$\varphi_0, \varphi_2, \varphi_2, \ldots, \varphi_e, \ldots$$

be an algorithmic enumeration of all unary partial computable functions on natural numbers (computed by the corresponding Turing machine programs). Some of these functions are computable. A function is *computable* if it is partial computable and defined on all of N. However, a diagonal argument can be used to show that there is no algorithmic enumeration of all computable functions.

A set X is c.e. if there is a computable function f that enumerates its elements. That is, the set X is the range (the set of all values) of f:

$$X = rng(f) = \{f(n) : n \in N\}.$$

It can be shown that a set is c.e. if and only if it is the domain of a partial computable function. The domain of a partial computable function φ_e is denoted by W_e. We say that an index e is the Gödel code of φ_e. Each partial computable function has infinitely many such codes. Hence

$$W_0, W_1, W_2, \ldots, W_e, \ldots$$

is an algorithmic enumeration of all c.e. sets.

It can be shown that a set is computable if and only if both the set and its complement are c.e. There are c.e. sets the complements of which are not c.e. Namely, there are noncomputable c.e. sets. For example, the Turing *halting set*

$$K = \{e : \varphi_e(e) \text{ halts}\} = \{e : e \in W_e\}$$

is c.e., but not computable. The set K is c.e. because it is enumerated by an algorithm that simultaneously runs, for more and more computational steps, $\varphi_0(0)$, $\varphi_1(1)$, $\varphi_2(2)$, ... and enumerates those e for which $\varphi_e(e)$ converges, as soon as the convergence occurs. We can show that the complement $\overline{K}$ is not c.e. Assume otherwise. Then $\overline{K} = W_i$ for some i and

$$i \in \overline{K} \Leftrightarrow i \in W_i \Leftrightarrow i \in K,$$

which is a contradiction. Infinite computable sets can be viewed as c.e. sets the elements of which are enumerated in strictly increasing order.

Computable sets describe decidable problems. Computably enumerable sets describe partial decidable problems. There are continuum many non-c.e. sets that are further classified into an infinite hierarchy according to their computability-theoretic complexity.

A set X of natural numbers is called *arithmetical* if and only if it is definable in the standard model of arithmetic. That is, X is definable in $\mathbb{N}$ if there is a first-order

formula $\alpha(x)$ in the language of arithmetic with a free variable x, so that X is the set of all elements n in N such that $\alpha(n)$ is true in $\mathbb{N}$. There is a similar definition for an n-ary relation P on natural numbers. Such an arithmetical relation P is classified as being Σ_n^0 (Π_n^0, respectively) if and only if it is definable by a Σ_n (Π_n, respectively) formula in $\mathbb{N}$. Moreover, as Gödel and Matiyasevich established, $\Sigma_1^0 \cap \Pi_1^0$ sets are exactly the computable sets, Σ_1^0 sets are exactly the c.e. sets, Π_1^0 sets are exactly the complements of c.e. sets, etc. Any set of sentences in a computable language (including any finite language) can be represented as a subset of N by identifying sentences with their Gödel codes. It turns out that Peano arithmetic (PA) is a c.e. theory (Σ_1^0 set), while $Th(\mathbb{N})$ is not Σ_n^0 for any n.

We say that a countable structure for a computable language $\mathcal{A}$ is *computable* if its domain A is a computable set and its relations and functions are uniformly computable. In computable structures, we have a decision algorithm not only for quantifier-free sentences, but also for quantifier-free sentences with constant symbols added as names for all elements of the domain. Examples of computable structures include the ordered sets of natural numbers, integers, rational numbers, the additive group of integers, and the standard model of arithmetic. Note that computable structures may have complicated theories such as $Th(\mathbb{N})$.

It is much harder to think of a countable noncomputable structure. In the following example of such structure, let X be any noncomputable set. Define a linear order

$$\mathcal{A} = (N, \prec)$$

with (computable) domain N and a special order relation $\prec$, which is the same as the usual order relation $<$ except that the order is switched on each pair $(2n, 2n+1)$ if $n \notin X$. That is:

$$2n \prec 2n+1 \text{ if } n \in X,$$
$$2n+1 \prec 2n \text{ if } n \notin X.$$

Note that $\mathcal{A}$ is not computable as a structure, because the membership in the set X can be computed from the order relation $\prec$ of $\mathcal{A}$. Moreover, $\mathcal{A}$ is isomorphic to the ordered set of natural numbers $(N, <)$.

The standard model $\mathbb{N}$ of arithmetic is computable, while, as Tennenbaum (1959) showed, nonstandard models are not computable. Namely, if $\mathcal{M}$ is a nonstandard model of PA with domain M, then $(M, +, 0)$ is not computable. For proof and ramifications of Tennenbaum's theorem see (Kaye 1991; Schmerl 2011; Ash and Knight 2000).

For more on computability theory see (Soare 1987; Rogers 1967; Smoryński 1991) and on computable model theory see (Ash and Knight 2000; Fokina et al. 2014).

3.1 Notes on Skolem's 1955 Paper

In 1934, Skolem (1934) gave a remarkable construction of a countable nonstandard model of arithmetic. In 1955, he (Skolem 1955) presented the same result using more contemporary notation and terminology. His model can be described using notions from computability theory. In the introduction to his 1970 paper, Lerman (1970) gave the following description of Skolem's model:

"In 1934, Skolem proved the nonaxiomatizability of arithmetic by constructing nonstandard models for arithmetic. He did so by taking all arithmetic functions of one variable, and factoring out by the equivalence relation: $f \sim g$ if and only if $f(x) = g(x)$ almost everywhere (a.e.) in A, i.e., for all but finitely many $x \in A$, where A is any arithmetically indecomposable set. The model thus obtained satisfies exactly the same first-order sentences as the nonnegative integers."

The elements of Skolem's model of arithmetic are equivalence classes of functions of arbitrary arithmetic complexity. There have been studies of more effective models of fragments of arithmetic by Feferman, Scott, and Tennenbaum (1959), Hirshfeld, Lerman, McLaughlin, and Wheeler (Lerman 1970; Hirshfeld 1975; Hirshfeld and Wheeler 1975; McLaughlin 1989, 1990, 2007). Recursive ultrafilter construction has also been studied by Nelson (1992). More recently, cohesive powers of computable structures have been studied by Dimitrov, Harizanov, Miller, Mourad, Shafer, A. Soskova, and Vatev (2008, 2009a, 2014, n.d.). In this section, we give a more detailed analysis of Skolem's construction and its connection with effective ultrapowers of computable structures, known as cohesive powers (see Dimitrov 2009a).

The language $\mathcal{L} = \{', +, \cdot, 1, =\}$ used by Skolem is essentially our language $\{S, +, \cdot, 0, =\}$, where $'$ is the successor function S. Skolem uses a standard axiomatization of arithmetic, similar to PA but excluding zero. Since $'$ is definable in $\mathcal{L}_1 = \{+, \cdot, 1, =\}$, Skolem's formulas are essentially the first-order formulas in $\mathcal{L}_1$. The formulas are built "by use of quantifiers on an elementary expression, namely built by use of &, $\vee$ and $\neg$ on equations with polynomial terms on both sides." In other words, formulas are assumed to be in the prenex normal form. For $\mathcal{L}_1$-formulas, Skolem first replaces $y \neq x$, that is, $\neg(y = x)$ with

$$\exists z((x = y + z) \vee (y = x + z)). \tag{1}$$

Assuming that the sentences are in the prenex normal form, Skolem proceeds to omit the other propositional connectives. He replaces

$$(x = y) \vee (z = t)$$

with

$$xt + yz = xz + yt. \tag{2}$$

He replaces

$$(x = y)\&(z = t)$$

with

$$x^2 + y^2 + z^2 + t^2 = 2xy + 2zt. \tag{3}$$

Thus, every sentence is equivalent to a single equation involving polynomials on both sides preceded by a sequence of quantifiers. Skolem then considers "the true" sentences of type

$$\forall x_1 \ldots \forall x_n \exists y \Phi(x_1, \ldots, x_n, y),$$

where the arithmetic complexity of Φ is unrestricted. According to Skolem "the word true may mean provable in the system or that the statement is assumed as a further axiom." So we can assume that $\forall x_1 \ldots \forall x_n \exists y \Phi(x_1, \ldots, x_n, y)$ is an element of $Th(\mathbb{N})$. Such sentences define the arithmetical functions (now also called Skolem functions) as follows:

$$f(x_1, \ldots, x_n) = y \Leftrightarrow \Phi(x_1, \ldots, x_n, y)\&(\forall z)(\neg\Phi(x_1, \ldots, x_n, z) \vee (y \leq z)). \tag{4}$$

In the expression above we assume that $\leq$ is defined in $\mathcal{L}_1$ as usual. The set of all such arithmetical functions $f(x_1, \ldots, x_n)$ is denoted by F. Skolem then performs what we now call Skolemization where we repeatedly replace the first existentially bound variable y that is in the scope of the universal quantifiers $\forall x_1 \ldots \forall x_n$ by the function $f(x_1, \ldots, x_n) \in F$ as described in (4). In the example given by Skolem,

$$(\forall x)(\forall y)(\exists z)((x = y) \vee (x = y + z) \vee (y = x + z))$$

is replaced by

$$(\forall x)(\forall y)((x = y) \vee (x = y + f(x, y)) \vee (y = x + f(x, y))),$$

where in this case the Skolem function $f(x, y)$ is the "distance" function,

$$f(x, y) = \mid x - y \mid.$$

Note that we leave the occurrences of $\vee$ in the sentence above for the clarity of presentation.

We can assume that all sentences in $Th(\mathbb{N})$ are in the *Skolem normal form* (a block of universal quantifiers followed by a quantifier-free formula). Since the set F of arithmetical functions is closed under function composition (also called nesting or substitution), each sentence in $Th(\mathbb{N})$ is the universal closure of a single equation involving elements of F. Before defining a countable nonstandard model $\mathbb{N}^*$ of $Th(\mathbb{N})$, Skolem proves an important lemma.

Lemma 1 *(Skolem, Satz 1 in (Skolem 1934), Arithmetical Lemma in (Skolem 1955))*

Let $F_1 = \{f_1(t), f_2(t), \ldots\}$ be the set of arithmetical functions of one variable. There is a function $g(t)$ in F_1 such that for all nonequal $i, j \geq 1$, exactly one of the following holds:

$$\forall t > \max(i,j)\Big(f_i(g(t)) < f_j(g(t))\Big),$$

$$\forall t > \max(i,j)\Big(f_i(g(t)) = f_j(g(t))\Big),$$

$$\forall t > \max(i,j)\Big(f_i(g(t)) > f_j(g(t))\Big).$$

Remark 1 We will not provide a proof of Skolem's lemma here. However, we will later modify a proof of the existence of a cohesive set, a result by Dekker and Myhill (see Theorem VI in 12.3 of (Rogers 1967)), in order to show its similarity to Lemma 1.

Next, fix a function g the existence of which is given by Lemma 1, and let

$$f_i =^g f_j \text{ iff } \Big\{t : f_i(g(t)) = f_j(g(t))\Big\} = N \text{ almost everywhere.}$$

It is easy to see that $=^g$ is an equivalence relation. For any $f \in F_1$, let $[f]$ denote the equivalence class of f:

$$[f] = \{h \in F_1 : h =^g f\}.$$

Let the domain N^* be the set of all equivalence classes:

$$N^* = \{[f] : f \in F_1\}.$$

Let $\mathbb{N}^*$ be the structure in the language $\{+, \cdot, 1, =\}$ with domain N^* where $=_{\mathbb{N}^*}$, $1_{\mathbb{N}^*}$, $+_{\mathbb{N}^*}$, and $\cdot_{\mathbb{N}^*}$ are defined as follows. The equality $=_{\mathbb{N}^*}$ is the equality between equivalence classes (the elements of N^*). The constant $1_{\mathbb{N}^*}$ is the equivalence class of the function with constant value 1, denoted by [1], and

$$[f] +_{\mathbb{N}^*} [h] = [f + h],$$
$$[f] \cdot_{\mathbb{N}^*} [h] = [f \cdot h].$$

Skolem then verifies that the sentences in $Th(\mathbb{N})$ hold in $\mathbb{N}^*$. His verification can be viewed in comparison with a proof of Łoś's Theorem for ultrapowers. The fact that $\mathbb{N}^*$ is a nonstandard model of arithmetic which has $\mathbb{N}$ as its submodel is verified as follows. For $n \in N$, let $[n] \in \mathbb{N}^*$ be the equivalence class of the function with constant value n. The set $\{[n]: n \in N\}$ of equivalence classes of the constant

functions provide a copy of $\mathbb{N}$ in $\mathbb{N}^*$. The sentence $\forall x \exists y(x = y)$ defines the identity function

$$id(x) = x.$$

It is obvious that $[id] \in \mathbb{N}^*$ and $[id] \neq [n]$ for any $n \in N$, and hence $\mathbb{N}^*$ cannot be isomorphic to $\mathbb{N}$:

$$\mathbb{N}^* \ncong \mathbb{N}.$$

The class of arithmetically definable functions is countable because the language is countable. The model $\mathbb{N}^*$ is countable because its universe consists of equivalence classes of an equivalence relation $=^g$ defined on the countable family F_1.

A theory is *countably categorical* if it has exactly one countable model, up to isomorphism. Skolem's result shows that neither PA nor $Th(\mathbb{N})$ are countably categorical. Hence, the hope that $Th(\mathbb{N})$ (or even PA) has only one countable model up to isomorphism, the familiar structure $\mathbb{N}$, is shattered. However, $\mathbb{N}$ is the only computable such model.

In the introduction to his 1955 paper, Skolem refers to the Löwenheim-Skolem theorem and Skolem's paradox. For him "the notion set and particularly the notion subset in the case of infinite sets can only be asserted to exist in a relative sense." Since an axiomatization of the natural number series exists within set theory, the axiomatization of the number series also cannot be expected to be absolute. The model $\mathbb{N}^*$ constructed by Skolem is remarkable also because it can be described using computability-theoretic notions, which were developed much later than Skolem's original 1934 paper.

3.2 Computability and Models of Fragments of Arithmetic

In this section we will exploit notions of modern computability theory to build nonstandard models of theories. We will start by comparing Skolem's nonstandard model $\mathbb{N}^*$ with the following models:

(i) A structure denoted by $\mathcal{R}/_{\sim A}$, which was proposed by Feferman, Scott, and Tennenbaum (1959) as a nonstandard model of arithmetic,
(ii) A structure denoted by $\Pi_C\mathbb{N}$, called a cohesive power of $\mathbb{N}$, which was introduced by Dimitrov (2009a).

4 Cohesive Sets

The two approaches (i)–(ii) use various notions of algorithmically indecomposable sets. Skolem's Arithmetical Lemma 1 also implicitly uses this notion. We will now give relevant definitions and results from computability theory.

Definition 2

(1) An infinite set C of natural numbers is called *cohesive* if for every c.e. set W, either $W \cap C$ or $(N - W) \cap C$ is finite. That is, a set is cohesive if it is indecomposable into two infinite parts by a c.e. set.
(2) Some cohesive sets have c.e. complements called maximal sets. That is, a set M is *maximal* if M is c.e. and its complement $(N - M)$ is cohesive.

The notion of cohesiveness was introduced by Rose and Ullian (1963) in 1963, and is related to the notion of indecomposability introduced by Dekker and Myhill (1960) in 1960. Friedberg (1958), answering a question of Myhill from 1956, constructed a maximal set in 1958 without using an explicit reference to the notion of a cohesive set.

Similarly, r-cohesive and r-maximal sets are defined, where r stands for recursive, which is a synonym for computable.

Definition 3

(1) An infinite set $C \subseteq N$ is *r-cohesive* if for every computable set W, either $W \cap C$ or $(N - W) \cap C$ is finite.
(2) A set M is *r-maximal* if M is c.e. and $(N - M)$ is *r-cohesive.*

Clearly, maximal sets are r-maximal since computable sets are c.e., but the converse does not hold.

Theorem 5 *There is a function g: $N \to N$ such that its range rng(g) is a cohesive set.*

Proof Let $E_0, E_1, E_2, \ldots$ be any list of all c.e. sets.

We simultaneously define by induction an infinite sequence of sets

$$C_0 \supseteq C_1 \supseteq C_2 \supseteq \cdots$$

and a function g.

Let $C_0 = N$. Let $g(0) = 0$.

Assume that we have defined C_n and $g(n)$.

$$\text{Let } C_{n+1} = \begin{cases} C_n \cap E_n & \text{if } C_n \cap E_n \text{ is infinite,} \\ C_n \cap (N - E_n) & \text{otherwise.} \end{cases}$$

Let $g(n+1)$ be the least $c \in C_{n+1}$ such that $c > g(n)$.

Remark 2 The proof of Theorem 5 has been presented as a construction of a function g: $N \to N$ such that $rng(g)$ is a cohesive set. The original theorem of Dekker

and Myhill establishes that every infinite set has a cohesive subset. While there are countably many maximal sets, there are continuum many cohesive sets.

We can prove Skolem's Lemma 1 using the procedure outlined in the proof of Theorem 5. Using Skolem's list of arithmetical functions we define the following sets for $i, j \geq 1$ and $i \neq j$:

$$A_{ij1} = \Big\{n : f_i(n) < f_j(n)\Big\},$$
$$A_{ij2} = \Big\{n : f_i(n) = f_j(n)\Big\},$$
$$A_{ij3} = \{n : f_i(n) > f_i(n)\}.$$

While the sets A_{ijk} may not be c.e. (although they are arithmetical), we can construct a function g such that $rng(g)$ is indecomposable for the sequence A_{ijk} where $k = 1, 2, 3$ and $i, j \geq 1$ and $i \neq j$. We can call $rng(g)$ an arithmetically indecomposable set.

4.1 Feferman-Scott-Tennenbaum Model

Following Skolem's construction of a countable nonstandard model of arithmetic, Tennenbaum asked whether starting with computable functions and an r-cohesive set C, we could produce a nonstandard model of arithmetic. Below we give a description of such structure and the negative answer to Tennenbaum's question provided in (Feferman et al. 1959) by Feferman, Scott, and Tennenbaum. The structure they built is a model of only a fragment of arithmetic but is very interesting due to its constructive properties.

Let $\mathcal{R}$ be the set of all computable (recursive) functions, and let C be a fixed r-cohesive set. Feferman, Scott, and Tennenbaum constructed a structure, denoted by $\mathcal{R}/\sim_C$, consisting of equivalence classes of computable functions modulo an equivalence relation $\sim_C$ on $\mathcal{R}$. More specifically, for computable unary functions f and g let

$$f \sim_C g \text{ iff } C \subseteq^* \{n : f(n) = g(n)\}.$$

We write $X \subseteq^* Y$ if all but finitely many elements of X are also elements of Y. The domain of the structure $\mathcal{R}/\sim_C$ consists of the equivalence classes of computable functions under $\sim_C$. The arithmetic operations of addition and multiplication are defined naturally (poinwise). Feferman, Scott, and Tennenbaum proved that $\mathcal{R}/\sim_C$ is a model of only a fragment of arithmetic. They constructed a particular Π_3 sentence σ such that

$$\mathbb{N} \models \sigma \text{ but } \mathcal{R}/\sim_C \models \neg\sigma.$$

4.2 Cohesive Powers of Computable Structures

Recent developments in the area of computability-theoretic ultrapowers of structures arose from Dimitrov's study (2004, 2008, 2009b) of c.e. vector spaces over computable fields. The study of the computable infinite-dimensional vector space V_∞ has been ongoing since Metakides and Nerode (1977) introduced it in 1977. The vectors in the space V_∞ are the finitely nonzero infinite sequences of elements from a computable field F. The most natural infinite computable field is the field $\mathcal{Q}$ of rational numbers. In (Dimitrov 2008), we discovered an interesting class of nonstandard fields, later called cohesive powers of $\mathcal{Q}$, and denoted by $\Pi_C \mathcal{Q}$, where C is a cohesive set. The field $\Pi_C \mathcal{Q}$ has certain similarities with the classical ultrapower construction. In (Dimitrov 2009a), we introduced the notion of cohesive powers of computable structures in general. While cohesive powers arose from investigating lattices of c.e. vector spaces (Dimitrov and Harizanov 2016, 2017, n.d.), it became clear that $\Pi_C \mathbb{N}$ was an interesting structure in itself. We later discovered the exact connection between $\Pi_C \mathbb{N}$ and the structure $\mathcal{R}/_{\sim C}$ of Feferman, Scott, and Tennenbaum.

A partial computable function φ can be thought of as having a partial algorithm that takes elements $n \in N$ as inputs and either halts and outputs the value $\varphi(n)$, or computes forever in which case $\varphi(n)$ is undefined. We denote the halting computation by $\varphi(n)\downarrow$ and computing forever by $\varphi(n)\uparrow$. The domain of φ, the set of all inputs on which the partial algorithm halts, is a c.e. set. Two partial functions φ and ψ are equal, denoted by $\varphi \simeq \psi$, if on every input either both are undefined, or both are defined and have the same value, denoted by $\varphi(n)\downarrow = \psi(n)\downarrow$. Determining whether a partial computable function is total (hence computable) is an undecidable problem.

Definition 4 (Dimitrov 2009a) Let $\mathcal{L}$ be a finite language and $\mathcal{A}$ be a computable $\mathcal{L}$-structure with domain $A \subseteq N$. Let $C \subseteq N$ be cohesive. The *cohesive power of* $\mathcal{A}$ *over* C, denoted by $\Pi_C A$, is the $\mathcal{L}$-structure $\mathcal{B}$ defined as follows:

- Let $D = \{\varphi: (\varphi: N \to A)$ is partial computable with $C \subseteq^* dom(\varphi)\}$.
- For $\varphi, \psi \in D$, let $\varphi =_C \psi$ iff $C \subseteq^* \{i: \varphi(i)\downarrow = \psi(i)\downarrow\}$. The relation $=_C$ is an equivalence relation on D. Let $[\varphi]$ be the equivalence class of $\varphi \in D$ with respect to $=_C$.
- The domain of $\mathcal{B}$ is the set $B = \{[\varphi]: \varphi \in D\}$.
- Let R be an n-ary predicate symbol of $\mathcal{L}$. For $[\varphi_1], \ldots, [\varphi_n] \in B$, define $R^{\mathcal{B}}([\varphi_1]), \ldots, [\varphi_n]$ by

$$R^{\mathcal{B}}([\varphi_1], \ldots, [\varphi_n]) \Leftrightarrow C \subseteq^* \left\{ i : \bigwedge_{1 \le m \le n} \varphi_m(i)\downarrow \wedge R^{\mathcal{A}}(\varphi_1(i), \ldots, \varphi_n(i)) \right\}.$$

- Let F be an n-ary function symbol of $\mathcal{L}$. For $[\varphi_1], \ldots, [\varphi_n] \in B$, let ψ be the partial computable function defined by

$$\psi(i) \simeq F^{\mathcal{A}}(\varphi_1(i), \ldots, \varphi_n(i)).$$

Define

$$F^{\mathcal{B}}([\varphi_1], \ldots, [\varphi_n]) = [\psi].$$

- Let c be a constant symbol of $\mathcal{L}$. Then $c^{\mathcal{B}}$ is the equivalence class of the total computable function with constant value $c^{\mathcal{A}}$.

The cohesive power of a finite structure is isomorphic to the structure. The cohesive power of an infinite computable (hence countable) structure produces an infinite countable structure.

In (Dimitrov et al. 2014), the authors demonstrated that $\mathcal{R}/_{\sim C}$ and $\Pi_C\mathbb{N}$ are isomorphic when the complement of the set C is a maximal set. In that case for every partial computable function $\varphi \in D$ there is a total computable function f such that $\varphi =_C f$, hence $[\varphi] = [f]$.

The following theorem is a part of a more general result in (Dimitrov 2009a).

Theorem 6 (1) *If σ is a Π_2 sentence or a Σ_2 sentence, then $\Pi_C\mathcal{A} \models \sigma$ if and only if $\mathcal{A} \models \sigma$.*

(2) *If σ is a Π_3 sentence and $\Pi_C\mathcal{A} \models \sigma$, then $\mathcal{A} \models \sigma$.*

The converse of (2) does not hold. In (Dimitrov et al. n.d.), the authors produced natural counterexamples for linear orders. Using the previous theorem it cannot be deduced that $\Pi_C\mathbb{N}$ is a model of the full theory $Th(\mathbb{N})$, but just of a fragment of $Th(\mathbb{N})$. As mentioned before, the cohesive power of a computable field is a field. This is because the field axioms are of complexity at most Π_2. This is the case with many other familiar structures. In (Dimitrov et al. n.d.), we have also investigated the relationship between additional algorithmic properties of a computable structure and the isomorphism type of its cohesive power.

4.3 Concluding Remarks

In this chapter we focused on the existence of various nonstandard models. The algorithmic complexity of these models varies. Uncountable models are considered noncomputable because of their size. Even all countable nonstandard models of arithmetic are noncomputable. The elements of Skolem's countable model of arithmetic are equivalence classes of functions of arbitrary arithmetic complexity. It is not a computable model but we can measure the complexity of the elements of the model. The elements of the Feferman-Scott-Tennenbaum structure, which is only a model of a fragment of arithmetic, are equivalence classes of computable functions. Unfortunately, there is no algorithmic enumeration of all computable functions. The elements of cohesive powers of a computable structure are equivalence classes of partial computable functions. In general, the preservation of satisfaction of sentences

in cohesive powers, as well as in the Feferman-Scott-Tennenbaum structure, is limited to lower levels of arithmetical hierarchy because it depends on the existence of uniform procedures for finding witnesses of existential quantifiers. Compared to Skolem's model these structures favor a more constructivist approach at the expense of satisfiability of sentences at higher levels of the arithmetical hierarchy.

Acknowledgments The first author would like to thank F. Stephan and D. Skordev for useful discussion regarding Skolem's 1934 paper. The second author was partially supported by the Simons Foundation collaboration grant 429466 and GW Dean's Research Chair award. The authors are listed lexicographically, indicating equal contribution to the chapter.

Abstract

For 300 years, Fermat's Last Theorem seemed to be pure arithmetic little connected even to other problems in arithmetic. But the last decades of the twentieth century saw the discovery of very special cubic curves, and the rise

of the huge theoretical Langlands Program. The Langlands perspective showed those curves are so special they cannot exist, and thus proved Fermat's Last Theorem. With many great contributors, the proof ended in a deep and widely applicable geometric result relating nice curves in rational coordinates to very nice surfaces in complex coordinates. This geometry is the only proof strategy for FLT yet known. Outstanding but not atypical of current mathematics, the proof challenges common philosophic views on abstraction and structure and raises still-open logical questions in arithmetic.

Structuralism · Fermat's Last Theorem · Geometry · Peano Arithmetic

1 Introductory Overview

For most of its 350-year history, Fermat's Last Theorem (FLT) was intriguing arithmetic of no special philosophic interest. Even in arithmetic, it had little relation to other theorems. A generalized "prime factorization" misused in a fallacious proof of FLT has been a driving force in number theory to this day. That has gotten philosophers' and historian's attention as an example of mathematical concept formation, see Sect. 3.2. But that strategy did not prove FLT (yet).

The proof of FLT in 1995 had two beginnings in the late 1960s. It involves much other mathematics. And it challenges philosophic views of modern mathematics.

One beginning was a surprising specific geometric observation on FLT. The other was the vast theoretical *Langlands Program* in arithmetic algebraic geometry, see Sect. 6. These two had no connection at first except that both descended from André Weil's lifelong project to geometrize number theory. Weil sketched in his dissertation (1928), and explained at length in later works (1987, 1991), how he built that project on his youthful reading of Diophantus, Fermat, and Poincaré.

The geometric observation came when Yves Hellegouarch and Vadim Andreevich Demyanenko independently noticed that if any of the curves defined by certain cubic polynomials had certain odd geometric properties, then FLT was false. This was not the most exciting direction of inference: No one knew how to find curves with those properties, and people rather expected there were none, since people expected FLT was true. And in the other direction, a proof that no such curves exist would only rule out one kind of counterexample to FLT. It would not prove FLT.

Still, it was a striking new connection for FLT.

Poincaré (1901) related arithmetic to the geometry of cubic curves following leads in Fermat among others. Poincaré's work was developed notably by Louis Mordell and André Weil and the subject was well established by the 1970s. Intriguingly, though, Hellegouarch and Demyanenko used a less known aspect of it, namely *rational torsion points* on *elliptic curves.* Jean-Pierre Serre at the famed Séminaire Bourbaki had to say one knows very little about them (1971, p. 282). Within a few

years, Barry Mazur (1977a, 1978) changed that with deep results on torsion and on *modularity:*

> Although it was not realized at the time, the chain of ideas that was to lead to a proof of Fermats Last theorem had already been set in motion by Barry Mazur in [these papers]. (Darmon et al. 1997, p. 8)

Mazur was not aiming at FLT per se. He was interested in geometrizing arithmetic in general.

Gerhard Frey (1986), with crucial input from Serre, gave a strategy for FLT using modularity: Show any counterexample to FLT would give an elliptic curve that is *not* modular. But also prove the *Modularity Theorem* (MT), saying every relevant elliptic curve *is* modular. Number theorists had known for years that MT would be powerfully useful if it was true. Where FLT was easy to state but had few consequences, MT was hard to state but had rich consequences.

Up to this point, all the arguments were virtually pure arithmetic. They made subtle calculations using sophisticated geometric concepts in arithmetic but used no higher order logic, except some real and complex analysis so concretely calculational that it should be conservative over (first order) Peano Arithmetic (PA). The arguments were basically expressed in PA except that the authors were not interested in formalization.

Experts found Frey's strategy persuasive and Ken Ribet (1990), drawing on ideas from Serre and Mazur, proved counterexamples to FLT would produce non-modular elliptic curves. Few believed the other step, MT, was within reach. Andrew Wiles pursued it in near total secrecy for 6 years, though, and shocked the world in 1993 by proving enough of MT to give FLT as corollary (with some corrections over the next 2 years). Ribet's and Wiles' proofs too are led by directly arithmetical ideas but both invoke higher level apparatus. Within 5 years, Wiles' method of *modularity lifting* plus a lot of skilled calculating led to a proof of the full Modularity Theorem and made modularity even more useful than had been known. While the proof of MT is extremely valuable, it was FLT that inspired Wiles since age 10 and FLT made headlines around the world and Fermat's own statement of it is quoted in Latin at the start of Wiles (1995a).

2 Basics

A *Pythagorean triple* is any triple $\langle a, b, c\rangle$ of nonzero integers with

$$a^2 + b^2 = c^2.$$

Some sources require a, b, c positive. This makes little difference since $x^2 = (-x)^2$.

Euclid's *Elements* Book 10 proposition 19 shows how to generate infinitely many of these. For any distinct, nonzero integers m, n take

$$a = 2mn, b = m^2 - n^2, c = m^2 + n^2. \quad (1)$$

Routine calculation shows this gives Pythagorean triples.

Conversely, every Pythagorean triple is a multiple of one formed by Eq. 1. There are several interestingly different proofs of this: by using ordinary prime factorization, or by factorization with complex Gaussian integers $a + b\sqrt{-1}$, or by the geometry of rational points on a circle. Each of these proofs is common in textbooks and they are all in the Wikipedia article *Pythagorean triples*.

Sometime around 1630 Fermat wrote in the margin of a book that he had a "marvelous proof" that there are no nonzero integer solutions for cubes or fourth powers or any higher order.

$$a^3 + b^3 = c^3 a^4 + b^4 = c^4 a^n + b^n = c^n \, n \geq 5.$$

Essentially Fermat's own proof for fourth powers is common in textbooks today. No proof by him of the cubic case is known. He may have believed for the rest of his life that he had a proof of the cubic case, but it seems he fairly soon came to believe he had no proof for higher powers. See Edwards (1977, p. 2) and Weil (1987, p. 104).

For ease of reference, define F_n to be the Fermat equation with exponent n including the requirement that none of *a, b, c* are 0:

$$a^n + b^n = c^n \text{ with integers } abc \neq 0.$$

Notice F_n has rational solutions if and only if it has integer solutions. An integer solution is rational. And conversely any rational solution can be expressed by fractions with a common denominator, and then

$$(a/d)^n + (b/d)^n = (c/d)^n \text{ is equivalent to } a^n + b^n = c^n.$$

So it does not matter whether FLT is stated for integers or for rational numbers.

Also, if F_n has a solution, and n factors as $n = k \cdot m$, then F_m has a solution:

$$a^{k \cdot m} + b^{k \cdot m} = c^{k \cdot m} \text{ is equivalent to } \left(a^k\right)^m + \left(b^k\right)^m = \left(c^k\right)^m. \quad (2)$$

Every integer $n > 1$ has prime factors, and Fermat proved F_4 has no solutions. So if FLT is not true, there must be some odd prime p such that F_p has solutions.

3 A Proof for $n = 3$ and a Valuable Mistake

In 1770, Leonhard Euler published a brilliant but unclear proof of the cubic case, saying F_3 has no integer solutions. It centered on factoring numbers of the form $a^2 + 3b^2$ where *a, b* are integers. Some steps were not justified clearly.

Edwards (1977, pp. 43ff.) relates Euler's proof to using complex numbers of the form $a + b\sqrt{-3}$ with ordinary integers *a, b.* These numbers add and multiply, keeping this form:

$$\left(a + b\sqrt{-3}\right) + \left(c + d\sqrt{-3}\right) = (a + c) + (b + d)\sqrt{-3} \tag{3}$$

$$\left(a + b\sqrt{-3}\right) \cdot \left(c + d\sqrt{-3}\right) = (ac - 3bd) + (ad + bc)\sqrt{-3}. \tag{4}$$

This connects to Euler's argument by a special case of Eq. 4:

$$\left(a + b\sqrt{-3}\right) \cdot \left(a - b\sqrt{-3}\right) = a^2 + 3b^2.$$

Euler's unwarranted assumption could be justified in these terms if unique prime factorization generalizes from the ordinary integers $\mathbb{Z}$ to these numbers $a + b\sqrt{-3}$, with the primes existing in this new context. And it sort of does. Only it requires using terms $\left(1 + \sqrt{-3}\right)/2$ with denominator 2 as well as integer multiples of $\sqrt{-3}$. This indeed is one way to prove F_3 has no solutions.

In modern terms, the ring called $\mathbb{Z}\left[\left(1 + \sqrt{-3}\right)/2\right]$ has unique prime factorization:

$$\mathbb{Z}\left[\frac{1 + \sqrt{-3}}{2}\right] = \left\{a + b \cdot \frac{1 + \sqrt{-3}}{2} \middle| a, b \in \mathbb{Z}\right\}.$$

In this context, for example, 7 is no longer a prime since it has smaller factors

$$7 = 2^2 + 3 \cdot 1^2 = \left(2 + \sqrt{-3}\right)\left(2 - \sqrt{-3}\right).$$

In the ring $\mathbb{Z}\left[\left(1 + \sqrt{-3}\right)/2\right]$, it turns out $2 + \sqrt{-3}$ and $2 - \sqrt{-3}$ are prime.

Rings like $\mathbb{Z}\left[\left(1 + \sqrt{-3}\right)/2\right]$ are today called *rings of integers of algebraic number fields.* They do not always have unique prime factorization and that has been the topic of a great deal of number theory. See many algebraic number theory textbooks, including, for example, Stewart and Tall (2001, Chap. 3), and see Sect. 3.2 below.

3.1 Proofs by Factorization

Over the next century, Euler's proof for F_3 was perfected, others used similar arguments to prove F_5 has no solutions, and Gabriel Lamé did it for F_7. Then in 1847, Lamé unified those proofs into a purported proof of all of FLT. He expressed the idea quite clearly and so he was clearly wrong. But he was not wholly wrong. The historic events are well known and vividly described by Edwards (1977, pp. 76ff.) and Stewart and Tall (2001, pp. 185ff.).

Because people knew our Eq. 2, Lamé just had to show F_p has no solution with odd prime p. For that case, Lamé would take a *primitive p-th root of unity.* That is a complex number ζ_p such that $\zeta_p^p = 1$ while $\zeta_p \neq 1$. These always exist. They are those roots of $X^p - 1$ that are not roots of $X - 1$, so long division of polynomials shows they are exactly the solutions to

$$X^{p-1} + X^{p-2} + \cdots + X + 1 = 0. \tag{5}$$

To verify this, just multiply that polynomial by $X - 1$.

Using Eq. 5, simple calculation (try it by hand for $p = 3$) shows for any integers *a, b* there is a factorization

$$a^p + b^p = (a + b)(a + b\zeta_p)\left(a + b\zeta_p^2\right)\cdots\left(a + b\zeta_p^{p-1}\right).$$

Thus any solution $\langle a, b, c\rangle$ to F_p has a factorization

$$(a + b)(a + b\zeta_p)\left(a + b\zeta_p^2\right)\cdots\left(a + b\zeta_p^{p-1}\right) = c^p. \tag{6}$$

This is all correct. Then Lamé proved Eq. 6 is impossible by using further steps which, as his colleague Joseph Liouville quickly pointed out, amounted to an unjustified assumption of unique prime factorization for this sort of number.

Liouville knew this was a major gap. Then Liouville got a letter from Ernst Kummer showing unique factorization actually fails for $p = 23$. In fact, it fails for all primes $p \geq 23$ (see the Wikipedia article *Cyclotomic fields* and references there).

Kummer extended this kind of argument to give some results even in contexts where unique factorization failed. Further work on FLT in this line became extremely sophisticated and unavoidably technical. It is well covered in Edwards (1977). This strategy remained the main engine for proving new cases of FLT right up until the 1980s. It did not lead to the current proof of FLT.

3.2 Further on Factorization in Rings

Fermat's Last Theorem was not the first reason mathematicians studied unique prime factorization in these algebraic contexts. But it was one. And the tools created to study factorization pervade all of algebraic geometry and algebraic number theory today, naturally including the proof of FLT. So a few more words on the topic are appropriate though it is not a specific theme leading to Wiles' proof of FLT.

Mathematicians made two related responses to failure of unique prime factorization in a ring R. First was to define new *ideal divisors* for R, which are not elements of R but serve some of the same purposes as ordinary prime factorization in the integers $\mathbb{Z}$. Second was to measure "how close" R is to having unique prime factorization, which became one source of the far-reaching subject of *Class Field Theory* (Cox 1989; Kato et al. 2011). Kummer himself took early steps on both of these Mazur (1977b).

Today *ideals of rings* are bread and butter for algebraists, and often get into sophomore algebra courses. Philosophers and historians have taken this as a major example of mathematical concept formation. See, for example, Avigad (2006) and Boniface (2016). Class Field Theory is so imposing philosophers have barely studied it, and then indirectly through another of its sources the Quadratic Reciprocity Theorem. See, for example, Tappenden (2008), Yap (2011, 2020), and D'Alessandro (2020).

4 Poincaré, Mordell, and Weil

> What we possess of [Fermat's] methods for dealing with curves of genus 1 [i.e. elliptic curves] is remarkably coherent; it is still the foundation for the modern theory of such curves. It naturally falls into two parts; the first one, directly inspired by Diophantus, may conveniently be termed a method of ascent, in contrast with the descent which is rightly regarded as Fermat's own. (Weil 1987, p. 104)

Weil (1987, pp. 104–18) features the rich history of connections between arithmetic and cubic curves. See also Stillwell (1995). Whether Diophantus or Fermat themselves thought of their calculations in geometric terms is not clear. Poincaré (1901) did explicitly when he systematized Fermat's methods, related them to Kronecker's and Weierstrass's complex analysis, and expanded them to new problems.

4.1 Rational Roots of Cubic Polynomials

This computation was obvious to Fermat:

Theorem 1 *If a cubic polynomial P(X) in one variable with rational coefficients has two rational roots, or one rational root of multiplicity 2, then all its roots are rational.*

Proof. If α_1 is a rational root of $P(X)$, then $X - \alpha_1$ divides $P(X)$ and the quotient $Q(X)$ is quadratic with rational coefficients. If α_2 is a distinct rational root of $P(X)$, then $X - \alpha_2$ divides $Q(X)$. If α_1 is a double root of $P(X)$, then $X - \alpha_1$ divides $Q(X)$. Either way leaves a rational linear polynomial which necessarily has a rational root, and that is all the roots of $P(X)$. QED.

Notice this is pure arithmetic calculation, requiring no general notion of real or complex numbers let alone, say, the fundamental theorem of algebra.

Moving to two variables, and thus to the geometry of curves in the plane, does not change the idea.

Definition 1 A *rational point* in the coordinate plane $\mathbb{R}^2$ is a point with both coordinates rational numbers.

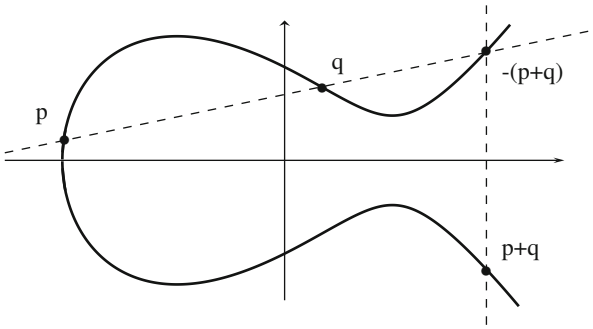

Fig. 1 The addition law on the elliptic curve defined by $Y^2 = X^3 - X + 1$

The curve in Fig. 1 is defined by a cubic equation in two variables

$$Y^2 = X^3 - X + 1. \tag{7}$$

Theorem 1 easily implies: If a straight line meets that curve in three points, and two of them are rational, then so is the third. And a line tangent to that curve at a rational point meets the curve in another rational point. To make those true even for vertical lines, we speak of a rational point on the curve at vertical infinity.

Equation 7 has six obvious rational (indeed integral) solutions: namely $\langle 0, \pm 1\rangle$, and $\langle -1, \pm 1\rangle$, and $\langle 1, \pm 1\rangle$. Take one of them, say $r = \langle 0, 1\rangle$. Routine calculation gives the tangent line to the curve at r, and by Theorem 1, it meets the curve in a new rational point, say s. Then take the tangent to the curve at s to find another rational point, and so on. Diophantus used this kind of algebra to find nontrivial rational solutions to suitable problems by starting from trivial ones.

Two questions naturally arise:

1. Is every rational solution to Eq. 7 generated this way starting from those six points? If not, does some other finite set of points generate them all?
2. Starting from a given one, say r, will this method continue generating new rational points? Or will it eventually return to r and start repeating?

The pursuit of those questions, and several other questions from number theory and from complex analysis, led to the idea of addition laws on elliptic curves.

4.2 The Addition Law on an Elliptic Curve

A wondrous geometric fact is that intersecting lines with a cubic curve produces an *addition law* so that the points of the curve form an Abelian group.

Definition 2 A *real elliptic curve* is a curve defined by an equation

$$Y^2 = X^3 + AX + B \tag{8}$$

where *A, B* are real numbers and the roots of $X^3 + AX + B$ are all distinct.

The addition law is uniquely determined by two rules:

1. The point at vertical infinity will be the 0 element.
2. For any three collinear points *p, q, r* on the curve, $p + q + r = 0$. (If the tangent to the curve at *p* also meets the curve at q, then $2p + q = 0$. And if *p* is an inflexion point then $3p = 0$.)

By these rules, if the line between points *r, s* on the curve is vertical, then

$$r + s + 0 = 0.$$

So define $-r = s$. Then look at the example in Fig. 1. The line connecting points *p, q* meets the curve in a third point and rule 2 says these three points add up to 0, so call that third point $-(p + q)$. Now the vertical line through $-(p + q)$ meets the curve in the negative of $-(p + q)$, thus $p + q$.

Simple reasoning left to the reader will verify most of the Abelian group axioms:

$$p + q = q + p, p + 0 = p, \text{for every } p \text{ there is a } q \text{ with } p + q = 0.$$

The associative law $p + (q + r) = (p + q) + r$ is not easy but it does follow by a classical geometric property of algebraic curves. See, e.g., Reid (2013, Chap. 2) or Stewart and Tall (2001, p. 229).

So each elliptic curve *E* has a group of real points $E(\mathbb{R})$ which is Abelian and contains at least the point at vertical infinity as 0 element. The same algebra gives an Abelian group $E(\mathbb{C})$ of the complex points on *E*. These geometric facts were important in early nineteenth century complex analysis, long before they were cast in group-theoretic form (McKean and Moll 1999, Chap. 2).

4.3 Rational Points on Arithmetic Elliptic Curves

Another wondrous fact is that the rationality considerations of Sect. 4.1 and the geometry and analysis of 1.4.2 fit right together to put Fermat's ascent and descent into modern geometric form.

Definition 3 An *arithmetic elliptic curve* is an elliptic curve defined by $Y^2 = X^3 + AX + B$ with rational coefficients *A, B*.

Theorem 1 shows the addition law on an arithmetic elliptic curve takes rational points to rational points, and so gives an Abelian group $E(\mathbb{Q})$ of rational points.

In this notation, the Fermat method of ascent by repeated tangent lines, described just after Eq. 7, takes a point r, then forms $s = -2r$, and then $-2\ s = 4r$, then $-8r$, $16r$, ... multiplying by -2 each time. The modern approach gives more points by repeated addition. Starting from one rational point r form the series:

$$r, r + r = 2r, 2r + r = 3r, 3r + r = 4r, 4r + r = 5r, \ldots.$$

A crucial concept is *torsion*. Point r is a torsion point if $n \cdot r = 0$ for some positive integer n, so that $(n + 1)\ r$ is just r again. Notice 0 is a torsion point trivially. And the sum of torsion points is torsion because $n \cdot r = 0$ and $m \cdot s = 0$ implies $mn \cdot (r + s) = 0$.

So, for every arithmetic elliptic curve E, the Abelian group $E(\mathbb{Q})$ of rational points has a subgroup $E_{tor}(\mathbb{Q})$ of rational torsion points. The questions at the end of Sect. 4.1 take this form:

1. Is the Abelian group $E(\mathbb{Q})$ generated by some finite set of its points?
2. Does $E(\mathbb{Q})$ have nonzero torsion points? If so, what are they, and what is the structure of $E_{tor}(\mathbb{Q})$?

Mordell proved the answer to the first is yes. Then Weil used a more transparent and systematic method extending this to a far more general result (Cassels 1973, p. 500). The question of how many elements it takes to generate a given $E(\mathbb{Q})$ drew a lot of attention, produced great results, and remains open. See the Wikipedia article *Birch and Swinnerton-Dyer conjecture*. For a recent Fields Medalist's contribution stressing elementary arithmetic aspects, see Bhargava and Shankar (2015).

While there had been notable work on rational torsion points, for example, by Beppo Levi (Schappacher and Schoof 1996), the torsion groups $E_{tor}(\mathbb{Q})$ were not well understood until Mazur's papers in the 1970s. A key consequence of Mazur (1978) shows how specific the arithmetic gets, and it will reappear in the noted "3–5 trick" in Wiles' proof (Sect. 7.2). For any point r on any arithmetic elliptic curve E, the smallest nonzero $n \in \mathbb{N}$ with $nr = 0$ in $E(\mathbb{Q})$ has to be either in the range 1–10, or else 12. Wiles (1995a, p. 542) uses the fact that it cannot be 15.

However, Mordell also built on Poincaré (1901) to pose a conjecture for other shapes of algebraic curves, which Weil could not settle.

5 The First Deep Geometric Result on FLT

> I asked myself whether many problems of indeterminate Analysis [in arithmetic] could not be connected to each other by a new classification of higher degree polynomials. . .. Poincaré (1901, p. 21)

The most obvious classification of polynomials is by degree. These two equations both have degree 3:

$$Y^2 = X^3 - X + 1 \tag{9}$$

$$Y^2 = X^3 - 3X + 2 \tag{10}$$

But Hilbert and Hurwitz (1890) already knew that in terms of number theory, Eq. 10 does not act like a cubic, it acts like a quadratic. It acts like a degree 2 equation. Hilbert, Hurwitz, and Poincaré all knew the right explanation is the geometry of the curves defined by these equations. The difference shows in plots of their real points. Compare Figs. 1 and 2. The curve defined by Eq. 10 crosses itself. Any cubic curve that crosses itself like that will behave arithmetically like a quadratic curve.

Specifically, all those mathematicians knew the important classification of polynomials for number theory is not by degree but by the *genus* of their curves. Here "curves" means spaces of complex number solutions, including points at infinity. Hilbert, Hurwitz, and Poincaré drew on Riemann's classification of what are now called Riemann surfaces (Riemann 1851; Pont 1974).

5.1 Curves as Surfaces

This idea is needed to state Mordell's conjecture, and again to describe modularity in Sect. 6.2. The conceptual point is to show these theorems involve perfectly concrete visual geometry.

Analysts talk about the *complex plane* while algebraic geometers call that same thing the *complex line.* More generally, the analyst's *Riemann surfaces* can be the geometer's *algebraic curves.* Of course, analysts and geometers are often the same people and the dual terminology has even been used as a textbook title: *Algebraic Curves and Riemann Surfaces* (Miranda 1995).

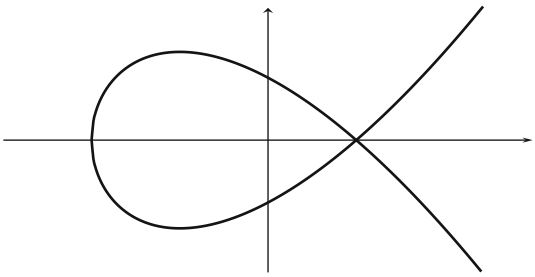

Fig. 2 The cubic curve defined by $Y^2 = X^3 - 3X + 2$

It is a choice between emphasizing topology or algebra. Topologically, the complex numbers form a plane with a real axis and imaginary axis, and small regions in a Riemann surface look like small regions in that plane. Algebraically, it is intuitive to say one equation in two variables defines a curve, and it is technically correct to say the complex numbers form a 1-dimensional complex vector space.

Visually, the curves in Figs. 1 and 2 formed by real solutions to Eqs. 9 and 10 are real cross-sections of complex curves – understanding that a complex curve is topologically a surface. Both curves go on to infinity so neither surface can be drawn whole to scale. But topologically, each curve expanding towards a point at infinity can be contracted down to put that point at a finite distance as in Fig. 3. Then the complex solutions to Eq. 9 form a torus. Those to Eq. 10 form a pinched torus where one part of the tube is pinched to a point. That pinch point is where the curve of real solutions in Fig. 2 crosses itself.

For more on genus, see numerous graphics in McKean and Moll (1999, Chap. 1) or the concise discussion in terms of algebra, topology, and differential geometry by Reid (2013, pp. 51ff.).

5.2 Mordell's Conjecture, Faltings' Theorem

In fact, quadratic curves (and self-crossing cubic curves) have genus 0, elliptic curves have genus 1, and when $n > 3$, then the curve of the Fermat equation F_n has genus greater than 1. Mordell conjectured that every algebraic curve with genus greater than 1 has at most finitely many rational points.

In 1983, Gerd Faltings proved this and much more (Mazur 1987). This was far-reaching arithmetic quite apart from FLT. It was beautiful classical arithmetic proved by insightful geometric means using the latest technology, including Grothendieck's *étale cohomology* (Faltings 1983). It was huge progress on FLT: No Fermat equation F_n with $n > 2$ has more than finitely many solutions! And several people gave explicit calculations based on this, concluding that F_n has no solutions, for the great majority of all $n > 2$ (Heath-Brown 1984). However, this proof did not identify which F_n have no solutions.

This result has not (yet) been the basis for any full proof of FLT.

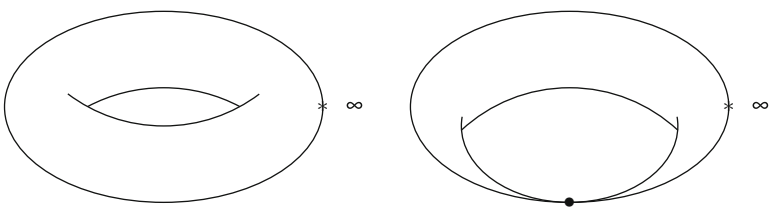

Fig. 3 The topology of a torus and a pinched torus, showing points at infinity

6 Elliptic Curves Meet FLT

Hellegouarch (1971) and Demyanenko (1971) independently used equations related to Eq. 11 below, to show that if certain kinds of torsion points can occur on elliptic curves, then FLT is false. It might naturally have occurred to one or both of them to turn this around and consider Eq. 11 for any hypothetical solution $\langle a, b, c\rangle$ to F_p for any odd prime p, but this never happened in print. Hellegouarch (2000) documents that he spoke on elliptic curves and FLT in the 1960s, but gives no details of what he said except that Serre corrected some errors.

At any rate, Hellegouarch and Demyanenko linked FLT to the arithmetic of elliptic curves. Mazur (1978) showed that Hellegouarch-Demyanenko torsion cannot occur on arithmetic elliptic curves; so these considerations would not refute FLT. But that did not prove FLT.

On the other hand, the beginnings of the Langlands Program are well documented, because in 1967, Robert Langlands wrote to Weil, to describe a huge unifying project (Mueller 2018). There has been great progress while a great deal remains to do.

> The Langlands Program is now a vast subject. There is a large community of people working on it in different fields: number theory, harmonic analysis, geometry, representation theory, mathematical physics. Although they work with very different objects, they are all observing similar phenomena. (Frenkel 2013, p. 77)

Wiles (1995a) is itself, technically, a step in the Langlands Program. But there is a persuasive argument that the overall concept of the Program mattered more in the process of proving FLT than the technical connection:

> Rather the crux of the Program is two pronged: its overall *vision* relating motives of all kinds to automorphic representations, and its *methods* which push representation theory to the forefront, and infuse the subject with a seemingly endless string of challenging problems. It is these aspects of the Langlands Program which (albeit indirectly) play a role in the proof of Fermat's Last Theorem. (Gelbart 1997, p. 191)

6.1 Frey-Hellegouarch Curves

Frey (1982) was apparently the first to associate with *every* integer solution to F_n

$$a^n + b^n = c^n$$

the elliptic curve defined by (Since Eq. 11 has nonzero term in x^2, it is not in the form of Eq. 8 used to define elliptic curves. But a linear change of variable $X' = X - ((a^n - b^n)/3)$ puts it in that form. Such issues often go without comment in the literature):

$$Y^2 = X(X - a^n)(X + b^n). \tag{11}$$

This is the Frey curve or Frey-Hellegouarch curve for the solution $\langle a, b, c\rangle$.

The goal would be to show this curve is impossible, and conclude there are no solutions to F_n. Frey suggested in a privately circulated note this curve could not be *modular,* as discussed in Sect. 6.2. A much fuller discussion was published with input from Serre (Frey 1986). See also Schappacher (1993/1994, p. 41).

This curve is better tied to F_n than appears at first. Obviously the roots of the righthand side are 0, and a^n and $-b^n$. But look at the differences between them:

$$a^n = a^n - 0b^n = 0 - (-b^n)c^n = a^n - (-b^n).$$

These differences are more intrinsic to the geometry of the curve than the roots are. A mere shift in the X-coordinate does not change the geometry. It changes the roots but does not change their differences. The most important classical invariant of a polynomial is its *discriminant,* defined by multiplying together the differences between its roots. The most obvious fact about the discriminant is that it equals 0 if and only if the polynomial has at least one multiple root.

6.1.1 Some Details of Arithmetic and Geometry

First, given $a^n + b^n = c^n$ with $abc \neq 0$, the discriminant of $X(X - a^n)(X + b^n)$ *is* $-(abc)^{2n}$ and thus nonzero. So the Frey-Hellegouarch curve is elliptic. Its plot over the real numbers $\mathbb{R}$ has no self-crossings. It cannot look like Fig. 2.

Second, if a and b are divisible by a prime number ℓ, then $a^n + b^n = c^n$ implies c is too. And any common factor of a, b, c can be divided out to give a smaller solution to F_n.

$$(k \cdot h)^n + (k \cdot i)^n = (k \cdot j)^n \text{ implies } h^n + i^n = j^n \text{ when } k \neq 0.$$

So, dividing out common factors, we can assume no prime divides both a and b. Such a solution to F_n is called *primitive* since it is not a multiple of any smaller solution.

Work on FLT requires calculating modulo various primes ℓ. So it is helpful that, for a primitive solution $\langle a, b, c\rangle$, the roots a^n and $-b^n$ of the righthand polynomial in Eq. 11 cannot both equal the root 0 modulo one prime ℓ. Intuitively, doing algebraic geometry modulo ℓ, the Frey-Hellegouarch curve looks at worst like Fig. 2. It cannot degenerate beyond one self-crossing. In the standard terminology, when $n > 3$, the Frey-Hellegouarch curve for a primitive solution to F_n is *semistable.*

6.2 Modularity

> I want to spend a few minutes considering one example (a conjecture, in fact) which shows how Number Theory can sometimes contrive to be a helpful, and possibly inspirational, goad to the rest of the Mathematical Sciences. (Mazur 1991, p. 593).

There is an obvious kinship between the geometry of the complex plane $\mathbb{C}$ and of the Euclidean plane $\mathbb{R}^2$ The absolute value of a complex number $a + b\sqrt{-1}$ equals the Euclidean norm of the vector $\langle a, b\rangle \in \mathbb{R}^2$:

$$| a + b\sqrt{-1} | = \left(a^2 + b^2\right)^{\frac{1}{2}} = \left\| \langle a, b\rangle \right\|.$$

By mid-nineteenth century, a similar link was known between the upper half of the complex plane on one hand, and the hyperbolic plane of non-Euclidean geometry on the other (McKean and Moll 1999, Sect. 9).

$$\mathbb{H} = \left\{ a + b\sqrt{-1} \in \mathbb{C} | b > 0 \right\}.$$

Essentially every account of elliptic curves describes how they can be covered by the complex numbers so that the curve gets a locally Euclidean structure. This has been central to the subject since the nineteenth century.

Mazur (1991) explains a late twentieth century discovery by Gennadii Vladimirovich Belyi: An elliptic curve can also get a locally hyperbolic structure from the upper half complex plane $\mathbb{H}$, if and only if it is defined by Eq. 8 with algebraic numbers *A, B* as coefficients (i.e., *A, B* are themselves the roots of integer polynomials).

A local Euclidean structure plus a local hyperbolic structure on one curve can have interesting interactions. But Mazur (1991) describes how much more happens when the local hyperbolic structure has a particular arithmetic form. Elliptic curves meeting that condition are called *modular* elliptic curves. Frey had suggested that Frey-Hellegouarch curves cannot be modular. That suggestion was proved by Ribet (1990).

The conjecture described in the quote of Mazur was called the conjecture of Taniyama-Shimura-Weil. Now it is the *Modularity Thesis* or *Modularity Theorem* (MT). It says every arithmetic elliptic curve is modular! Given Ribet's proof, a proof of MT would prove FLT. Indeed, by the considerations described in Sect. 6.1.1, FLT would follow just from proving every semistable elliptic curve is modular. That seemed out of reach to most experts in 1991, but Wiles (1995a) would prove it.

7 The Ideas and Methods of Ribet's and Wiles's Proofs

The proofs discussed up to here used extremely sophisticated conceptions and calculations but – with the notable exception of Faltings (1983) – did not use machinery so advanced that a graduate student in number theory would not normally know it. The success of Faltings (1983) and the progress through Frey (1986), plus the whole tendency of the Langlands Program, brought such machinery to the fore.

7.1 Ribet

Ribet (1990) proved an arithmetic conjecture by Serre. It turned out the most useful calculational handle on modular covers of elliptic curves, for this purpose, is certain technical witnesses to such covers. These witnesses are called *newforms.* Every modular cover of a given elliptic curve will be witnessed by many different newforms. Ribet showed that if a Frey-Hellegouarch curve did admit a hyperbolic structure making it modular, then any newform witnessing it could be reduced to one on a lower *level,* and then a lower one, to the point of impossibility. So Frey-Hellegouarch curves cannot have such witnesses and cannot be modular.

The essence of the argument is geometrically motivated calculation. The steps of the proof are largely calculational, albeit the calculations are often organized in terms of uncountable structures like the real, complex, and p-adic numbers, as well as the absolute Galois group $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ named in the paper's title.

As is typical of major proofs today, simply doing the calculations does not suffice to prove they work. Ribet uses considerable resources over several sections. He names just the chief ones in his summary:

> In §2, we recall material due to Raynaud [24] concerning Neron models of Jacobians. . .. In the next two §§, we recall the work of Deligne and Rapoport [4] and Cerednik-Drinfeld ([3], [7]) on the bad reduction of classical modular curves. . .. [To prove] the Main Theorem [w]e begin, in §6, with Mazur's result [20]. . .. (Ribet 1990, p. 433)

It should be obvious on its face that to bring all these resources into one comprehensible argument, the sources themselves must give concisely quotable theorems in relatively uniform terminology. This has to be done well to make proofs like Ribet's feasible to discover, and to make them reliable once given.

7.1.1 Structural Mathematics

Indeed the working methods are *structural* in that they define their objects just up to isomorphism, as philosophers have been remarking for some time. However, this has different goals and means in mathematics than philosophers usually discuss. Benacerraf (1965) depicts two young mathematicians using different "set theoretic" definitions of the natural numbers just because they were taught to. Benacerraf notes the two definitions work equally well because they produce isomorphic "structures," and proposes philosophers explore this as an issue for the ontology of mathematics. But it is also practical mathematics.

Generally, in practice, different constructions of one structure do not "work equally well." Different ones work best depending on context. And more:

1. A result proved in one context may be needed in another.
2. Efficiency may demand using a (reliably proven) result without lingering to specify any one construction or proof or context for its proof.

So mathematicians already have efficient, rigorous, routine ways to describe common structure behind different constructions.

The concept of structure that works for Ribet and his sources is the language of exact sequences and functors – in short categorical language. Some mathematicians will stress that Ribet and the others are not doing category theory. They are not lingering on categorical issues. But they use that language. That is how it is done.

7.2 Wiles

> To set the stage for the proof in (Wiles 1995a) one begins by replacing the problem on elliptic curves with a problem on Galois representations. (Wiles 1995b, p. 244)

After Ribet's proof, it remained to show all elliptic curves are modular – or at least all semistable ones – and that would prove FLT. Instead of working directly with hyperbolic covers of elliptic curves, Wiles used *Galois representations* which are algebraic constructs associated to elliptic curves. Wiles found modular elliptic curves can be recognized by their associated Galois representations, so these ones can be called *modular* representations. Then he used Mazur's theory of *deformations* of Galois representations (Mazur 1997).

Through all the technicalities, Wiles' proof has a clear conceptual outline often called an "$R = T$ strategy." In Wiles' case:

1. R captures a wide sense of "deformations" of modular representations of semistable elliptic curves, which reaches all Galois representations of those curves.
2. T captures a narrow sense of "deformations" of modular representations of semistable elliptic curves so the results of deformation remain modular.

The expression "$R = T$" is shorthand for proving the reach of T actually covers the reach of R (Saito 2013, Chap. 5). All the relevant Galois representations are reached from modular ones by deformations that preserve modularity. So all semistable elliptic curves are modular.

Of course Wiles' conceptual strategy did not erase concrete problems. Just the contrary. It pointed out certain concrete problems as decisive. The most famous example from arithmetic is the "3–5 trick," the topic of (Saito 2013, Chap. 4) and of many other publications and webpages. Wiles makes sophisticated use of a concrete fact of arithmetic on elliptic curves: the Abelian group $E(\mathbb{Q})$ of an arithmetic elliptic curve E cannot have both a point $r \neq 0$ with $3r = 0$ and a point $s \neq 0$ with $5\ s = 0$. It might have either one but cannot have both. This is not easy to prove. It was well known to Wiles since one proof of it is Mazur (1978). See Wiles (1995a, p. 542) or Saito's Proof of Proposition 4.3.

Wiles solved massive specific problems of many kinds to define the R and T he needed, and prove their relation. Wiles (1995a) gives 100 pages of detail, and that is dauntingly concise for all but leading experts. This has led to many more results on modularity and applications in number theory. And it finished the proof of FLT.

Here the numerous outside results needed, and the Grothendieckian functorial-categorical nature of the arguments, are even more prominent than in Ribet's case.

8 The Quondam Problem of Grothendieck Universes

> To avoid certain logical difficulties, we will accept the notion of a Universe, which is a set 'large enough' that the habitual operations of set theory do not go outside of it. (Grothendieck 1971, p. 146)

Whether this avoided difficulties or caused them has been a matter of controversy. Some mathematicians explicitly accept the large sets so as to use Grothendieck's large structure tools. Others reject the tools, or at least avoid using them in proofs, because of set theory. Everyone involved knew very well from the start how to give the specific number theoretic or geometric applications without these large structure tools. But the tools themselves were described, notably in Artin et al. (1972), using large cardinals which create a stronger set theory than ZFC.

The proofs bearing on FLT, including Ribet (1990) and Wiles (1995a), never mention Grothendieck universes. They have no reason to. But they refer to work in the Grothendieck school that does use them (McLarty 2010).

The set theoretic issue is moot now since even Grothendieck's largest structure tools turn out to be available in *finite order arithmetic,* far weaker than ZFC. Set theory at this level has been reinvented in many guises. It can take the form of Simple Type Theory (with arithmetic), or the Elementary Theory of the Category of Sets, or Zermelo set theory with Bounded Separation. Conservative extensions of any of these set theories can formalize Grothendieck's large structure tools by essentially the same definitions, and with the same theorems and proofs, as Grothendieck originally did (McLarty 2020).

Since this has been proved, no one who accepts anything like ZFC need feel any logical qualms about using these tools.

Intuitively, finite order arithmetic posits a set $\mathbb{N}$ of natural numbers, and a power set $P(\mathbb{N})$ containing all sets of natural numbers, and a power set $P^2(\mathbb{N})$ containing all sets of sets of natural numbers, and so on up through any finite level $P^n(\mathbb{N})$. This is a natural foundation for free and easy work in classical and basic abstract mathematics. It is too weak for some well-known purposes (Mathias 2001). But only very low levels of $P^n(\mathbb{N})$ are mentioned much in existing proofs of FLT. Likely no power sets are needed in principle, as discussed in the next section.

9 Peano Arithmetic

> $\mathbb{R}$, $\mathbb{C}$, $\mathbb{Q}_p$, and $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$, and the Tate modules are all completions of finitist arithmetical structures. A substantial amount of their first-order theories admits natural finite approximations that do not quantify over second-order entities. Putting proofs of MT into PA will

> involve finding finite approximations of MT and of all the other principles that go into its proof. (Macintyre 2011, p. 15)

Peano Arithmetic (PA) is an axiomatic theory in first order logic, widely described in logic texts and online. On its face, PA deals with the natural numbers

$$\mathbb{N} = \{0, 1, 2, 3 \ldots\}.$$

Methods already familiar to Leopold Kronecker (1882) allow PA to interpret the integers $\mathbb{Z}$, rational numbers $\mathbb{Q}$, and even algebraic numbers $\mathbb{A}$. The algebraic numbers A are all the real or complex roots of polynomials with integer coefficients. Finite lists of numbers can be expressed in PA. So, for example, PA can interpret polynomials with integer coefficients by using their lists of coefficients.

While PA cannot talk about arbitrary real, or complex, or p-adic numbers, it can talk about and prove things about rational approximations to all these. This is crucial to discussing proofs of FLT in PA. Of course PA cannot prove as much about approximations to those sorts of numbers as even Second Order Arithmetic can, let alone stronger set theories. As a rule of thumb, algebraic calculations with these kinds of numbers can be approximated in PA. Arguments that depend on the entirety of some infinite series (or an exact limit to it) are a problem for PA.

Also crucially, PA can define some sets of numbers though these sets will not exist in PA. For example, PA can define prime numbers.

Definition 4 A natural number $n > 1$ is *prime* if and only if no natural numbers *k, m* both >1 have $n = km$.

So the set of prime numbers is called *definable in* PA. Notably, PA can state and prove that every natural number is the product of some finite list of prime numbers (unique up to reordering the list).

For any arithmetic elliptic curve E, PA can define the groups $E(\mathbb{Q})$ and $E_{tor}(\mathbb{Q})$. But when E($\mathbb{Q}$) is infinite, it will not itself exist in PA.

All of the work described above through Sect. 6 fits easily into PA in these ways (except Faltings', which is not used in the proof of FLT). The same is likely true of Ribet (1990) described in Sect. 7. But Ribet deals with the absolute Galois group $\mathrm{Gal}\left(\overline{\mathbb{Q}}/\mathbb{Q}\right)$. Neither that group, nor even its elements, can be defined in PA. Its elements can only be approximated in PA. Ribet gives a sustained argument absorbing much previous work that should be better explored in logic than it is yet.

The Macintyre quote opening this section well indicates the real challenge for proving FLT in PA: finding approximations for the Modularity Theorem. He says

> Spelling out the approximations would be a lengthy enterprise, and here it would be useful to have some metatheorems to apply. (Macintyre 2011, pp. 15 f.)

He points to a wide array of results already known for some areas of the proof, or close to areas of the proof. Number theorists often seek such approximations for

practical use quite apart from logic. They can be hard to find, and informative when found. As to logic:

> [There are] a number of distinct regions of [Wiles'] proof, almost all hitherto unvisited by proof theorists. . .. Some but certainly not all this territory is known to some model theorists. . .. Macintyre (2011, p. 8)

The project has not been completed. And even just to show that FLT is provable in PA in principle, there is no means currently known except to show at least in principle that such approximations can be given.

Then there are other important methods in current number theory, notably étale cohomology, not used in proving FLT and not much explored by logicians. These may well turn out to be easier than MT to get into PA. The language of MT is analytic geometry over the complex numbers, which can go beyond PA. Étale cohomology is closer to arithmetic in the first place.

10 The Wide-Open Question

> I want to stress that it is by no means clear to me right now how much induction is needed for [. . .] a proof of Wiles' theorem in PA. In particular, I think there is little evidence that bounded arithmetic plus the totality of exponentiation would suffice. . .. [O]ne has so little experience of more modern mathematics in the system that one should be cautious. (Macintyre 2011, p. 9)

Bounds in arithmetic are akin to approximations. Proving approximations to MT in bounded arithmetic (with any given kind of bounds, such as exponential) is akin to approximating MT in PA to begin with. There is little evidence on what bounds might work for MT because little is known of approximations to it in PA at all.

As a general fact of logic any theorem provable in PA is provable in some strictly weaker fragment of PA. This is because a proof of a theorem uses only finitely many axioms, and PA proves the consistency of all its finitely axiomatized subtheories (Hájek and Pudlák 1993, p. 168).

But it is a striking fact of proof theoretic experience that many interesting theorems are provable in the specific agreeably weak and conceptually attractive fragment that Macintyre calls bounded arithmetic with exponentiation. It is also called EFA, abbreviating two of its common names *Elementary Function Arithmetic* and *Exponential Function Arithmetic.* See Avigad (2003).

Since Wiles' proof was literally published in the *Annals of Mathematics,* it is a natural test case for Harvey Friedman's Grand Conjecture:

> Every theorem published in the *Annals of Mathematics* whose statement involves only finitary mathematical objects (i.e., what logicians call an arithmetical statement) can be proved in EFA. (Avigad 2003, p. 258)

No clear example is yet known to refute this claim (Early issues of the *Annals* had light articles on superexponential functions in arithmetic but these are not seriously to the point of Friedman's conjecture.)

Whether MT might refute Friedman's Conjecture remains to be known.

The real value of pursuing provability of MT, or FLT, in PA is likely to be not just securing the answer "yes it is provable in PA" or "no it is not provable in PA," but learning what resources from PA those theorems actually use. What fragment of induction suffices? To lift words from the quote of Macintyre above, the value would be to add some experience of more modern mathematics to proof theory.

11 Conclusion

The proof of FLT raises conceptual points listed here with the most relevant sections. Section 6.2 on modular curves, and Sect. 7 on the ideas of Ribet's and Wiles' proofs, are pivotal to the whole argument:

1. It showcases the geometric unity of current mathematics. It refutes persistent rumors that mathematics today is fragmented into specialities and that geometry was neglected in the twentieth century. Sections 4, 5, and 6.
2. It typifies current major proofs as key steps are long and rely on many prior advanced theorems. To make this work, theorems must be stated concisely and precisely, by uniform means. This is the practical reason for *structuralist* mathematics. It is not like the versions of structuralism most philosophers of mathematics consider. Section 7.
3. Far from displacing concrete arithmetic (as critics of "modern abstraction" feared), the modern techniques mobilize it. No one could find such long intricate proofs as these *without* concrete arithmetic as a guide. (The entire article.)
4. Some structural tools originally relied on large sets, though practitioners knew how to cut those tools out of the proof if desired. Now it is known these tools themselves can be rigorously founded without large sets. Section 8.
5. It is overwhelmingly likely that FLT is provable in PA but Macintyre (2011) documents points where this has not been demonstrated. Section 9.
6. The wide-open logical issue is that the leading ideas of the proof are so explicit that FLT is probably provable in some truly finitary fragment of PA. We are far from verifying what fragment. Section 10.

Section VIII

Proof

Bart Van Kerkhove and Joachim Frans

With immense sadness, we had to say a final goodbye to Joachim Frans (1989–2023), co-editor of this section. Joachim died on the morning of 7 December 2023 in a tragic traffic accident. He will be sorely missed by his colleagues and loved ones. We dedicate this section to his memory as a token of our deepest sympathy and appreciation.

Abstract

This introductory chapter sets the stage for an engaging exploration of the multifaceted concept of proof in the philosophy of mathematical practice. As a fundamental pillar of mathematics, proof has long been a subject of intense scrutiny for mathematicians and philosophers alike. Traditionally, proofs have been perceived as rigorous and deductive arguments, and this analysis was directed towards the notion of formal proof. However, recent developments have challenged this traditional view, highlighting the dynamic and evolving nature of mathematical proofs. In this section, we bring together diverse perspectives from leading scholars to delve into the philosophical significance and complexity of mathematical proof.

Keywords

Mathematical proof · Informal proof · Mathematical practice · Proof values · Diagrams · Social epistemology

1 Introduction

The fundamental aspect of proof in mathematics has long been emphasized by mathematicians and philosophers throughout history. Initially, proofs were perceived as rigorous arguments that logically derived new knowledge from accepted statements through precise step-by-step reasoning. This traditional view received significant philosophical attention, focusing on formal proof, justification, reliability, and truth.

However, upon closer examination of actual mathematical practices, a multitude of other questions and challenges emerge. These questions arise from questioning the belief that proofs are flawless deductive arguments, as informal arguments are also accepted as proofs in practice. This prompts exploration into the nature and persuasiveness of informal proofs. Additionally, understanding the process behind proofs and the reasoning patterns leading to their formation becomes a significant inquiry. The role of proofs in mathematical practice is also explored, since proofs can be valued for their elegance, beauty and various types of intellectual satisfaction.

Various researchers have paved the way toward a new attitude regarding the philosophical significance of mathematical proof. Imre Lakatos (1976), inspired by George Pólya (1945), highlights the heuristics and problem-solving strategies underpinning mathematical proofs and underscores the fallible and revisable nature of the proving process. Thomas Tymoczko (1979) encourages a reflection on the evolving nature of mathematical proof, especially in light of technological advancements and the upcoming role of computers in mathematical research. Philip Kitcher (1984) addresses the dynamic nature of mathematical discovery and the importance of looking at the historical development of mathematics. Yehuda Rav (1999) has made notable contributions to discussing the importance of proofs beyond their justificatory power and the relationship between formal and informal proofs.

While this introductory section cannot encompass the full scope of debates surrounding the role of proof in mathematical practice, it emphasizes its enduring significance in the philosophy of mathematical practice. As a pervasive theme, proof connects to various debates and approaches in the field. Attention toward questions concerning proof will always be present in each influential work in the philosophy of mathematical practice, such as Paolo Mancosu's (2008) introduction to different topics of philosophy of mathematical practice, William Aspray and Philip Kitcher (1988) and José Ferreirós and Jeremy Gray's (2006) volumes on the relationship between the history and philosophy of mathematics, and Benedikt Löwe and Thomas Müller's (2010) collection on the social dimensions of mathematics. This is not any different in this book, and the attention to mathematical proof will surpass the chapters within this section. Therefore, before presenting the contributions of this

specific section, we refer readers to other chapters that explore the multifaceted nature of mathematical proofs.

For instance, Otavio Bueno's chapter on heuristics and mathematical practice includes an insightful analysis of different types of mathematical proofs and the roles they can fulfill. Fenner Stanley Tanswell and Matthew Inglis' chapter on the language of proofs presents an empirical study on the use of imperatives in mathematical proofs, which they connect to the recipe model of proofs in their analysis. Jody Azzouni's contribution to this book offers another perspective on mathematical proofs through the algorithmic-device view. Giovanni Ferraro's chapter provides a detailed narrative of Euler's working method, shedding light on how he approached proofs. This list is not exhaustive, and we encourage every reader interested in the diverse philosophical aspects of mathematical proof to delve into this book and be captivated by its wealth of insights.

2 The Chapters in This Section

2.1 Valeria Giardino: Diagrammatic Proofs in Mathematics: (Almost) 20 Years of Research

Valeria Giardino delves into a widely discussed topic in the philosophy of mathematical practice, namely, the role of diagrams in mathematics. Diagrams are pervasive in various mathematical contexts, including recreational, educational, and research settings. Regardless of whether one deals with elementary or advanced mathematics, using diagrams to introduce concepts, convey understanding, and even prove mathematical results is ubiquitous.

This observation gives rise to numerous philosophical questions, with a central inquiry that has captivated philosophers of mathematical practice: What is the role, if any, of diagrams in mathematical proofs? Giardino highlights two distinct waves in the philosophical exploration of this question.

The first wave approaches the topic by examining and discussing specific case studies. These case studies often draw from Greek mathematics, given the prevalence of diagrams in this mathematical tradition. Through these case studies, philosophers can develop accounts of the precise role that diagrams play in mathematical proofs. However, as Giardino demonstrates, the first wave also goes beyond Greek mathematics and extends its investigations to contemporary mathematical practices, further evaluating the role of diagrams in proofs.

The second wave involves philosophical accounts that aim to provide a broader perspective on mathematics, and in doing so reevaluate our understanding of the role of diagrams in proofs. Rather than focusing solely on concrete cases, these approaches tackle questions about the nature of visual reasoning, the role of heterogeneity in mathematics, the reassessment of what constitutes a mathematical proof, and the conceptualization of the various roles that diagrams can assume.

By examining both specific case studies and overarching philosophical accounts, Giardino offers a comprehensive exploration of the role of diagrams in mathematical

proofs, shedding light on their significance in mathematical practice and prompting a reexamination of our understanding of proofs in mathematics.

2.2 Line Edslev Andersen: The Social Epistemology of Mathematical Proof

Line Edslev Andersen starts from the social epistemology of mathematics. Traditionally, mathematics has been regarded as an autonomous discipline, impervious to social and cultural influences, where results are deemed valid through objective and deductive reasoning processes. However, this viewpoint has encountered substantial challenges within the field of philosophy of mathematical practice. The central premise of social epistemology posits that mathematical knowledge is developed and refined through interactions and collaborations among mathematicians. Andersen's chapter focuses on two primary themes emerging from this endeavor.

The first theme consists of shedding light on the norms employed by the mathematical community to establish distinct standards for deductive proofs and other forms of mathematical justification. Andersen seeks to offer valuable insights into the (un)willingness to accept diverse mathematical validation methods.

The second theme pertains to the process of proof checking and the attendant issues concerning the authority and trustworthiness of mathematical knowledge. Given the impracticality of every mathematician thoroughly scrutinizing every result upon which their work relies, and the limitations imposed by the length or specialized expertise required for evaluating new proofs in their entirety, reliance on experts becomes necessary to discern what qualifies as a legitimate proof. Andersen provides an overview of various approaches that address how and when the mathematical community can accept an argument as valid proof.

While examining these two themes, Andersen presents challenging cases that underscore the fact that not all instances align with the existing framework offered by social epistemology. Consequently, the future holds intriguing and complex challenges yet to be fully addressed by the field.

2.3 Rebecca Lea Morris: The Values of Mathematical Proofs

Given the fundamental role of mathematical proofs in establishing the validity of mathematical theorems, it is unsurprising that philosophers have devoted significant attention to understanding the nature of mathematical justification. However, a closer examination of mathematical practice reveals that mathematicians are not solely concerned with proofs for their role in justification. Instances such as the practice of reproving theorems demonstrate that mathematicians attribute value to proofs beyond their justificatory function, and mathematicians frequently judge mathematical proofs using values that are not reducible to correctness.

Rebecca Lea Morris explores a range of proof values, distinguishing between practical values and abstract values. Practical value arises when proofs enhance the accessibility of mathematical knowledge, stimulate new discoveries, or foster innovative modes of thinking. While some practical values are intrinsic to all proofs, others are specific to certain proofs. Abstract values, on the other hand, extend beyond pragmatic objectives. Proofs possessing abstract value exhibit inherently valuable qualities. Morris delves into philosophical analyses of four abstract values: explanation, beauty, fit, and motivation.

In the concluding section of her chapter, Morris highlights the potential relationships between abstract and practical values, as well as the interconnections among abstract values themselves. This underscores the notion that comprehending the nature of a particular value represents merely the initial step in these philosophical inquiries, as the interplay between values opens up new and captivating avenues for research.

2.4 Danielle Macbeth: Formal Proofs in Mathematical Practice

The interest of the philosophy of mathematical practice in mathematical proofs is intricately linked to the recurring tension between fully formalized proofs and the proofs encountered in research practices. Proofs in actual research practices often exhibit gaps or exceed pure deductive reasoning and are commonly referred to as informal proofs. This tension becomes even more pronounced when considering recent advancements in formal proof checking and contemplating the relationship between informal proofs and their formal counterparts. Danielle Macbeth identifies two different positions concerning the relation between formal and informal proofs. On the one hand, she describes formalists who believe that informal proofs are in fact sketches of their formalized counterparts. On the other hand, you have the non-formalist position, which rejects the idea that formal proofs have an essential role to play in mathematical practice. This is closely related to the discussion of what these different types of proofs have to offer. There are various perspectives regarding the advantages or disadvantages of transitioning between these two types of proofs. Intuitively one might expect that formalized proofs possess persuasive strengths, while informal proofs contribute to insightful understanding.

Macbeth highlights the need for critical investigation of these perspectives and defends the view that the distinction does not simply lie in whether or not a proof is gap-free and whether or not the proof is infused with meaning. To accomplish this, she draws upon the historical contributions of Descartes, Leibniz, and Frege. By examining these figures' work on mathematical language, and emphasizing the importance of the distinction between different types of language, Macbeth argues that there is still a meaningful difference between rigorous and gap-free mathematical proofs and formal proofs, in the sense that the former can be seen as contentful and the latter not.

2.5 Karine Chemla: The Dark Side of the History of Proof: Proving the Correctness of Algorithms in the Ancient World

Karine Chemla directs our attention to the contrast between computation and proof. One possible understanding of this distinction is to view computation as a process of rule-following, where the content does not hold an essential role, while proof is connected to questioning and establishing relationships between statements. However, as Chemla's analysis reveals, this perspective does not withstand a more profound analysis.

What is particularly intriguing about Chemla's analysis is her departure from the standard narrative, often entailing an interpretation rooted in the Western history of mathematics. Instead, she challenges this view regarding proof and computation by exploring the history of verifying algorithm correctness in Chinese mathematics.

By examining the historical context of algorithmic validation in Chinese mathematics, Chemla offers a fresh perspective that challenges the traditional understanding of the relationship between proof and computation as well as to what is "proper" mathematics. In doing so, valuable insights are provided into alternative approaches of this central matter, enriching the discourse surrounding the interplay between proof and computation.

3 Conclusion

This section focuses on the philosophy of mathematical proof, which is essential in understanding mathematical practices. The following chapters explore various perspectives on the significance and intricacies of mathematical proof, providing readers with a comprehensive understanding of the subject.

Our hope is that this collection of chapters not only informs readers about the current state of research but also acts as a catalyst for future investigations. We believe that the insights and discussions presented here will serve as a solid foundation for further explorations. As the philosophy of mathematical proof continues to evolve, our goal is to inspire additional inquiry and encourage scholars to delve deeper into this captivating area of study.

Abstract

The objective of this chapter is to introduce some of the views that have been put forward in almost 20 years of research on diagrammatic proofs in the philosophy of mathematical practice. In Sect. 1, some contextual elements will be presented on the reasons why diagrammatic proofs have attracted so much philosophical attention in the past years. In Sect. 2, the "first wave" in the research on diagrammatic proofs based on the analysis of case studies will be described: this is how it started. In Sect. 3, the "second wave," which is calling for "big pictures" and divides into two different strategies, will be discussed: this is where it is going. In Sect. 4, some conclusions will be drawn.

1 Introduction

It is undeniable that diagrams are part and parcel of the practice of mathematics: mathematicians draw them on blackboards and occasionally on napkins at conference lunches; they use them to teach students and to show to colleagues that some relations obtain or more simply to share ideas with them; in some cases – but not as often compared to their heavy presence in more informal exchanges – diagrams end up being published in handbooks, encyclopedias, or research articles. How can the pervasiveness of diagrams in the practice of mathematics be accounted for? To clarify, this phenomenon can be investigated in two related but conceptually distinct ways.

First, very general questions can be asked. Why do diagrams seem so effective in mathematics (and beyond)? How are they used? Do they help understanding and explanation? If so, do they in all cases? What cognitive advantages do they offer? What are their cognitive costs? What are the cognitive foundations of the reasoning based on them? Are diagrams typical of Western mathematics or are they also found in other mathematical cultures? And how are they related to other forms of visualization? All these questions are of crucial interest not only for philosophy but also for other disciplines in its vicinity, such as history, sociology, anthropology, cognitive science and education.

Additionally, a second, more specifically philosophical, question can be raised about the role that diagrams might – or might not – play in mathematical *proofs*. Of course, answers to the first set of questions are relevant to discuss diagrammatic proofs; nonetheless, it is important to note that the second question is relatively independent from the first set of questions: it is indeed possible to accept that diagrams are omnipresent and useful tools in the practice of mathematics, that they are important heuristic tools used for discovering or even for proving some mathematical results, and yet to consider that they are not and cannot be parts of proofs or necessary for them.

In this chapter, I will focus on the second question, that is, on the possibility of finding proofs in the practice of mathematics that make use of diagrams. My objective will be to survey some of the views that have been put forward so far in the literature in the philosophy of mathematical practice. In order to do that, at times I will raise some of the more general questions; however, this will be done only to the extent that some of the replies can be used as evidence for the presence of diagrams in proofs. I will proceed by presenting some of the available proposals and by describing how the discussion in the philosophy and partially in the history of mathematical practice has taken shape in the last 20 years or so.

In the following, I will introduce some contextual elements that are essential to understand the reasons why diagrammatic proofs have attracted so much philosophical attention in the past years. As already said, it is undeniable that diagrams appear in some proofs; however, the nature of their contribution is controversial; that is, there is no agreement on whether diagrams are necessary for the proof to go through or whether they are just useful illustrations that can be in principle removed from the proof without epistemic loss. Before proceeding, a word of caution is necessary

regarding the meaning of the term "diagram." It is evident from the literature that there is no consensus on how to define diagrams. "Diagram" has indeed been used for a long time in a loose way, in order to refer to different objects, spanning from Euclidean diagrams (figures?), to diagrams (schemas?) in category theory. As I will show, some scholars consider two-dimensionality as a necessary feature for something to be considered as a diagram, while others focus on the manipulations that can be performed on the diagrams to be their characteristic feature, thus opening the way for linear notations to be included into the class of diagrams. In this chapter, I will keep using "diagram" in a general fashion, as a sort of umbrella term encompassing several kinds of representations, without taking any stance on the debate on how to better define them.

The relation between diagrams and proofs is as old as mathematics. Famously in his *Parallel Lives*, in the section entitled *Marcellus* (second century AD), Plutarch describes the death of Archimedes, which deeply afflicted Marcellus. In this account, Archimedes happened to be by himself, "working out some problem *with the aid of a diagram*, and having fixed his thoughts and his eyes as well upon the matter of his study, he was not aware of the incursion of the Romans or of the capture of the city" (*emphasis mine*). A soldier ordered him to go with him to see Marcello, but Archimedes refused because he wanted to first establish his proof. Hearing these words, the soldier got angry, drew his sword, and killed him. Archimedes was thus attempting to prove a result by fixing *not only his eyes but also his thoughts* upon the matter of his study – the diagram itself or what it represents? Whatever the reply to this latter question, Plutarch's story tells us that nothing at the time prevented a mathematician to use a diagram in a proof – at the exception of a Roman intruder.

As is well known, things had changed by the late nineteenth century, when the urge to make mathematics rigorous had grown stronger and stronger, to the point of pressing Pasch to claim that "the theorem is only truly demonstrated if the proof is completely independent of the figure" (see Pasch 1882). Dedekind was also very much dissatisfied with the appeal to diagrams that exploited geometric intuition in analysis – notwithstanding the fact that his manuscripts are replete of tables, doodles, and sketches (see Haffner forthcoming) – and Russell (1901) agreed that the best (mathematical) books do not contain figures. (For the details of this historical background and a general discussion of the epistemology of visual thinking in mathematics, see Giaquinto (2020).)

These attitudes contributed to the definition of what has been labeled the "received view" of mathematics (see van Bendegem 1993), according to which only reasoning that is expressed in formulas can bear epistemological weight, while the rest of the representations that are found in the practice of mathematics – for example, geometric figures – are just illustrations or at best a form of heuristics that would facilitate the grasp of the content of their linguistic counterparts, but nothing more. This received view, inherited from the nineteenth century, became the standard in the philosophy of mathematics of the twentieth century, as summed up in Tennant (1986, p. 304)'s claim: "[the diagram] has no proper place in the proof as such. For the proof is a syntactic object consisting only of sentences arranged in a finite and inspectable array." (This passage from Tennant (1986) is quoted in

Barwise and Etchemendy (1996, p. 3) as expressing the "dogma of logocentricity" that the authors want to challenge. Despite the fact that the context here is logic, the quote is still relevant for mathematics. I will briefly refer to the relation between the question about diagrammatic proofs in logic and in mathematics later in the article.) Despite the fact that diagrams can be important for understanding or explanation, they have no place in proofs.

The context changed again at the beginning of the present century (for a survey, see Giardino 2017a, and Carter 2019a): in 2005, Mancosu, Jørgensen, and Pedersen edited a volume of essays that were devoted to "new" – compared to the received view – research subjects: *Visualization, explanations and reasoning styles in mathematics* (Mancosu et al. 2005). In the introduction to this volume, the editors explain how the focus of the research in philosophy of mathematics should be on "what mathematicians are actually doing when they produce mathematics," thus posing the foundations for a philosophy of the practice of mathematics. Indeed, 3 years later, Mancosu edited a new collection of articles on *The Philosophy of the Mathematical Practice*, to show that several topics – concept-formation, understanding, heuristics, changes in style of reasoning, analogies, and diagrams – still belong in the domain of philosophy, despite the fact that philosophers had neglected them for a century or so (Mancosu 2008). The essays collected in these volumes constitute evidence for a restored interest in subjects that, according to him, were complementary to more traditional and "received" questions, for instance, the one about the access to mathematical objects. A challenge for research was to put these questions in relation with each other, for example, by exploring how mathematical concepts and objects are generated and how the process of justification works. In Mancosu's words, epistemology of mathematics could not be reduced to "a torso" (Mancosu 2008, p. 1), and it was time to return to issues like fruitfulness, evidence, visualization, diagrammatic reasoning, understanding, and explanation.

In this renewed philosophical panorama, studies on diagrams ended up occupying a preeminent position. The aim of this chapter is to trace back the literature about the role of diagrams in proofs starting from the publication of Mancosu's 2008 volume, that is, 15 years ago. However, given this long period of time, it will be impossible to cover all of the details – other people, including myself, have done it already (see for example Giardino 2017b). What I will try to do is rather to propose a narrative of how this research started and where it is going today. Given the distinction I made between two different sets of questions concerning diagrams, I will focus on the second one and therefore on a selection of studies devoted to giving an account of cases in which diagrams are part and parcel of mathematical proofs. In order to do that, it is necessary to specify which features they possess and how they are intended to be used and furthermore which relations they entertain with other elements of the practice of mathematics.

On this last point, let us recall an important methodological issue. To say that a proof is "diagrammatic" does not mean that it is "without words," as three celebrated volumes edited by Nelsen seem to suggest (Nelsen 1997, 2001, 2015). The proofs making use of diagrams that scholars are interested in are *always* proofs that also include some form of *text*, be it the labels accompanying the diagrams or the

formulas obtained by considering some of the diagram's features. The point about diagrammatic proofs is precisely to understand how diagrams and text – two crucial elements in the practice of mathematics – are related and how the contribution of the diagram to the information presented in the text can be (or not) essential for the proof to go through. In epistemological jargon, the interesting question is about how a mathematical belief that is obtained by looking at the spatial features of the diagram and by manipulating it can be raised to the status of knowledge in the absence of independent textual grounds, as well as be related to other pieces of knowledge expressed in the text.

The narrative that I propose is the following. In Sect. 2, I will quickly describe the "first wave" in the research on diagrammatic proofs. As I mentioned above, at the beginning of the 2000s, old topics were brought back to the front by raising questions that had been almost forgotten. This is how it started. Since then, many articles have been published that present case studies of diagrammatic proofs, with Greek mathematics taking center stage; as we will see, we have to wait until the beginning of the 2010s for case studies in contemporary mathematics. In Sect. 3, I will describe what I call the "second wave" in the research on diagrammatic proofs. This is where it is going. Now that the richness and the variety of diagrammatic proofs have been demonstrated, it is time to draw big pictures, which is what some scholars are presently trying to do. In order to introduce this second wave, I will first focus on pioneering work on the richness of mathematics and then on two strategies that are emerging today, aiming to specify what is meant by "proofs" (first strategy), and by "diagrammatic" (second strategy), in "diagrammatic proofs." In Sect. 4, I will briefly sum up the topics of the chapter.

Two last methodological notes. First, nothing of what I will write about in this chapter will refer to research on diagrammatic proofs *in logic*, despite the fact that some of the questions and resources in the literature are common to the two disciplines. The reason for this is that I consider that the practice of logic has its own specificities and thus deserves a separate treatment. (There are several studies that are relevant in this respect, for example, Shin (1995), Allwein and Barwise (1996), or Stenning (2002). More recently, Dutilh-Novaes (2012) discussed the role of formal language and notation in logic.) However, logic will be evoked at times in discussing rigor in contemporary mathematics. Second, I will mainly focus on studies in the *philosophy* of mathematical practice. I am aware that enormous work has been done in history – and I would say also archeology – of mathematics on diagrammatic proofs from the past, not only in the West but also in places such as old China and Mesopotamia (see for reference Chemla 2005, and Høyrup 2005). Many of the chapters of this handbook are devoted to the history of the practice of mathematics and will tackle the subject of diagrammatic proofs among others; therefore, for pragmatic reasons, I will not go into that research here. However, integration between the historical and philosophical points of view on diagrammatic proofs is desirable: as testified by the first of Mancosu's collections in 2005, historians and mathematicians started working together on these new-old topics. Since then, the two disciplines took their own research paths; it is time to foster again collaboration between the two to give an account of the practice of mathematics.

(Another subject I will not touch upon in this section is computational approaches to diagrammatic proofs. Some relevant references can be found in Giardino (2017b).)

2 The First Wave of Research on Diagrammatic Proofs: Looking for Case Studies

2.1 The Philosophers' Darling: Greek Mathematics

The Greek diagram is to some extent the paradigm of diagrammatic reasoning in mathematics, which explains why it has been a privileged target of research for philosophy for a long time. There is no need to be a philosopher or a mathematician to be familiar with Euclidean geometry, and in Euclidean geometry, the recourse to diagrams is natural and spontaneous: starting from a very early age, these geometrical figures become part of our visual repertoire. From this, can we take their presence and effectiveness in proofs for granted?

As Netz (1999) pointed out, diagrams are interdisciplinary research objects, because they are of interest both for the science of cognition that is looking at knowledge from the point of view of its practices and for history of science that studies cultural artifacts. For this reason, diagrams are the perfect subjects for what he calls a "cognitive history" and can be approached from many different points of view. I agree with this and I consider philosophy as the approach targeting more specifically their role in proofs. In his book on deduction in Greek geometry – going also beyond Euclid's *Elements* – Netz defends the idea that the "lettered diagram" is an effective geometric *tool* because of the richness of the different levels at which it can be accessed, which is what makes it appropriate to promote and justify deduction and, as a consequence, to demonstrate mathematical propositions.

The lettered diagram can in fact be considered from several points of view: logical, cognitive, semiotic, and historical. At all of these levels, it combines two elements that would normally be considered to be in contrast to each another, if one follows the standard opposition between image and language: lines and letters at the logical level, visual features and models at the cognitive level, icons and indices at the semiotic level, and a kind of know-how together with a very sophisticated reflexivity at the historical one. According to Netz, a proof in Greek geometry is based on the lettered diagram and, as a consequence, is an *event* that occurs on a papyrus or in a given oral communication. Despite its singularity, it is *felt* to be valid: the materiality of the proof is important as well as its immateriality, since the proof is considered as an *invariant* under the variability of the single action of drawing one diagram on the papyrus or of presenting the particular proof orally. The proof can be *repeated*, which is what matters for it to be recognized as a proof; contrary to what we are used to think today, the focus is not on the possibility of generalizing the result. For Netz, in order to give an account of how the lettered diagram makes the proof go through, it is necessary to consider its cognitive appeal. The diagram is in fact a static object that is nonetheless related to the text via the letters, which makes it *kinesthetic*: a diagram gets constructed and can be manipulated.

In a very renowned paper, which has been circulating since the 1990s but was published only in 2008, Manders (1995/2008) investigates Euclidean geometry specifically. He reminds us that up to the nineteenth century no one would have denied that the practice of Euclidean geometry was *rigorous*; rather, such a practice was considered to be the *most* rigorous practice among the various human ways of accessing knowledge. In Manders' view, such a practice is based on a division of labor between two artifact types – the diagram and the text sequence – that must be considered together. As humans, we have cognitive limitations, and therefore we cannot control the interpretation of a diagram so as to avoid any case that is alternative to the correct one; for this reason, the text is introduced. In the practice, diagram and text share the responsibility of allowing the practitioners to respond to physical artifacts in a "stable and stably shared fashion" (p. 83). In this framework, proofs have a verbal and a graphical part – the *diagram* and the *discursive text*: the diagram makes the very objects of traditional geometry appear, while the text ascribes particular features to the diagram, the so-called diagram *attributions*. Letters are introduced so as to facilitate cross-references between the text and the diagram. In this reconstruction of the Euclidean practice, Manders introduces a distinction between *co-exact* and *exact* features of a diagram that became very influential. (Mander's work was influential to the point of inspiring cognitive research. See Hamami and Mumma (2013) and the more recent Hamami et al. (2021).) A co-exact feature is a feature that can be directly attributed to the diagram, having certain perceptual cues that are fairly stable across a range of variations; such a feature cannot be readily eliminated, because of what Manders calls the diagram *discipline*, that is, the proper exercise of skill in producing diagrams that is required by the practice. An exact feature is instead in general affected by deformation, and it is licensed by the discursive text: for example, the fact that in a diagrams two segments have to be considered as – seen as – equal. Note that in both Netz' and Manders' proposals, the diagram is part and parcel of the proof *because* of the combination of diagram and text and thanks to its *dynamic* features: invariances or co-exact features – not varying under deformations.

Macbeth (2012, 2014) proposed another account for the use of diagrams in Euclidean proofs that emphasizes their nature of "signs." She considers Euclid's *Elements* as a system of *natural deduction*, where common notions, postulates, and definitions are not intended as premises, but as *rules* or *principles* according to which to reason. Along these lines, she suggests that in order to understand and use a diagram, one has to recognize the *intention* that is behind its construction. Moreover, in her view, a diagram is fruitful because it is an *icon*; that is, it "resembles" what it signifies. The Euclidean diagram has to be considered at different levels: first, it has primitive parts – points, lines, angles, and areas; then, thanks to the concepts of geometry, one gets the elements that someone doing geometry will be interested in – for example, an equilateral triangle is "seen as" composed of three equal lines; finally, one has to consider the diagrams as a *whole*, which shows at a glance the elements in the other two levels. In this sense, a Euclidean diagram is not different from other kinds of representations such as the famous Wittgensteinian duck-rabbit.

Consider, for example, the diagram of an equilateral triangle obtained from a segment AB by drawing two circles with centers A and B, respectively, intersecting in C. Draw the two segments from A to C and from B to C – this is Euclid I, 1: the "same" segments, AB, AC, and BC, are "seen as" the sides of the triangle *as well as* the radii of the same circle (see Fig. 1). Thanks to the combination of all these different elements in the same icon, one reasons *in* the diagram and obtains the proof. (Actually, there is a difference between the duck-rabbit and the triangle in Euclid, since the second is not an instable percept; on the contrary, someone who is competent in geometry will be able to see the two aspects and acknowledge that they are not incompatible. For a discussion of this point, see Giardino and Wöpking (2019).)

Another interesting notion to apply to Euclidean proofs was proposed by Azzouni (2005). In his view, traditional mathematical proofs imply the appeal to a kind of know-how and tacit knowledge involving "inference packages" applied to the proof as "black box units." The elements encapsulated by an inference package are in principle not visible by introspection as a list of assumptions, for the reason that these assumptions have been "knit together" in the representations of the objects. In traditional proofs – compared to derivations in algorithmic systems – it is not the case that each step follows from some sentences appearing earlier in the proof: traditional proofs work "semantically" rather than "syntactically"; that is, mathematicians recognize properties of the objects their inferences are *about* by operating with the available representations. The details of the inferences provided by inference packages are thus not only left out because everyone is familiar with them but because they are not introspectively accessible to practitioners. In this semantic view of proofs, representations – for example, some particular diagram – have precisely the role of allowing for a form of intuition to apply the inference package that comes with them, and for this reason, they should be at the core of the philosophical investigation (Azzouni 2005, pp. 23–24). (To learn more about Azzouni's view, see ► "The Algorithmic-Device View of Informal Rigorous Mathematical Proof," this volume.)

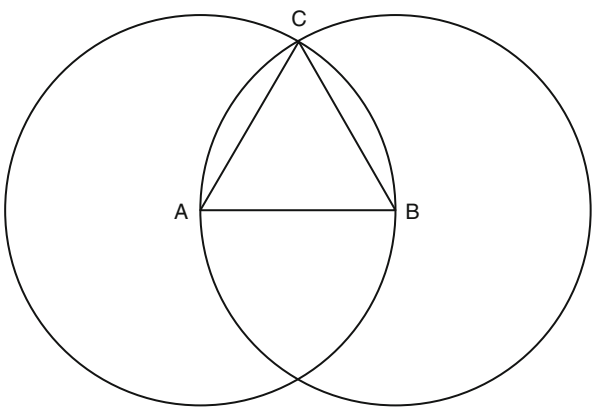

Fig. 1 *Euclid, Elements*, Book I, Proposition 1. *To construct an equilateral triangle on a given finite straight line*

I have discussed elsewhere these views and others focusing on the case of Greek diagrams and diagrammatic proofs (Giardino 2017b), and therefore I will not go here into further details. In the following, I will simply sum up some of the important points that have been proposed for the case of Euclidean (or Greek) diagrammatic proofs. It is crucial to note that all these studies show that in order to give an account of diagrammatic proofs, it is necessary to go beyond the insistence on the alleged opposition between a "visual" and a "linguistic" part of mathematical proofs, for two reasons. First, diagrams have to be considered together with the text, and therefore the focus of the research should be on the way in which the two relate. Second, diagrams can be interpreted as *dynamic*: for example, co-exact properties are not subject to modifications – which suggests that the diagram has to be manipulated in order to "test" our correct interpretation of it; the text clarifies what the intentions in the construction of the diagrams are in relation to the properties that may vary under the same manipulations. Such manipulations allow for particular inferences that are not accessible through the text only. Seeing the same configuration "differently," by identifying several levels that have to be considered separately but also as a whole, may be considered as a very basic way of making the diagram "dynamic" without modifying it. Moreover, the proof is an "event" that can be repeated, once the diagrams and the text are correctly put together.

In the following subsection, we will look at more recent case studies taken from contemporary mathematics and see how they relate to the features that emerged in the analyses of Greek mathematics.

2.2 Contemporary Mathematics Enters the Scene

If Greek diagrams have been at the center of philosophical discussion for a long time, case studies of diagrammatic proofs taken from contemporary mathematics have started becoming of interest to philosophers in most recent years, approximately after 2010. Why so late? Of course, a strong background in the practice of mathematics is necessary to get the gist of the examples taken from contemporary mathematics. Only recently, philosophers who were previously trained in mathematics started tackling specific questions about diagrammatic proof and collaborations between philosophers and mathematicians have developed – a good thing, given the interdisciplinary nature of the topic. It should also be noted that the support of interdisciplinarity in education today is encouraging more than before – when the training was more rigidly disciplinary – the creation of a new generation of interdisciplinary scholars. I have already presented elswhere some of these more recent case studies in detail (Giardino 2017b); in the rest of this section, I will sum up some of these results.

Carter (2010) was one of the first scholars to introduce case studies from today's mathematics – as well as one of the first who are now trying to think in terms of more comprehensive pictures, as we will see below. In her contributions, she focused on the role that diagrams have in a proof to define its *strategy*. She analyzes a case from free probability theory, where diagrams are introduced in informal discussions

among mathematicians to represent particular mathematical entities, for example, permutations (see Fig. 2). Carter argues that diagrams make it easier to evaluate relevant properties, e.g., whether the permutation is crossing or not or whether neighboring pairs can be canceled. Despite the fact that they are *not* published in the final article, it can be shown that they still suggest definitions and proof strategies, thus inspiring at least a part of the formal version of the proofs. Diagrams here function as a *framework* for the proof and help breaking it down into parts that are more manageable than the whole proof. We mentioned above the importance of the relationship between diagrams and text in Greek diagrams: here, some properties of the diagrams *correspond* to formal definitions, but *experiments* are performed on the diagrams. (On experiments and diagrams, see ▶ "Mathematical Experiments on Paper and Computer" in the chapter by Schlimm and Fernández González, this volume.) However, the relations used in the proof based on the diagrams refer to relations that *also* hold in the algebraic setting, which allows going back from the diagram to the algebraic setting. Moreover, some features of the diagrams – for example, crossings and neighboring pairs – are indeed co-exact properties, since they do not change under a series of variations. Carter's inspiration is C. S. Peirce's philosophy, according to which all mathematical reasoning is *diagrammatic*: in her case studies, diagrams are considered as "icons" in relation to the algebraic setting. However, one recognizes in them "indices" – letters – as an element that captures attention and, as Peirce writes, tells the user to look "There!" (*CP* 3.361).

Another case study Carter focuses on is directed graphs (Carter 2018). Also here diagrams are icons, that is, mediating objects, which link – metaphorically – two types of mathematical objects. This is possible because they constitute a "faithful" representation, which is able to put together the metaphorical aspects of using a mathematical diagram with the control that it is necessary to exercise on its manipulation. In fact, manipulations that are performed on the diagram respect the relations between the concepts that they represent, and this leads to the definition of new

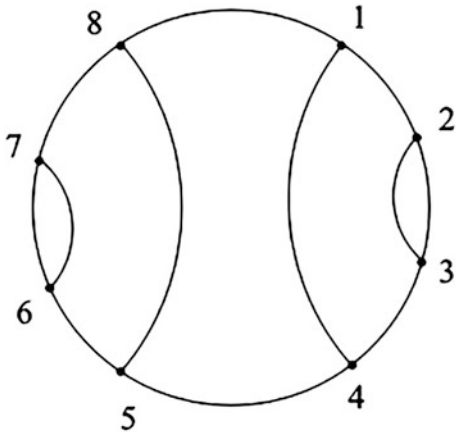

Fig. 2 An example of a diagram of a permutation, in Carter (2010)

relations between parts of those concepts that were not appearing at the beginning. (In a more recent paper, Carter (2021) reviews some of her previous examples by referring to the notion of "free ride" as proposed by Shimojima (2015). In the paper, she shows that "free rides" are not completely "for free": in most cases, some interpretation is required to "read off" some properties from a diagram, and therefore a free ride is not always a free sight.)

In Carter's view, diagrams are fruitful frameworks in parts of proofs because they trigger imagination. She refers to the notion of "manipulative imagination" as introduced by De Toffoli and Giardino (2014) in the context of an analysis of the role of knot diagrams in topology (see Fig. 3). In our reconstruction, experts in knot theory have developed a form of imagination that allows them to manipulate these diagrams – by redrawing them or by figuring out in their mind which kinds of actions can be performed on them. (In previous work, I defined diagrams as "props" – by referring to Walton's theory of imagination – for some mathematical object: working with them would correspond to test ways in which the mathematical objects they allude to might "behave" (Giardino 2018a). On the notion of manipulative imagination, see also Giardino (2018b).) Manipulative imagination is very effective in low-dimensional topology, where diagrams are used to explore the properties of mathematical objects and eventually to prove theorems about them, for example, in Rolfsen's demonstration of the equivalence of two presentations of the Poincaré homology sphere (see De Toffoli and Giardino 2015). In our view, the actual practice of proving in low-dimensional topology involves a kind of reasoning that requires intuition: the manipulations that are allowed for and on the representations as well as the representations themselves are *epistemologically relevant*, because they are integral parts both of the reasoning and of the justification provided by the proofs.

In a more recent paper, De Toffoli (2017) describes commutative diagrams and the "diagram-chasing" technique in homological algebra, where a new feature of diagrams in proofs emerges. Diagrams indeed can correspond to an abstract counterpart of geographic maps. (For case studies in category theory, see Halimi (2012)

Fig. 3 An example of a knot diagram. By applying the appropriate manipulations, one finds out that this is a knot diagram of the unknot

and Weber (2013).) As she explains, the *Five Lemma* and the *Fundamental Theorem of Homological Algebra* are both based on chasing an element in different places *in* the diagram, which in the second case is potentially infinite (see Fig. 4). The chase aims to identify paths in the diagram by exploiting its commutativity in order to verify some algebraic properties. The basic idea is to imagine moving an element around the diagram by following the relations that are there displayed (perhaps the analogs of the "co-exact" properties of Euclidean diagrams), according to some definitions (the "exact" attributions of the text). De Toffoli explains that in the case of homological algebra, commutative diagrams play the two roles already identified by Carter, that is, they inspire the proof strategy and they offer a framework that allows getting to it. However, they also have two additional roles: first, they display algebraic content in a way that is meaningful and *mathematically tractable*; second, they allow for *calculations* that can be integral parts of the proof. In De Toffoli (2023), she argues that commutative diagrams (as well as certain topological diagrams) not only can be used within rigorous proofs but are even essential to the proofs in which they figure. This would mean that non-diagrammatic conversions of such proofs would plausibly be classified not as different presentations of the same proof, but as different proofs.

To sum up, a look at case studies from contemporary mathematics shows that diagrams happen to be used effectively in proofs, for the reason that they can make new properties or relations appear. Of course, this is done in reference to some mathematical context. However, there are some caveats. First, not all diagrams are used specifically in proofs: some diagrams support intuition in the context of discovery. (For an interesting case on Caley graphs and their use for discovery, see Starikova (2010).) What emerges clearly from the literature is in fact the variety of diagrams: diagrams to display permutations have very different features compared to, say, commutative diagrams. This said, a common feature seems to be their way of triggering some form of intuition or imagination – whether they can be ultimately part and parcel of a proof depends on the control that may be applied to them by fixing their interpretation. To use an expression from Larvor (2012), within a certain diagrammatic practice, some actions on the diagrams are recognized by the experts as "permissible" or not. There is something more to note – to which I will return when I will discuss where we are now in the research on diagrammatic proofs: cases in contemporary mathematics show that diagrams and notations can be brought together. In her paper on homological algebra, for example, De Toffoli explicitly argues for diagrams as a subset of notations and gives three criteria to evaluate them as such: *expressiveness*, *calculability*, and *transparency*. For Carter as well, a piece

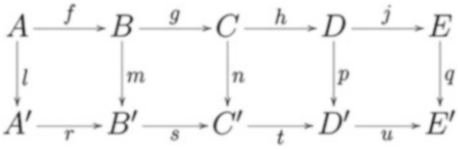

Fig. 4 The commutative diagram used in the proof of the *Five Lemma*

of notation such as $2\ k + 1$ for some natural number k is also a case of a faithful iconic representation of the concept of odd number. I will return to this issue below.

3 The Second Wave: Calling for Big Pictures

3.1 Pioneering Work on the Richness of the Practice of Mathematics

In the narrative that I propose in this chapter about these past 20 years or so of studies on diagrammatic proofs, I maintain that the urge for providing a big picture about their role in proofs has appeared only very recently. However, I will focus here on two scholars who were undoubtedly the first to try to offer a comprehensive account of the richness of the mathematical practice related to diagrammatic proofs. (Another important early publication on diagrams in mathematics is Brown (1999), where several cases of diagrammatic reasoning are discussed. Brown's view has strong Platonic assumptions: his "bold conjecture," as the author famously put it, is that (some) pictures *"are not really pictures, but rather are windows to Plato's heaven"* (p. 40, emphasis in the original).)

Giaquinto (2007/2011) was maybe the first to consider *visual* thought in mathematics in an interdisciplinary fashion, by relying on some explanations coming from cognitive science, which was on the rise at the time. The general aim of his book was to give an account of the complexity of mathematical thinking. To do so, he explored and presented some results in cognitive science about our capacity for visualizing in an attempt to integrate them with other more theoretical reconstructions of high-level processing of information. The book is interestingly devoted to discovery in mathematics, which, according to Giaquinto and in line with the revival for the attention to the practice of mathematics, is a subject that had been neglected by the most recent philosophy of mathematics as not legitimately philosophical. However, there are parts of the book where Giaquinto discusses the possible presence of diagrams in proofs. In his view, there is no need to give a uniform story about visual thinking in mathematics, which comes in a variety of ways: depending on the specific mathematical context, visual operations can be different, and consequently it may be possible to consider differently their epistemic value.

One point that seems important in the present context is Giaquinto's focus on *aspect shifting* in mathematics. Consider, for example, a possible proof of the Pythagorean theorem. In order to understand that it is valid, here is one possibility (see Fig. 5). First, one reasons geometrically and arranges a small square and four right triangles in a bigger square, so that the sum of the two sides of the triangle correspond to the side of the bigger square and their hypotenuses form the smaller square. Then, one reasons algebraically and calculates the area of the smaller square plus the areas of the four triangles and equates it to the area of the bigger square. Some more calculations and the claim is established. This procedure is accessible because we shift from one aspect, what we "see" in the diagram, to the other, what the rules on how to obtain the area of a square and of a triangle tell us. If this is the

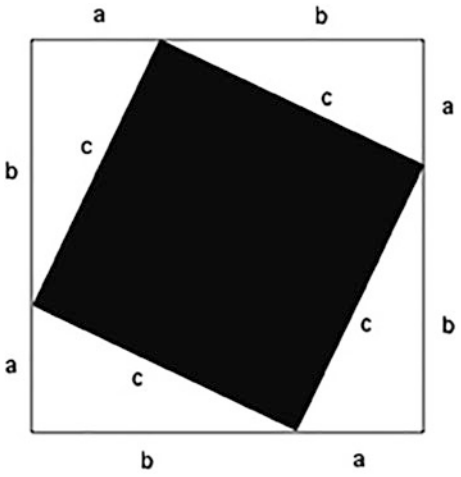

Fig. 5 One of the many so-called "visual proofs" of the Pythagorean theorem

case, would this reasoning be primary geometric or primary algebraic? In the last chapter of the book, Giaquinto suggests that neither of these two categories would be fully appropriate to capture it. Is this a general feature of mathematical reasoning?

Another interesting early work was Grosholz (2007, 2011), which discussed at depth the *heterogeneity* of mathematical reasoning as something that has been overlooked by what she identifies as the Russell-Carnap tradition – the received view? Also in this case, the practice of mathematics went back to the center of the philosophical investigation. In Grosholz' reconstruction, the Russell-Carnap tradition represents an epistemological ideal whose objective is to unify mathematics, or mathematics and the sciences, in one formalized theory. With this objective in the background, this tradition demands that logic is the homogeneous idiom constituting the only vehicle for deductive inference. Macbeth's view that was mentioned in the previous section on Euclidean diagrams recalled Grosholz' notion of "productive ambiguity" of diagrams, which is precisely what allows us to see different things in the same configuration – the sides of an equilateral triangle and the radii of the same circles – and to put the two together in order for the proof to go through. However, productive ambiguity and heterogeneous reasoning go beyond geometry: one of Grosholz' examples is Gödel's procedure in his incompleteness theorem. In her reconstruction, by his use of numbering as a strategic bridge between formalized arithmetic qua logical system and arithmetic, Gödel exploits a "carefully controlled and fruitful ambiguity" (Grosholz 2011, p. 421), which multiplies the information that is available to a mathematician. As she puts it, "it is hard for a logician to admit that he is *trafficking in heterogeneity*" (ibid., p. 425, *emphasis mine*). As we see, the richness and the variety of the representations involved in the reasoning process were extended to other parts of mathematics and even to logic. This opened up a new research horizon that will constitute a heritage for the views that I will present in the next subsection.

3.2 Today's Views on Diagrammatic Proofs

In Sect. 2, I summarized some of the case studies of diagrammatic proofs that were subject to philosophical scrutiny, starting from Greek mathematics and growing into cases from contemporary mathematics. This variety called for some kind of comprehensive framework that could account for them. However, how is it possible to talk in terms of a "big picture" for a phenomenon that is so diverse and that also depends – as Giaquinto suggests – on the specificity of the mathematical context considered in turn?

Let us focus on the term "diagrammatic proofs" and the way in which it is commonly intended. On the one hand, "proofs" is here meant narrowly, mostly in the sense of the received view: the question about diagrammatic proofs is whether forms of reasoning that make use of diagrams reach the standards of what is commonly considered as a proof – to the point that "diagrammatic proofs" may sound to some as an oxymoron. On the other hand, "diagrammatic" is interpreted as having a very wide scope so as to include many case studies and thus has the advantage of accounting for their richness. However, the fact that the term is used very loosely has also its disadvantages. What exactly is a diagram? Are geometrical figures diagrams? Are they analogous to a matrix? What is the relationship between diagrams and notations? Are they one and the same thing?

In my view, the strategies to give a comprehensive account of diagrammatic proofs can be divided into two groups. First, one might argue for a notion of proof that moves away from definitions *à la* Tennant and easily includes diagrammatic proofs as perfectly acceptable. Second, one might try to put forward some criteria for different categories of diagrams in mathematics, thus providing a taxonomy and more importantly drawing a line between diagrams that can be reliably used in a proof and others that play the role of useful illustrations or good heuristics but do not possess the necessary features to be considered part and parcel of a proof.

In the following sections, I will briefly present some of the accounts that correspond to these two strategies, which would give in my view a fair picture of where the research on diagrammatic proofs is going today. (Given that the studies I will refer to are newly published, I might happen not to know yet about other studies that could easily be included in this survey.)

3.2.1 First Strategy: What Is a "Proof"?

The first strategy that has recently emerged in the literature is the focus on mathematical proofs in the practice. Such an investigation does not target diagrams in particular, but aims to move away from the narrow definition of proof typical of the received view. I will present here some frameworks that would allow for diagrams to have a constitutive role in proofs: I will start from the recipe model of proofs introduced in Tanswell (forthcoming) and then briefly discuss recent work on informal proofs. It is important to note that the topic of informal proof in particular would demand a chapter of its own, and for reasons of space, I will not be able to go into the details; my discussion will be limited to the aspects of this debate that are relevant for diagrammatic proofs.

In Tanswell (forthcoming)'s "recipe model," proofs are to be intended as analogous to cooking recipes since, as cooking recipes, they give instructions on how to carry out actions – in the case of a proof, "mathematical" actions – in order to obtain the desired result. Of course, this does not conform with the received view, according to which the proof is a deductive syntactic argument that moves from some axioms to a conclusion by following some pre-established inference rules. In Tanswell's view, despite the success and fruitfulness of such a definition of proof, it is time to provide a new definition that would be more faithful to the practice of contemporary mathematics: written proofs are written records of how the theorem is obtained, and their main objective is to explain to the reader how to actually do the reasoning that is required in order for the proof of the theorem to go through. As in the case of recipes, proof has a communicative intention and there might be different styles of presenting the same proof.

The evidence that Tanswell brings about to argue for this analogy is first of all linguistic: the texts of proofs include instructions in the imperative tense (see "Imperatives in Mathematics" in the chapter by Tanswell and Inglis, this volume). However, such a view of proof allows including diagrams and figures interacting with the text as alternative means of giving instructions. The opposition between assertions on the one hand and pictures on the other is ill-posed: both of them can convey instructions, and for both of them, some competence for interpretation is required. However, in Tanswell's view, pictures give instructions more directly than text, as is the case for LEGO games or IKEA furniture: there is no reason to require that a picture corresponds to a particular sequence of assertions, since what matters are the actions that it guides the reader through (Tanswell 2017). It is important to note that such a view stresses the role of *action* in proving, which is in line with what we have seen so far in interpretations of diagrammatic reasoning as based on conceiving the legitimate operations and manipulations they make accessible. Moreover, such a conception is also related to wider debates; in the following, I will focus on three of them.

First, as Tanswell himself explains, the focus on action is inspired by other work on informal proofs, in particular Azzouni (2004) and Larvor (2012). The topic of informal proofs is very much discussed in the literature and clearly goes beyond the scope of this chapter. However, some of the elements of this debate are relevant for proofs using diagrams. I will refer to Burgess and De Toffoli (2022), who claim that the standard view, according to which a mathematical argument is a rigorous proof if and only if it can in principle be converted into a formal derivation, is a very general claim – a family of views rather than a single view – that can be specified in many different ways. However, the two authors themselves assume different positions in relation to the role of diagrams in proofs. According to Burgess (2015), there is a correspondence between the formalized version of the steps of an informal proof and the components of the formal proof. Formalization is thus a process of *filling in* the details, and the analysis of the role of diagrams is thus excluded from this account of rigor. However, De Toffoli (2021) argues that this is difficult to accept if one looks at the practice of mathematics: a definition of rigor such as this one would exclude a considerable number of proofs that mathematicians believe to be rigorous, which is not a desideratum if one moves from within a perspective that is interested in the

practice. (As I will explain in the next section, the way to go according to De Toffoli is to focus on what kinds of diagrams one refers to when asking questions about their being part and parcel of rigorous proofs.) As a consequence, diagrams, they claim, are relevant to the debate. This is because if the connection between a proof and one of its formal counterparts is simply the one of filling in, then diagrams cannot be part of rigorous proofs. However, the relation between informal and formal proofs might be more complicated and the existence of informal proofs still consistent with some versions of the standard view. (On the standard view, see also Hamami (2022).)

Second, the recipe model of proofs can be seen as an element of a larger picture where the focus is on the *activity* of proof (Hamami and Morris 2021). If a mathematical proof is to be intended as a sequence of deductive steps, then there is an isomorphism between such steps and the sequence of deductive *inferences* constituting the proof activity. The analogy here is between proof activity and other more ordinary activities such as travelling, where actions need to be planned in advance in order to be able to move from the current location to the desired one. (For a survey on the recent studies about agency in mathematical practice, see ▶ "Agency in Mathematical Practice" in the chapter by Hamami, this volume.)

Third, alternative models of proofs might have important consequences in other related research domains such as mathematics education. If students are taught the received view according to which proofs are sequences of assertions, they will miss important elements of the practice; for example, they will not be aware of the fact that there are imperatives in the written reports of a proof and that these are what would guide them through the steps of the proof (see Weber and Tanswell 2022). Why should students be taught definitions of proofs that do not correspond to what is really going on in the practice of mathematics and in the very practice of learning? More in general, the results of a philosophical approach to the practice of mathematics are opening up a potentially very fruitful space for discussion with education (see for reference Hamami and Morris 2020). Giaquinto, in his pioneering work, was one of the first to recognize the potential of such a collaboration and to foster it.

Once again, these topics go beyond diagrammatic proofs, and therefore for the details, I would encourage the reader to refer to the articles in the bibliography. However, from the narrative that I offer in the present chapter, it emerges that the questions that were raised in the context of diagrammatic proofs have at least in part contributed to the definition of these new research topics.

3.2.2 Second Strategy: What Is a "Diagram"?

The second strategy to formulate a big picture concerning diagrammatic proofs is based on a focus on the variety of diagrams and the different roles that they might play in the practice of mathematics, some of them being relevant for proofs.

One way to go is to "zoom out" and to consider diagrams as "representational cognitive tools," that is, as a kind of multi-recruiting systems constituting an "interface" on which information coming from perception or action, already at play in ordinary pragmatic contexts, and other more cognitive resources such as conceptual knowledge gets integrated (Giardino 2018b). However, this more cognitive approach will not suffice to respond to the specific question about the possibility of including

diagrams as part and parcel of proofs. In order to do that, one useful notion would be the one of "material anchor," as introduced in cognitive anthropology (Hutchins 2005). Mathematics would offer physical structures – diagrams and other representations – that result from a cultural process of "crystallization" of conceptual models into external and material objects. Such objects, when correctly interpreted, can be manipulated meaningfully; in some particular contexts, physical manipulations can correspond to mathematical operations so as to reduce memory and processing loads. In some cases, the particular physical structure would have an influence on the way in which the mathematical content is understood or conceptualized. Some other notions coming from cognitive science can in this respect be applied to such tools, so as, for example, the notion of *affordance*: diagrams afford some epistemic actions on them, given their physical features and more importantly their correct interpretation – the consideration of physical features, if not controlled, can lead us astray. As Rabouin (2018) has pointed out, the notion of material anchor might also be relevant to account for Netz' or Manders' studies of Greek mathematics, which consider how external resources are manipulated in order to operate on imagined structures. In his view, the historical evolution of mathematics has brought to a progressive "internalization" of these structures: representational tools such as figures still remained important, but new symbols were introduced in order to better control these operations on the imagined mathematical structures.

Another possibility to work on a big picture is to go in the opposite direction and "zoom in," by considering again the specifically mathematical case studies that have been produced so far in order to give a more precise characterization of what can be recognized in them as a diagram.

In a recent paper, Carter (2019b) goes back to her notion of *fruitful diagrams* to put together the several examples of diagrammatic proofs that were discussed in the literature. She refers to Macbeth's work on diagrammatic reasoning and her claim that diagrams and, more in general, other forms of notations are fruitful because they make mathematical objects "pop out," thanks to the way in which the representation is constructed. However, if this were the case, what would the peculiarity of diagrams be compared to other forms of representation? Carter's proposal is to define the appropriate class of objects to think in, which is the one of "faithful representations." Her background is once again Peirce's semiotics, according to which icons – a type of sign – divide into (i) *images*, resembling what they represent, (ii) *diagrams*, displaying relations, and (iii) *metaphors*, depending on conventional rules or structural similarities. Faithful representations are defined as icons, that is, as images, diagrams, or metaphors in Peirce's sense; moreover, manipulations made on them would respect manipulations made on "the object of study," which may be properties, relations, concepts, or more simply objects – we are not far from the idea that they are material anchors. These representations are fruitful precisely because manipulations performed on them can make new relations appear. It is important to note that the border between diagrams and notations in general gets blurred; Carter is aware of this and argues for two peculiarities of diagrams. First, diagrams show

that a relation holds between objects by joining their respective representations by a line; in some cases, the nature of the relation is given by the figure. Second, thanks to two-dimensionality, diagrams can be used to show that an object is related to multiple objects, as shown in Macbeth's example.

In some of her recent work, De Toffoli (2022) tries to give a more precise definition to the vague notion of diagrams that has been considered in the philosophy of mathematical practice. The taxonomy that she proposes is flexible enough to allow for borderline cases but has the advantage of offering a tool that is useful to navigate the literature by pointing to the relevant differences. In her reconstruction, and in line with her previous work, the starting point is notational systems in general, some of which are geometric-topological (GT), that is, they possess geometric-topological features that are relevant to enable the use of a form of intuition. GT figures can be diagrams or illustrations, but only the first are used in a systematic way, so as to allow them to eventually be part and parcel of a proof. Moreover, GT diagrams – it is the case of the knot diagrams briefly mentioned above – trigger enhanced manipulative imagination. However, other more precise distinctions have to be introduced. In fact, it is only thanks to further elements that the class of mathematical diagrams can be defined: mathematical diagrams are indeed systematic notational items that are either GT or two-dimensional or both.

There are two important points to note: first, the diagrams that constitute a challenge for the received view of proof – and the ones that we have mostly discussed so far in this chapter – are specifically GT. In fact, non-GT diagrams are generally accepted in proofs – this is, for example, the case of commutative diagrams. However, it is only after the middle of the twentieth century that non-GT mathematical diagrams entered the scene. (It would be interesting to discuss the relation between the process of internalization as mentioned above by Rabouin and the return to diagrams in a very different formal and formally controlled context.) To sum up, according to De Toffoli's big picture, notational systems can be distinguished across three orthogonal dimensions: (i) systematic vs. nonsystematic use, (ii) geometric-topological vs. non-geometric-topological, and (iii) two-dimensional vs. non-two-dimensional. Borderline cases are accepted. We now have a map to situate the different case studies, also in relation to the questions about which of these dimensions are decisive to allow for diagrams to be part and parcel of diagrammatic proofs.

This second strategy also opens up new research territories. On the one hand, diagrams can be considered as externalizations for thought, and therefore they can be inquired from the point of view of cognitive science – as Netz and Giaquinto had already been suggesting. Would that be some piece of evidence in favor of an "extension" of the mind? On the other hand, diagrams can be intended as signs and so they have to be studied in relation to other kinds of notations; as a consequence – as already proposed by scholars like Carter – diagrammatic proofs are a subject also for semiotics. (This latter research direction is developed in the section of this handbook on the "Semiology of Mathematics." See, for example, ▶ "Signs as a Theme in the Philosophy of Mathematical Practice" in the chapter by

Waszek, this volume that, as other papers in the same section, partially overlaps with some of the topics of the present chapter.)

4 Conclusions

In this chapter, I tried to build a narrative about how the views on diagrammatic proofs have developed in the philosophy of mathematical practice, starting from the first pioneering works that appeared at the beginning of the 2000s and getting to the most recent publications. I have shown that the interest in diagrammatic proofs was promoted by renewed attention to topics that were excluded from the philosophical research by the so-called received view of mathematics. The question about the role of diagrams in proofs is specifically philosophical despite the fact that it relates to other more general questions about the effectiveness of diagrams and their omnipresence in mathematics.

The research on diagrammatic proofs is characterized by two waves. The first wave focused on case studies, in particular from Greek geometry and more recently from contemporary mathematics. The second wave, to which we assist today, is instead aimed to build comprehensive frameworks on how to account for diagrammatic proofs. In my view, this wave is characterized by two strategies. First, it is possible to stretch the notion of proof as inherited from the received view and to consider alternative models for it, which would allow including diagrammatic representations in proofs. Second, it is desirable to focus on the term "diagram" and on its cognitive features or to distinguish several taxa for mathematical representations. For both strategies, it is evident that the research on diagrammatic reasoning has to widen its scope, either by relating to broader contexts – such as the reflection on rigor and formal and informal proofs in mathematics – or by opening up to new research domains, such as the consideration of the role of cognitive tools for thought and the philosophical study of notation in mathematics, which are both crucial issues for education and cognitive science. This sums up how the interest in diagrammatic proofs started – almost 20 years ago – and where it is going today.
